BRIDGE MAINTENANCE, SAFETY, MANAGEMENT, DIGITALIZATION AND SUSTAINABILITY

Bridge Maintenance, Safety, Management, Digitalization and Sustainability collects the lectures and technical papers presented at the 12th International Conference on Bridge Maintenance, Safety and Management (IABMAS 2024, Copenhagen, Denmark, 24-28 June 2024). This Open Access book contains 480 contributions, including the T.Y. Lin Lecture, 9 Keynote Lectures, and 470 technical papers from 44 countries.

The contributions are presented bring together academic and technological developments in **Bridge Maintenance, Safety, Management, Digitalization and Sustainability**, to solve new and old problems with innovative solutions. Major topics include: advanced bridge design, construction and maintenance approaches, safety, reliability and risk evaluation, life-cycle management, life-cycle resilience, sustainability, standardization, analytical models, bridge management systems, service life prediction, structural health monitoring, non-destructive testing and field testing, robustness and redundancy, durability enhancement, repair and rehabilitation, fatigue and corrosion, extreme loads, needs of bridge owners, whole life costing and investment for the future, financial planning and application of information and computer technology, extensive data analysis and artificial intelligence for bridges, among others.

Bridge Maintenance, Safety, Management, Digitalization and Sustainability provides an up-to-date overview of the field of bridge engineering and significant contributions to making more rational decisions on bridge safety, maintenance, management, life-cycle, resilience, sustainability, and bridge innovations to enhance society's welfare. The Editors hope that this book will serve as a valuable reference to all concerned with bridge structure and infrastructure systems, including engineers, researchers, academics, and students from all areas of bridge engineering.

Aesthetic value of bridges 3
M.-C. Tang

KEYNOTE LECTURES

Assessment of post-tensioned bridges in Norway 17
L. Bathen

Sustainability and digitalization in bridge management: How far we are? 27
J.R. Casas

Bridge management – past, present, and future 40
R.M. Ellis

Bridge engineering - Proving the sustainability case for refurbishment v replacement 50
D.K. MacKenzie

Thermo-mechanistic approach for evaluating service life of bridges and structural concrete 64
K. Maekawa & T. Ishida

From empirical and subjective O&M to statistical and objective asset management 77
S.C. Nørager

Innovations in building and bridge engineering associated with circular economy 85
L.M. Ottosen

AI support for bridge SHM and life cycle assessment 93
G. Marasco & S.N. Pakzad

Innovations in bridge management in Australia to rise to the challenges of today and the future 106
N.G. Powers

MINI-SYMPOSIA

MS01: Prediction and extension of the service duration of bridges
Organizers: A. Miyamoto, E. Brühwiler, R. Kiviluoma & A. Yabe

Field tests for remaining life prediction of aged bridges 119
A. Miyamoto

Behavior analysis of an integrated column by multiple steel pipes using monitoring measurement 132
S. Akamatsu, M. Hattori, Y. Taniguchi, M. Nishimura, Y. Aoki, S. Miyata & K. Sugiura

Prediction of bridge service duration for CBM by the indirect monitoring using vehicles 141
A. Yabe

Combining monitoring information and UHPFRC strengthening to extend bridge service duration 149
N. Bertola & E. Brühwiler

UHPFRC technology for the extension of the service duration of bridges 158
E. Brühwiler

Interpreting monitored responses of an orthotropic steel deck using FEM 167
S. Ye, R. Gibson, N. Yeung & S. Kite

Predicting time history response of bridges under vehicle load using CNN 175
H. Li & T. Wang

Behavior of CFST piers with compound concrete under cyclic lateral loading 184
J.-J. Wang, J.-L. Fu, S.-G. Cao, H. Hu & H. Tian

Extending the service duration of bridges by means of (R-)UHPFRC 192
S.D. Maria & D. Briccola

Optimization study on wet joints construction of steel plate composite beams 200
B. Wang & Z.Q. Liu

Analysis of the effect of hoop prestressed steel wire rope reinforcement on bridge piers and the loss of prestress 207
D.H. Sun, Z.Q. Liu & B. Huang

Development and application of anti-differential disturbance concrete for widening bridge 216
D.H. Chen, J. Song & C.Y. Zhu

Safety performance evaluation of suspension bridge tunnel anchor structure 226
W. Dou, Z.Q. Liu & J. Song

A review of the durability of concrete wet joints under the loading and corrosion 234
Y. Wang, Y. Shen & Y. Wang

PC-PINNs: Physics-informed neural networks for solving the phase-field model of pitting corrosion 244
N. Chen, R. Ma, A. Chen & C. Cui

Sensitivity analysis on the fatigue factors for fatigue reliability evaluation 253
M.Z. Mili, K. Sugiura, Y. Kitane & R. Matsumoto

Structural analysis of dapped-end beams through machine learning techniques 261
V. Picciano, G. Santarsiero, A. Masi & A. Digrisolo

Assessment of the efficiency of the base-isolation for a bridge structure 270
T. Zhelyazov, S. Ólafsson & R. Rupakhety

Fracture toughness of structural steel in Swedish bridges 278
M. Ablahad & H. Pétursson

MS02: Field testing of existing bridges
Organizers: E. Lantsoght, G. Sas & J. Schmidt

Collapse test of prestressed concrete slab-between-girder bridge 289
S.W.H. Ensink, E.O.L. Lantsoght & M.A.N. Hendriks

Bridge load testing: Recent advances in research, collaboration, and codes 297
E.O.L. Lantsoght, J.W. Schmidt & G. Sas

Reliability of I-girder PC bridges through proof load testing: Preliminary results 306
G. Addonizio, R. de Vries, E.O.L. Lantsoght & D. Losanno

Danish concrete bridge proof loading procedure and considerations 315
J.W. Schmidt, C.O. Christensen, R. Bang, C. von Scholten, P. Goltermann & S. Engelund

A comparative study of proof load configurations related to bridge classification 323
K.D.S. Damsgaard, S. Engelund, J.D. Sørensen, J.W. Schmidt, C.O. Christensen & C. von Scholten

Static and dynamic monitoring of bridges with contactless techniques 332
T. Moser, W. Lienhart & F. Schill

Shear stop criteria for reinforced concrete slab strips 341
G.I. Zarate Garnica, E.O.L. Lantsoght, Y. Yang & M.A.N. Hendriks

Development of a guideline for proof loading of bridges 350
S. Engelund, J.D. Sørensen, J.W. Schmidt, C. von Scholten & R. Bang

Load testing on existing prestressed concrete bridges to determine long-term effects on strain measurement 358
H. Burger, T. Tepho, O. Fischer & N. Schramm

Load testing and evaluation of inverted T-section slabs in road bridges 366
C.O. Christensen, J.W. Schmidt, R. Bang, C. von Scholten, P. Goltermann, K.D.S. Damsgaard & S. Engelund

Lessons learnt from load testing in the UK 375
D.P. Cousins

Long-term monitoring of ASR deteriorated bridges after reinforcement 383
M. Tsuda, S. Kagatani, S. Ura & K. Torii

The use of smart bridge bearings for railway bridge monitoring 391
P. Olaszek, A. Sakowski, N. Kur & M. Smoliński

Development of a proof loading method for railway bridges with masonry abutments 399
C. Wang, J. Gonzalez-Libreros, L. Elfgren, G. Sas, C. Daescu, O. Enoksson & T. Hojsten

Structural reliability updating using monitoring data from in-situ load testing and laboratory test results 409
R. de Vries, E.O.L. Lantsoght, R.D.J.M. Steenbergen, M.A.N. Hendriks & M. Naaktgeboren

Load testing of the first stress ribbon bridge in Slovenia 418
Đ. Đukić, D. Hekič, M. Kosič, R. Vezočnik, A. Anžlin, A. Štrukelj, M. Pipenbaher & T. Weingerl

Damage evaluation of a road bridge subjected to an avalanche 426
H. Naito, A. Uchida, K. Yoshinaga, A. Kamura & M. Kazama

In-situ, lab testing and FE simulations historical steel-concrete bridge decks 435
A. de Boer, B. Renckens & L. Ha

Practical experience with proof loading – examples from 3 bridges 444
J.H. Roldsgaard, J.K. Nørregaard, C. Pedersen, J. Vig & A. O'Connor

Integrated utilization of infrared and ultrasound technologies for bridges 453
I. Alqurashi, M. Debees, M. Matsumoto, A. Alqarfi & F. Necati Catbas

Determining load distribution in a riveted railway bridge through controlled field testing 460
B. Imam, S. Biswal, M.K. Chryssanthopoulos & P. Wildbore

Field assessment of a vibration-based damage identification procedure 469
J. Raedersdorff, A. Chateauneuf, D. Clair & A. Bouchaïr

Road overpasses with Gerber half-joints: Field tests and numerical models 477
D. De Domenico, M. Mazzeo, D. Messina & A. Recupero

MS03: Life-cycle performance assessment of existing bridges in an aggressive environment
Organizers: M. Akiyama, D.M. Frangopol & H. Matsuzaki

Self-healing performance of aged bacteria-based cementitious materials: An overview 487
N. Kim, S. Kim & H.K. Lee

Degradation prediction of FRP bars within concrete bridge decks in service 491
X.L. Zhao, Q. Zhao, I. Keitai, J.G. Dai & M.F. Kai

Load-bearing capacity assessment of RC beams using corrosion crack widths 497
T. Adachi, M. Akiyama, T. Yamada, S. Nakamura, Z. Xu & D.M. Frangopol

Probabilistic structural identification using time-dependent deflection of prestressed concrete bridges 503
S. Jia, M. Akiyama & D.M. Frangopol

Advanced framework for degradation modeling of operating structures 510
M.E.A. Ben Seghier, A. Jiménez Rios, J. Dai & V. Plevris

Modeling the deterioration of road bridges at the provincial level in Lao PDR 518
H. Silimanotham, A. Amir & M. Henry

Experimental investigation on shear behaviour of corroded and repaired prestressed concrete beams 525
B. Belletti, S. Ravasini, A. Sirico, J. Sanchez Montero, J. Torres, N. Rebolledo & P. Saura

Risk-based retrofit optimization of deteriorating reinforced concrete bridge columns subjected to corrosion and earthquakes 533
S. Kim, Y. Yang & D.M. Frangopol

Life-cycle assessment of riverine bridges under flood and corrosion 540
R.K. Arora, S. Banerjee & A. Kumar

Life-cycle cost-benefit analysis of an SMA-steel reinforced bridge under earthquakes 548
J. Qian, T. Guo, Y. Dong & Y. Zheng

Probabilistic assessment of corrosion initiation in RC structures under chloride attack 556
G.H. Vieira, L.C. Meneghetti, R.M. Teixeira & M.A. Silva

Why is maintenance and management of rails so important to railway bridges? 565
J. Wuorenjuuri

Retrofit of PRC bridges by external post-tension under different corrosion scenarios 571
G. Santarsiero, V. Picciano, A. Masi & G. Ventura

Life-cycle environmental impact assessment of bridge designs considering maintenance strategy 580
S.H. Lee, L.S. An & H.K. Kim

Damage assessment and expert system for the repair of ageing reinforced concrete components 586
F. Binder, U. Schneck & A. Strauss

MS04: Life-cycle redundancy, robustness and resilience of bridges and infrastructure networks under multiple hazards
Organizers: F. Biondini & D.M. Frangopol

Connectivity of road network with bridges and slopes under rainfall 597
Z. He, P.S. Firdaus, M. Akiyama, D.M. Frangopol & H. Matsuzaki

Measuring the extreme risk of coastal bridges under tropical cyclones 604
Y. Li, D. Zhu & Y. Dong

Resilience-based countermeasure strategy for bridges under multiple hazards 610
H. Ishibashi, M. Akiyama & S. Koshimura

Enhancing seismic resilience of aging highway bridges using FRP retrofit 617
V. Singh, S. Shekhar & N. Kotoky

Fragility curves for regular and irregular RC bridges via non-linear static analysis 626
H. Rezaei, E.M. Dehcheshmeh & Y. Tsompanakis

Connectivity of post-earthquake bridge networks under aging of isolators 634
H. Matsuzaki

Computational analysis of resilience in reinforced concrete railway bridge 642
A.L. Gamino, R.R. Santos, T.N. Bittencourt & M.M. Futai

Assessment of honeycomb cushion for enhancing bridge deck impact protection 650
H. Mraih, J. Hashemi, R. Kalfat, R. Al-Mahaidi & G. Lu

Multi-hazard resilience-based bridge prioritization for aging bridge networks in a changing climate 658
L. Jafari & F. Biondini

Probabilistic capacity model for concrete-filled steel tubes 666
A. Aloisio, A. Contento, J. Xue, G. Quaranta, P. Gardoni & B. Briseghella

MS06: AI and robotics for bridges: Monitoring, assessment, and maintenance
Organizers: Y. Dong, D.M. Frangopol, B. Wang & X. Lei

Bridge condition assessment with full-scale view and computer vision methods 679
X. Lei, Y. Dong & D.M. Frangopol

Data-driven prediction models for extreme wave impacts on coastal bridges 685
D. Zhu, J. Zhang & Y. Dong

Digital twin for intelligent maintenance towards sustainable bridges 693
J. Heng, L. Lai, Y. Dong, S. Kaewunruen & C. Baniotopoulos

Structural damage detection approach using input-output monitoring system and transfer learning 701
L. Ge, D. Dan & A. Sadhu

Data fusion in structural health monitoring: Integrating computer vision and strain gauges for enhanced inspection 709
K. Aminfar, M. Ghyabi, Y. Shen, D. Lattanzi, G. Ciaramella, M. Gherlone & C. Surace

A smart robotic system for autonomous inspection of large-scale concrete girder 717
Y. Cui, Y. Pan, D. Wang, M. Ji & S. Cao

LSTM-based structural pattern recognition for floating bridges 726
S. Ryu, S. Min, Y.J. Kang & S. Kim

Vision-based structural displacement measurements using deep learning and super-resolution 735
M.F. Abu Zouriq, D.G. Linzell & R. Nasimi

Multimodal data collection using mobile robotics for rapid structural assessment 742
F. Luleci, A. AlGadi & F. N. Catbas

MS08: Sustainable and efficient monitoring and digitization-based decision-making models
Organizers: A. Strauss & D.M. Frangopol

Human role in existing bridge digital twin frameworks, towards Industry 5.0 753
A. Jiménez Rios, V. Plevris & M. Nogal

Overview of assessment for bridges affected by HS2 tunnelling, UK 761
J. Tsekhanskiy, A. Bariyya, G. Ledsham-James, D. Shapley & Y. Li

Comparison of modal parametric and nonparametric vibration-based techniques 769
A. Dia & N. Makhoul

Limits of digital twin modelling 777
A. Beigel, A. Strauss, D.M. Frangopol & M. Cao

Vehicle impacts on reinforced concrete railway bridges 785
M. Reiterer, A. Strauss, B. Täubling & D.M. Frangopol

Advanced modelling methods of the Jauntal railway bridge 793
A. Strauss, B. Täubling-Fruleux, L. Novák, D. Novák, A. Oplustil, M. Kaulfus, H. Steiner, R. Zedlacher, A. Hüngsberg, G. Oberlerchner & D.M. Frangopol

Generation of digital twins for bridges of medium spans - Schwindegg Bridge pilot project 800
J. Wimmer & T. Braml

ANYTWIN – standardizing monitoring-based safety assessments of bridges and the integration into Digital Twins 808
A. Lazoglu, J.H. Bartels, R. Stein, M. Maibaum, L. Puttkamer & L. Ulbrich

Condition assessment of mechanical fasteners by use of smart bolts 817
M. Reiterer & R. Thukbatullin

MS09: Novel technologies and information fusion for structural health monitoring of bridges
Organizers: C.-W. Kim, V. Sarhosis, J. Li & Y. Zhang

Real-time scour depth estimation of a pier using vibration monitoring 827
D. Kawabe, C.W. Kim & V. Sarhosis

Structural integrity estimation of bridges based on acceleration measurement 835
H. Yu & C.W. Kim

Research on application of real-time dynamic safety monitoring system for medium and small span bridges 844
H. Hong, S.G. Cao, J.L. Fu & Y.K. Xu

Enhancing structural performance evaluation of PC girder bridges through Bayesian model updating 853
D.B. Chen & C.W. Kim

Framework of UAV bridge inspection with computer vision and deep learning 862
K. Yen & C.-M. Chang

Vision-based optimal sensor selection for full-field displacement reconstruction 870
Y.F. Weng, S.T. Quek, K.W. Yeoh & X.L. Lu

Domain adaptation for bridge health monitoring via physics-informed generative adversarial learning 878
L. Ge & A. Sadhu

Anomaly detection of bridges by Bayesian method with optimized sensor placement 887
C.W. Kim & Y. Hirate

Converting finite element models to irreducible element models for use in population-based SHM 896
C. O'Higgins, D.S. Brennan, C. Kent, D. Hester & S.E. Taylor

Impact factor of a seven span continuous cable-stayed bridge 904
S. Kimura, C.W. Kim, H. Sugiyama, M. Isa & K. Ono

Distributed fiber optic sensors for structural health monitoring of post-tensioned bridges 912
B. Piątek, T. Howiacki & T. Siwowski

Modeling temperature impact on sensor data in prestressed concrete bridges 921
V. Coric, C. Wang, J. Gonzalez-Libreros, L. Elfgren & G. Sas

Field testing of the longest Polish footbridge made of FRP composites using distributed fibre optic sensor system 929
M. Kulpa & T. Siwowski

Online noise parameters estimation for sigma-point Kalman filter using sequential importance resampling 937
W. Liu & F.-L. Zhang

MS10: MS Application of probabilistic techniques for the assessment and performance prediction of corroding concrete bridges
Organizers: R. Caspeele, W. Botte, R. Vrijdaghs, B. Belletti & J.R. Casas

Bayesian-updated POD of ultrasonic tomography in the inspection of PT bridges 947
I. Mazzatura, J.R. Casas, S. Caprili & W. Salvatore

Influence of repair interventions on the safety of a reinforced concrete road bridge subjected to chloride ingress 956
K. Van Den Hende, S. Helderweirt, W. Botte, S. Matthys, R. Caspeele & G. Lombaert

Probabilistic assessment of the moment-curvature response of PC beams with different corrosion scenarios 965
B. Belletti, S. Ravasini, S. Sandrini, R. Caspeele & W. Botte

A dynamic Bayesian network approach for multi-component fragility of aging bridges 974
F. Molaioni, C.P. Andriotis & Z. Rinaldi

Selection of NDT/PDT locations in a box culvert using value of information 983
S. Karmakar, S. Ghosh & S. Dauji

Assessment of a 60-year-old corroded concrete girder through finite-element analysis 992
L. Soto, M. Noël, B. Martín-Pérez & L. Sanchez

Analysis for the bridge fatigue failure and weight limit using the probabilistic machine learning method 1000
W. Yan

Stationary proposal importance sampling for structural reliability of aging RC bridges 1008
L. Capacci

MS11: Towards the realization of the submerged floating tunnels
Organizers: Y. Xiang, H.K. Lee, B. Faggiano, R. Landolfo & L. Martinelli

Coupled dynamic analysis method for wave action on a submerged floating tunnel 1019
B. Huang, W. Luo, X. Cui, S. Wang, H. Ding, K. Li & L. Cheng

Dynamic substructuring technique for submerged floating tunnels 1029
S. Corazza, F. Foti & L. Martinelli

Forming guidelines for software evaluation in bridge structural health monitoring systems 1037
T.A. Bayda, H.W. Shenton & M. Chajes

Nonlinear seismic-response time-history analysis of submerged floating tunnels 1044
Y.Q. Xiang, Y.G. Shen, C.F. Chao & L. Deng

Experimental investigation for dynamic behavior of the scaled segment model of submerged floating tunnels under waves 1054
H. Ding, L. Cheng, K. Li, D. Zhong & X. Hu

Numerical simulation of motion response of submerged floating tunnel under wave action 1063
H.B. Jiang, H.D. Zhao, W.D. Chen, P.Z. Lin & B. Ren

Modeling of two-dimensional water motion field during a seaquake 1071
V. Maugeri, L. Martinelli & F. Perotti

Analysis of hydroelastic response of a SFT based on the Discrete-Module-Beam method 1079
C. Ji, Y.Q. Chen, X.T. Zhang, X. Li, K. Li, D. Zhong & Zhou

Main issues of the structural analysis of SFT against environmental loads 1087
G. Iovane, F.M. Mazzolani, R. Landolfo, E. Begovic, E. Bilotta & B. Faggiano

MS12: Decision-making in bridge management - Gaps between research and practice and recommendations for the future
Organizers: P. Linneberg & A. Strauss

Current and future decision-making in Danish and Austrian bridge management 1099
P. Linneberg & A. Strauss

Comparison of ranking frameworks for specification of bridge scour monitoring systems using a case study database 1108
W. Yaqoobi, G. Gavriel, T. Tryfonas, P.J. Vardanega & M. Pregnolato

Next generation risks challenge bridge maintenance and management in Finland 1116
J. Wuorenjuuri

The effect of conceptualization on bridge maintenance prioritization 1122
K. Zangpo, A. Amir & M. Henry

Bridge condition index: A review of methodologies used in Bridge Management Systems 1130
A. Agredo Chávez, J. Gonzalez-Libreros, C. Wang & G. Sas

MS13: Bridge loading – measurement and modelling
Organizers: C. Caprani, A. Nowak, E. O'Brien & X. Ruan

Braking effects on vehicle-bridge interaction 1141
A. Aloisio, G. Quaranta, A. Contento & M.M. Rosso

Distributed fiber optic sensing during static and dynamic bridge loading 1148
L. Strasser & W. Lienhart

Structural load modelling of walking humans with gait cycle-dependent model parameters 1156
M.J.A. Fritzsche, S.R. Lorenzen, C. Hübler, A. Firus, M.A. Stasica & A. Seyfarth

CFD analyses for wind load assessment of the new Bomarsund arch bridge 1165
F. El Azrak, S. Sadrizadeh, J. Leander & R. Karoumi

Bridge damage evaluation model based on vehicle excitation and ML 1173
Z. Xiong, T. Cong, W. Zhang & Z. Liang

Experimental determination of trough bridges pressure distribution 1181
S. Sarmiento, J. González-Libreros, G. Sas, O. Enoksson & T. Höjsten

FE model and verification as digital twin of structural behavior for infrastructure management 1190
H. Shirahata, T. Kawai, M. Tai, T. Aoki & H. Hara

On the assessment of the vibrational response of highly-skewed high-speed railway bridges 1199
M.D. Martínez-Rodrigo, J.C. Sánchez-Quesada, E. Moliner, A. Romero & P. Galvín

Modal identification and soil-structure interaction analysis of a portal frame railway bridge 1207
J. Chordà-Monsonís, J.C. Sánchez-Quesada, E. Moliner, M.D. Martínez-Rodrigo, A. Romero & P. Galvín

Enhancing structural performance prediction through Bayesian updating with considering load and speed uncertainty 1215
F. Shaker & C. Caprani

Utilizing bWIM-data to calibrate new traffic load models on embankment 1224
H. Lilja, J. Qvisen & A. O'Connor

Torsion effects in Super-T girder grillage analysis 1232
J.W. Ngan, C.C. Caprani & M. Melhem

Reliability calibration of load factors for the Australian rail traffic load model 1239
C.C. Caprani & M. Shihabuddin Khan

Probabilistic updating of characteristic train load for the Little Belt Bridge anno 1935 1247
J.H. Roldsgaard, C. Pedersen, S.T. Nielsen, A. O'Connor & S.E. Gaardmand

Influence of the correlation of GVWs in the simulation of vehicle spatial distribution of extreme effects in long-span bridges 1255
X. Wang, X. Ruan, J.R. Casas & M. Zhang

PyBTLS: A Python package for traffic load simulation on short-to-medium bridges 1263
Z. Zhou & C. Caprani

SPECIAL SESSIONS

SS01: Short-span bridges and culverts: Analysis, evaluation, durability, and rehabilitation
Organizers: D. Beben, H. Sezen, J. Vaslestad & T. Maleska

Restoration of the Rochers Noirs Viaduct 1273
E. Combescure, S. Doussau, C. Lacipiere, N. Aubree & L. Pace

Load rating of cast-in-place reinforced concrete box culverts based on load testing 1281
A. Peiris, C. Hutchinson, I. Harik, A. Cole & E. Russell

Seismic finite element method simulation of a soil-steel bridge with a gravel-rubber mix 1288
T. Maleska, D. Beben, J. Nowacka, A. Fiamingo & M.R. Massimino

Long-term monitoring of earth pressure in a soil-steel composite railway tunnel 1296
T. Maleska, D. Beben & J. Vaslestad

Experimental tests of a soil-steel culvert with a shallow soil cover under static loading 1304
T. Maleska, D. Beben, P. Bobra & B. Jedraszak

Maximum shear strength of prestressed concrete deep beams 1312
X. Duanmu, D. Xu & K. Hu

Low carbon solution for short-span bridges: Soil-steel composite bridges versus concrete bridges 1320
G. Du & A. Czerepak

Soil-steel composite bridges, advantages – based on case studies 1329
B. Şentürk & M.N. Nonbo

The corrosion of reinforced concrete bridge structures and its influence 1336
G.-O. Shijir, D. Yagaanbuyant, K. Sambuu, M. Duinkherjav, S. Namsraijav, A. Gantulga, K. Tumur-Ochir & N. Bayasgalan

SS02: Bridge Weigh-in-Motion: Recent experiences, technology developments, and new applications
Organizer: D. Cantero

New feature based on influence lines for anomaly detection in bridge monitoring 1347
A. Döring, M. Vogelbacher, O. Schneider, J. Müller, S. Hinz & J. Matthes

Vehicle speed estimation in BWIM systems via convoluted reciprocity 1356
D. Cantero & C.W. Kim

Strain-based FEM-aided bridge health monitoring: A case study 1364
P. Rizzo, A. Enshaeian & A. Ghahremani

Actual bridge verification of monitoring technique using optical fiber sensors 1372
S. Aoki, T. Maeshima & I. Iwaki

Bridge Weigh-in-Motion applied to heritage iron truss bridges in France 1380
F.-B. Cartiaux, V.L. Corvec, J. Semiao & B. Jacob

Assessment of the accuracy of Bridge Weigh-In-Motion (B-WIM) system in Indonesia 1388
W. Nugraha, S. Ramadhani & G. Sukmara

Bridge weigh-in-motion event detection using wavelet scattering features and unsupervised learning 1397
V. Bokaeian, J. Bowmaster & K. Arjomandi

Machine-learning for analyzing bridge displacement using radar data 1405
M. Arnold & S. Keller

Accuracy of BWIM considering autocorrelation in bridge dynamic response 1413
K. Maruyama, I. Yoshida & H. Sekiya

Exploring Kriging metamodeling for applications in bridge Weigh-in-Motion prediction 1422
P. Agüero-Barrantes, S. Lobo-Aguilar, R.E. Christenson & A. Hain

Challenges of implementing bridge weigh-in-motion on a century-old steel-riveted railway bridge 1429
D. Hekič, M. Kosič, J. Kalin, A. Žnidarič & A. Anžlin

Radio-interferometry based continuous bridge deformation monitoring – a case study 1437
K. Leppänen, J. Salmi, M. Fattah, T. Heikkinen, M. Lehtinen, O. Leppänen, N. Väisänen, T. Tirkkonen & H. Raunio

A regression based B-WIM method for railway bridges 1445
S. Lachinger, J. Struhar & M. Ralbovsky

A deep learning-based BWIM system of a cable-stayed bridge 1452
B. Szinyéri, B. Kovari, I. Völgyi, D. Kollár & A.L. Joó

Load estimation precision for moving forces with position uncertainties through AKF 1460
C.Y. Zhou & C. Demartino

SS03: Estimating future preventive bridge interventions
Organizers: B.T. Adey, H. Mehranfar & S. Chuo

Improvements in providing overviews of future bridge interventions, their possession windows, and costs 1471
H. Mehranfar, B.T. Adey & S. Chuo

Connecting predictive algorithms to BIM to improve the planning process 1479
S. Chuo, H. Mehranfar, B.T. Adey & G. Elshani

Bridge deterioration modeling considering the climate change effects 1487
S. Moghtadernejad, Z. Lounis & J. Zhang

Application of open deep learning datasets for building vision-based bridge condition monitoring solutions 1496
K. Tomaszkiewicz & T. Owerko

Influence of the pavement conditions on the bridge response 1504
M.G. Mulas, M. Riso, A. Sgambati, F. Basone & M. Longo

SS04: Advances in machine learning and data-driven system identification techniques for structural health monitoring
Organizers: J. Diaz-Rozo, C. Bielza, C. Ocampo-Martinez & P. Larrañaga

Long-term performance evaluation of low-cost sensors using AI-driven tools 1515
F. Lozano-Galant, S. Emadi, S. Komarizadehasl, J. González-Arteaga, Y. Xia & J.A. Lozano-Galant

Fast bridge health monitoring deployment with transferable expertise 1523
R. Sojo-García, P. Larrañaga, C. Bielza & J. Díaz-Rozo

Anomaly detection with switching Kalman filter and imitation learning 1531
Z. Xin & J.-A. Goulet

Improving frequency-features by parametric study of data-driven SHM schemes 1539
C. Puerto-Santana, J. Diaz-Rozo & C. Ocampo-Martinez

Robust modal identification of a large-span bridge with the new SpCF technique 1547
S.D.R. Amador, L. Gaile, R. Brincker & C.E. Ventura

SS05: Underground and above-ground infrastructure resilience and sustainability
Organizers: M. Domaneschi, B. Chiaia, G.C. Marano, V. Villa & S. Argyroudis

Development of a novel bridge deck-to-pier connection for improved tsunami resilience 1559
R.K. Pagel, A. Palermo, I.N. Robertson & G.D. Francesco

The seismic response and resilience of nearby underground infrastructures 1567
M. Dalmasso, M. Civera & B. Chiaia

Blockchain technology conception in digital data collection for damage assessment and L.C.A. 1575
L. Gioberti, M. Domaneschi, V. Villa, B. Chiaia & N. Catbas

Analytical seismic resilience identifiers of bridges 1583
F. Soleimani & D. Hajializadeh

Dynamic measurements for assessing bridge response to foundation scour 1592
M. Aimar, M. Civera, B. Chiaia, S. Foti, A. Quattrone & D. Sabia

SS06: Forensic engineering and damaged structures. Critical cases studies and lesson learned of LATAM road bridges
Organizers: M.A. Valenzuela, M. Marquez, F. Cerda & G. Valdebenito

Seismic design modifications for damage prevention in skewed bridges 1603
T. Amaya & H. Santa María

Collapse of Cau Cau Bridge: Forensic engineering study 1611
M.A. Valenzuela & M. Márquez

Use of advanced non-destructive methods for the structural diagnosis of the Cau-Cau Bridge, Chile 1619
G. Valdebenito, M. Marquez, M. Valenzuela & J.L. Seguel

A study on machine learning for creating crack images of RC columns 1626
H. Yasukawa, H. Naito, H. Fujioka & S. Fujikura

SS07: Vehicle-based sensing solutions for indirect bridge condition monitoring
Organizers: R. Corbally, A. Malekjafarian, S.R. Lorenzen & C.-H. Kim

Mitigation of unwanted effects in drive-by acceleration data for bridge monitoring 1637
M. Casero, A. González & K. Feng

Smartphone-based monitoring: Improving the bridges braking force model 1646
M. Breveglieri & G. Feltrin

Bridge damage classification using multiple responses of vehicles and 1-D convolutional neural networks 1655
Z. Li, Y. Lan & W. Lin

Crowdsensing and indirect structural health monitoring in HE FUTURAL 1664
D. Garcia-Sanchez, D. Zamora, I. Arakistain & T. Katika

Fleet monitoring using a Bayesian approach to detect bridge bearing damage 1672
E.J. OBrien, Y. Ren, T.T.X. Tran, E. Ozer & V. Pakrashi

Indirect bridge condition monitoring using feature selection strategy 1679
R. Ghiasi, R. Corbally & A. Malekjafarian

Crowd-sensing drive-by monitoring for bridge frequency identification 1687
Y. Lan, Z. Li & W. Lin

Bridge low-frequency displacement estimation using bridge acceleration for a VBI system 1695
X. Lu, L. Sun, Y. Xia, C.W. Kim, K.C. Chang & Z. Han

Automated analysis of drive-by monitoring data 1704
J. Brötzmann, Y. Yang, U. Rüppel, M.M. Rupp & S.R. Lorenzen

OMA-driven structural assessment to prevent fatigue-induced failure in steel bridges 1712
G. Du, R. Brincker, S. Amador & U. Alibrandi

SHM for railway bridges: Real time analysis of the train transit and thermal data 1719
G. Ascari, A. Dalle Fratte, A. Terraneo & P. Scali

A deep-autoencoder-based drive-by methodology for high-speed railway bridge damage detection 1728
E.F. Souza, C. Bragança, T.N. Bittencourt, D. Ribeiro & H. Carvalho

Indirect continuous monitoring of bridge transitions using the CTM 2.0 1736
M.M. Rupp, S.R. Lorenzen, C. Hübler, K.U. Wolter, G. Grunert & R. Stein

Drive-by monitoring to assess railway bridge accelerations 1745
S.R. Lorenzen, M.M. Rupp & C. Hübler

Empirical study on smartphone-vehicle trip metadata and bridge modal property estimates 1754
T.J. Matarazzo, L. Cronin, G. Marasco, I. Dabbaghchian, S.N. Pakzad, S.S. Eshkevari, D. Sen, P. Santi & C. Ratti

SS08: Posttension analysis, design, and assessment in bridge construction
Organizers: U. Attanayake, H. Aktan, M. LaViolette & C. Rogers

Simplified stage construction and creep analysis of a segmental precast concrete bridge 1763
A. Guarnieri, F. Bontempi & F. Petrini

NDE for pre-stressing systems condition: Metrological validation 1772
S. Zorzi, F. Rossi, D. Tonelli, E. Tubaldi & D. Zonta

The impact of post-tension modeling techniques on calculated concrete member stresses 1780
K. Basnayake & U. Attanayake

Service life determination of post-tensioned hanger rods 1788
A.P. Ranasinghe & H.T. Al-Khateeb

The comparative analysis of post-tensioned tendons in ultra-high-performance box girders 1793
M. Tsas-Orgilmaa & H.S. Mook

Finite element analysis of over-height vehicle collisions on prestressed girder bridges 1801
A. Samadzad, S. Cathey, M. Whelan, N. Braxtan & S. Chen

Assessment of internal condition of a post-tensioned tie girder during construction 1809
U. Attanayake, H. Amunugama, K. Basnayake, H. Aktan & E. Niederleithinger

Reliability analysis of end cracking in continuous prestressed concrete girders 1817
A.M. Okeil & S. Ghimire

Selection of post-tensioned tie girders for the 2nd Avenue network tied arch bridge 1825
M. LaViolette, U. Attanayake & B. Wagner

Post-tensioning tendons under strand breakages: Modelling approach for bonded tendons 1834
B. Vecino, C.M.C. Renedo, J. Naranjo-Pérez, I.M. Díaz & J.H. García-Palacios

SS09: New Concepts and approaches in bridge management – BIM based bridge management, artificial intelligence, and other new concepts influencing future BMS
Organizers: R.M. Ellis, R. Hajdin & B. Baktas

Digital twin, BIM and asset management systems implementation 1845
E. Spallarossa & A. Bonicelli

Establishing data-driven life cycle benefits of bridge maintenance 1853
B. Bektaş

Sensitivity analysis of bridge structural vulnerability class based on Italian Guidelines 1861
S. Bianchi & L. Capacci

Automated construction of BIM models from point clouds to digitalise bridge assets 1869

R. Hajdin, L. Rakic, H. Diederich, R. Richter, J. Hildebrand, S. Schulz, J. Döllner & J. Bednorz

Leveraging digital twin tools for the Minnesota DOT Robert Street Bridge inspection 1877
S. Becher & B. Lovelace

SS10: Artificial Intelligence for uncertainty, risk, and reliability assessment of bridge infrastructure
Organizers: D. Choe & M. Roohi

A chain-based construction method for bridges monitored within one cluster 1887
K. Wang, X. Ma, Z. Jiang & Y. Liu

Deep learning of smart aggregate's impedance signal for damage monitoring 1894
Q.B. Ta, N.L. Pham, J.T. Kim & Q.Q. Pham

Neural network-based connectivity reliability analysis for bridge networks 1902
J. Wang & S. Li

Forward UQ based on Bayes-informed mixture distribution 1908
Y. Zhang, Y. Dong & R.W. Feng

Connectivity analysis of transportation networks incorporating bridges and pavements under uncertainty 1916
J. Xin, D.M. Frangopol, M. Akiyama & X. Han

U-Net model-based XCT images segmentation for steel corrosion in concrete 1922
M. Zhang & W. Wang

Fragility interval predictions in non-seismically designed bridges 1929
H. Neduri & J. Ghosh

Damage evaluation of steel columns using vibration testing and transfer learning 1937
K. Watanabe, H. Naito, T. Kimoto, M. Matsumura, N. Takeshima, S. Okada & K. Ono

Probabilistic modeling of bridge deterioration due to earthquakes 1946
L. Iannacone & P. Gardoni

A data-driven approach for quantifying reliability and resilience of transportation network 1955
S. Ghasemi, V. Aghaeidoost & M. Roohi

SS11: Approaches to bridge management/bridge management systems in response to today's challenges
Organizers: R.M. Ellis & R. Hajdin

Forecasting the condition of British railway bridges via a hindcast 1967
M.J. Hamer & G.S. Calvert

Vulnerability of network infrastructure due to potential extreme weather in PEI, Canada 1976
D.J. Evans & R.M. Ellis

Considerations for vulnerability and risk assessment of bridges and culverts including extreme weather events 1984
R.M. Ellis & Z. Kamranian

Province of New Brunswick Bridge Management System 1993
Z. Kamranian & R.M. Ellis

Bridge deterioration prediction models: A review of management systems in the world 2000
C.A.F. Souza, J.M.F. Carvalho, A.C.P. Martins, F.G. Bellon, M.S. Andrade, D.S. Oliveira, J.C.L. Ribeiro, K.M.L. Cesar, B.S. Borges & G.P. Teixeira

Developing a guideline for structural health monitoring of road bridges in Germany 2009
F. Hille, R. Herrmann, R. Schneider, S. Pitters, F. Wedel & I. Hindersmann

SS12: Realising the extension of BIM for existing bridges
Organizers: N. Powers, V. Samec & M.A. Valenzuela Saavedra

Overview of the use of BIM for bridges across Australia and New Zealand 2021
N.G. Powers

BIM-data of baseline digital twins for a new bridge maintenance system 2028
C.S. Shim, G.T. Roh, D.H. Kang & J.W. Park

Condition integration in BIM for existing bridges 2034
M. Köhncke & S. Keßler

Cloud-based asset management for image-based inspections of infrastructures 2040
G. Morgenthal & M. von Butler-Helmrich

Linking BrIM to BMS for bridges – validation of concepts 2048
V. Samec, K. Aas-Jakobsen, P. Hawryszków, I. Heise, M.A. Valenzuela & C. Shim

Strategies for effective bridge information management with OpenBIM 2057
C. Gragnaniello, G. Mariniello & D. Asprone

SS13: Design, construction and evaluation of steel/FRP & concrete composite bridge structures
Organizers: H. Xin, X. Xu, R. Liu & J. He

Cyclic behavior of replaceable LYP steel coupling beam with corrugated web 2067
J. He, S. Feng, Y. Ma, Q. Teng & W. Lin

Fatigue life extension for cracked OSDs using semi-rigid pavement layer 2076
B. Wang, R. Gong, D. Wang & A. Chen

Experimental and numerical study on static performance of steel cap beam 2083
S. Chong, S. Qingtian & L. Jinguo

Real-time multi-objective topology optimization method via deep learning 2090
C. Xiang, A. Chen, D. Wang & R. Ma

A method for stochastic modelling of fatigue stresses in orthotropic bridge decks subjected to local and global traffic loading 2098
A.G. Johansen, F.-I.G. Giske & M. Storheim

SS15: Steel bridge rehabilitation
Organizer: M. Sakano

Application of microwave vibrometry in bridge monitoring & dynamic analysis 2109
T. Bao & S. Bai

Maintenance of large expansion joint in Honshu-Shikoku Bridges 2115
M. Hongo, A. Moriyama, Y. Yano & Y. Yokoi

Fatigue behavior of steel plates subjected to marine environment 2122
A. Chang & Q.Q. Yu

Fatigue effect of welded gusset plate in steel-concrete composite bridge 2129
S.L. Yan, S.Y. Jia, S.W. Xu, J.N. Li & Y.Z. Wang

Evaluation of fatigue environment in welded parts of orthotropic steel deck 2137
K. Yoshida & H. Sekiya

A study of the effect of skew angle on natural frequencies of bridge girders 2144
M. Satomi, R. Handa, Y. Sugimoto & H. Onishi

The application of abrasive water-jet treatment on severely corroded weathering steel bridge 2153
Y. Toyota, S. Kainuma, S. Park, T. Ikeda & T. Arakawa

Analytical study on stress concentration zone of aseismic reinforced deck type arch bridge 2159
M.O. Ouchi, T.S. Suzuki & H.S. Shirahata

Rehabilitation methodology of a corroded steel-riveted highway bridge in an urban setting 2167
I. Netzer & A Kedar

Study on fatigue detection of weld toe in orthotropic steel deck 2175
R. Harashima, C. Hashizume, H. Sekiya, S. Morichika & M. Saeki

Fatigue crack detection in out-of-plane gussets using crack detection sensor 2183
K. Sunada, T. Kuroiwa, R. Kasakura & H. Sekiya

Fatigue crack monitoring by measuring strain without loading 2189
T. Ishikawa, N. Matsumoto & K. Komon

Mechanical properties of steel tube with partially bonded CFRP 2197
Y. Maeda, M. Mizutani & T. Ishikawa

Estimation of elastic buckling loads of defective steel plate repaired with CFRP 2206
M. Mizutani, E. Yo, T. Ishikawa, Y. Hidekuma & M. Dogaki

Fatigue retrofit using TRS for trough rib-to-crossbeam connections in orthotropic steel decks 2215
L.H. Ichinose, A. Tanabe, Y. Teranishi & M. Sakano

SS16: Redundancy in bridges: Design, fabrication and bridge maintenance
Organizer: A. Mosavi

Internal redundancy approach for built-up mechanically fastened steel tension members in the United States 2225
J.B. Lloyd

Development of the current AASHTO integrated fracture-control plan for steel bridges 2232
R.J. Connor

Fabrication aspects of redundancy 2238
R.D. Medlock

UHPC beam end encasement for the design of maintenance-free steel bridges 2245
B. Lassy, A. Hain & S. Motaref

Identifying system redundant members in a steel arch bridge through advanced finite element analyses 2253
A. Mosavi, H. Yuan, M. Tatarsky & M. Carter

SS17: Integrating digital twin with machine-learning techniques for structual damage identification
Organizers: J.F. Jiménez-Alonso, I. Duvnjak & I.M. Diaz

Bridge condition and performance monitoring: An engineering approach 2263
P.S. McCarten

Determination of precast concrete bridge slab connection stiffness by developing a digital twin 2271
S. Ereiz, I. Duvnjak, J. Pajan, M. Bartolac, J. Košćak & D. Damjanović

Damage detection of riveted truss bridge using ANN-aided AMS optimization method 2279
B. Šplíchal, D. Lehký & K. Lamperová

Evaluation of Low-cost Adaptable Reliable Accelerometer (LARA) technology 2287
E. Delgado, V. Torralba, S. Komarizadehasl, G. Ramos, J. Turmo & J.A. Lozano-Galant

Performance comparison between several SHM solutions: A viaduct of the Italian highway 2295
M. Ciano, M. Malavisi, D. Buggiani, L. Grottoli, D. Bolognini & F. Dacarro

Vibration-based NDT system for external tendons: Anomaly detection through machine learning classifiers 2303
J. Naranjo-Pérez, J. Jiménez-Alonso, I.M. Díaz, J.H. García-Palacios & C.M.C. Renedo

Machine learning-based clustering and regression for assessing temperature-induced variations on external tendon's natural frequencies 2311
L. Chillitupa-Palomino, C. Barrera-Vargas, J.H. García-Palacios, I.M. Díaz & J. Naranjo-Pérez

Integrating CWT and CNN for damage detection in high-speed railway bridges 2319
J.F. Jiménez-Alonso, J. Naranjo-Pérez, C.M.C. Renedo, J.H. García-Palacios & I.M. Díaz

Data-driven framework for damage detection in structural system 2327
R. Ghiasi, J.F. Jiménez-Alonso & A. Malekjafarian

Measurement and structural behavior of suspended swaying pedestrian bridge 2334
E.-S. Hwang, S.-H. Shin, T.R. Park & D. Hwang

SS18: Human-bridge managing interfaces through digital twinning
Organizers: R. Chacón, I. Stipanovic & J.R. Casas

A framework for an integrated & digitally-supported bridge management 2345
S. Moghtadernejad, Z. Lounis & J. Zhang

PONTI: An open WebGL-based tool in support to defect analysis and 3D visualisation of bridges 2353
R. Fascia, F. Barbieri, F. Gaspari, F. Ioli & L. Pinto

Advancing bridge asset management in Indonesia: Integrating scan-to-BIM for digital twin approach 2362
H.T. Saksena & R.P.P. Sastrawiria

Material characterization for HBIM data structures on a masonry arch bridge 2370
R. Chacón, C. Ramonell, H. Posada, L. Pelà, L. García-Ramonda, S. Gönen & A. Cabané

Integration of BIM and MIVES to automate the sustainability assessment of viaducts 2379
F. Lozano-Galant, J.C. Jurado, A. de la Fuente, J.A. Lozano-Galant & J. Turmo

SS20: Sensing technology and data processing algorithm towards bridge life-cycle maintenance and safety
Organizers: H. Qu, C. Guo & H. Zhang

A new multi-source data fusion method for seismic identification of bridge 2389
A. Chang & H. Qu

Defects detection of concrete bridge decks using UAV-based infrared thermography 2395
H.B. Zhang, Z. Zhou & G. Chen

Senmos: A user-centered approach to structural health monitoring with applications on Lillebæltsbroen af 1935 2401
K. Myrtue, S.D. Myrtue, J. Larsen & P.N.L. Sørensen

Investigation of the effect of surface condition variation on infrared imaging of concrete delamination 2409
C. Cheng, D. Chen, H. Cai, S. Wang, R. Wang & X. Cheng

Structural health monitoring of the 1915Çanakkale Bridge in Turkey, the largest monitoring system for the longest suspension bridge in the world 2417
S. Joye & M.D. Witt

SS22: Advancements in intelligent monitoring and maintenance of bridge infrastructure
Organizers: S. Setunge, A. Alani, G. Heravi, R. Dissanayake, T. Bui-Tien, M. Mahmoodian & A. Sidiq

Real-time structural integrity assessment of bridge infrastructure 2425
S.C. Jayasinghe, T.M. Nanayakkara, A. Alavi, M. Mahmoodian, A. Sidiq, Z. Sun, F. Shahrivar & S. Setunge

Optimal sensor placement applications for bridge structural health monitoring using the effective independence method 2433
Z. Sun, M.I. Manuel, M. Mahmoodian, A. Sidiq, R.W.K. Chan, S.C. Jayasinghe, F. Shahrivar & S. Setunge

Recent studies on the dynamic behaviour of various bridges in Spain 2441
J.A. López-Aragón & M.A. Astiz

Equivalent structural stress concentration factor for non-planar oblique butt joints 2450
X. Wei & Q.L. Jia

Electrochemical-chemical-mechanical phase field model for corrosion-induced cracking 2459
X. Fang, Z. Pan & A. Chen

Analysis of monitoring data on prestressed concrete bridges under construction 2466
T. Ohno, H. Sekiya, I. Yoshida, S. Morichika, A. Yasuda, M. Uno & N. Yoshiura

Piezo-Electric Dampers (PiDs) for energy harvesting purposes 2473
J.F. Martins, M. Francioli & F. Petrini

Infrastructure structural health monitoring of bridge with polarimetric radar sensor 2481
L. Zou & A.M. Alani

Precise 3D simulations in bridge deck inspections of ground penetrating radar survey 2490
D. Dai, Y. Zheng, H. Liu, L. Zou & A.M. Alani

New trends and possibilities of GPR in bridge inspection 2498
M. Solla, A. Elseicy & A. Alonso-Díaz

Øresund Bridge: Case study of a monitoring system for movement of bridge bearings 2507
A. Paciacconi & T. Richli

Thermal response prediction of the MX3D bridge's operational dataset 2511
T. Glashier, C. Buchanan & R. Kromanis

Identification of main cable shape of suspension bridge based on 3D point cloud 2520
R. Pan, D. Dan & Y. Li

A framework for bridge condition assessment using graph neural network 2528
G. Marasco, S. Sadeghi Eshkevari, I. Dabbaghchian, S.N. Pakzad & D. Sen

An innovative approach for a sustainable monitoring of large infrastructures networks 2536
M. Longo, S. Cirelli, D.L. Mazza, I. Alovisi, P. Darò, G. Mancini

Field monitoring of bridge link slab performance under long-term and live load effects 2544
A.M. Okeil & M. Canales

SS23: Structural health diagnosis under limited supervision for large bridges
Organizer: Y. Xu

Big model for bridge health diagnosis by cross-modal learning 2555
Y. Xu

Large vision model-based crack segmentation under limited supervision 2562
Y. Guo, S. Li & Y. Xu

Vibration-based fatigue assessment and damage detection in bridge cables 2567
B. Xu, J.R. Casas & Z.R. Wu

Monitoring to secure the Ile-de-Ré viaduct France 2576
S. Joye & M.D. Witt

SS25: Vulnerability assessment and retrofit of in-service bridges: Contributions and experiences
Organizers: M. Domaneschi, R. Cucuzza, G.A. Ferro, S. Mitoulis, M. Noori & V. Villa

Reliability of UT for the grouting inspection in PT bridges: A case study 2585
I. Mazzatura, J.R. Casas, S. Caprili & W. Salvatore

Resilience and sustainability assessment of a prestressed concrete viaduct 2594
M. Domaneschi, R. Cucuzza, R. Di Bari, S. Argyroudis, S. Mitoulis & N. Kopiika

Deterioration rate diagnosis to global climatic change: The case of Dnipro Dam in Ukraine 2603
N.S. Kopiika, J. Ninic, R. Cucuzza & S.A. Mitoulis

Model-driven strategy for bridge measurement-system design 2612
R. Galli & D. Briccola

Quality assurance of intervention in reinforced concrete bridges 2620
A.C.P. Martins, G.F.B. Milagres, J.M. Franco de Carvalho, C.A.F. Souza, F.G. Bellon, M.S. Andrade, D.S. Oliveira, K.M.L. César Jr & J.C.L. Ribeiro

Fatigue analysis and maintenance strategies for details in long-span bridge girders 2628
C. Deng, Y. Ren, X. Xu, Z. Fan, Q. Huang & Y. Li

A comparison of Italian and UK guidelines on the vulnerability assessment of bridges 2636
A. Lipari & P. Clemente

The knowledge process for the structural assessment of existing concrete bridges with post-tensioned cables: Application to a case study 2645
A. Natali, S. Celati, D. Gaudioso, W. Salvatore, D. Coletta & M. Malavisi

Sustainable repair of concrete structures in Denmark 2654
J.M. Frederiksen & C.M. Nielsen

Vulnerability assessment of timber piles by bending wave and dispersive wave testing methods 2662
W. Zatar & H. Nghiem

SS26: Risk-informed decision making and asset management of highway bridge portfolios
Organizers: A. Du, X. Wang & A. Shafieezadeh

Maintenance plan optimization system based on remaining life prediction 2673
A. Miyamoto

Risk-informed approach to determining optimal bridge inspection frequency for periodic replacement policies 2684
A.X.-X. Yuan & W. Chen

Fragility assessment of water-crossing bridge structures exposed to flood hazards 2693
J.M. Patel & J.E. Padgett

Combining condition deterioration and seismic risks for bridge asset management 2702
A. Ghavidel, A. Du & S. Kameshwar

A short-term hyperlocal meteorological forecast tool for mitigating bridge risks 2710
C.T. Georgakis, N. Lagaros, P. Tsakalis, I. Chamatidis & C. Demartino

SS27: Life-cycle performance safety, reliability, and risk of bridges and infrastructure systems under climate change
Organizers: F. Biondini, Z. Lounis & M. Ghosn

Remaining fatigue service life of the Hillsborough River Bridge in PEI, Canada 2721
C. MacAulay, G. MacDonald, A. MacDonald, R. Keefe & D. Evans

Climate change challenges: A study on bridge accessories and structural performance 2730
D. Greco, A. Moscatelli & D. Briccola

Fatigue life assessment of steel wires with multiple corrosion pits based on peridynamics 2738
Y. Yang, Q.W. Zhang, J.F. Liu, Y.F. Ji & Y.C. Ni

Fatigue life estimation for long span suspension bridges due to buffeting 2747
Z.Z. Banday, A. Fenerci, T.M. Lystad & O.A. Øiseth

Cellular automata damage models incorporating climate change effects for life-cycle assessment of concrete bridges 2755
G.V. Nava, A. D'Iorio & F. Biondini

SS28: Probability-based life-cycle design analysis of bridge engineering
Organizers: L. Wang, J. Peng, J. He, W. Lin & X. Zhou

Robustness evaluation of a twin I-girder bridge 2767
P. Acharya, R. Hao & W. Lin

Fatigue reliability analysis for welding details under traffic flow 2775
Q. Zheng, Z. Pan, X. Fang, R. Ma & B. Wang

Static and fatigue tests for hybrid welded-bolted demountable shear connectors 2783
J. He, Z. Wang, L. Wang, G. Vasdravellis & H. Xin

Optimization of maintenance program for bridge cable in service lifetime 2791
S. Liao, J. Peng, L. Wang & J. Zhang

Probabilistic inspection planning for the life cycle management of railway bridges 2797
I. Ames, T.N. Bittencourt, M.M. Futai, A.T. Beck & H. Carvalho

SS29: Risk-based assessment and prioritization of bridge stocks
Organizers: N. Scattarreggia & R. Monteiro

Management of earth retaining structures based on condition and criticality 2807
J.L. Amado, M.A. Pratas, B. Monteiro, A. Costa & M. Pinheiro

Automatic calibration of structural BIM models applied to bridges 2815
F. Lozano-Galant, E. Atencio, N. Tošić, J. González-Arteaga, Y. Xia & J.A. Lozano-Galant

Sustainable-centered approach for bridge management: A game-changer paradigm 2823
D. Duzzi & D. Briccola

Expediting the bridge management practice: A structural reliability-based method 2831
F. Brighenti, M.F. Bado, F. Poli, F. Romeo, D. Zonta, J.D. Rotilio & A. Ferman

Development of a bridge rating tool for optimised multi-hazard life-cycle-based maintenance 2840
M. Calò, N. Scattarreggia, G. Mucedero & R. Monteiro

Enhancing bridge monitoring through supervised anomaly classification 2848
I. Bayane, J. Leander & R. Karoumi

Reshaping bridge inspection with AI, 3D tools and BIM: Outcomes from an R&D initiative 2856
T. Mendonça, V. Brito, S. Costa, J. Matos & S. Fernandes

A quantitative methodology for risk-based priority ranking of deteriorated bridges: Application to a bridge stock 2865
S. Hamidpour, N. Scattarreggia, R. Nascimbene & R. Monteiro

An index-based method for risk assessment of existing bridges subjected to multiple hazard 2873
L.A. Grieco, N. Scattarreggia, R. Monterio & F. Parisi

The Italian guidelines for risk and safety evaluation of existing bridges: A case study 2882
P.P. Rossi, N. Spinella & A. Recupero

SS30: Virtual inspection
Organizers: P. Linneberg & S. Gjerding

Immersive visualization for enhanced operations and management of bridges 2893
B. Aryal & P. Linneberg

Digital transition in asset management – Virtual inspections of bridges 2901
N.L. Barnes & E.D. Hartwich

Norwegian coastal bridges 2909
T. Kvamstad, H.A. Moe & I.A. Lervik

Virtual supervision of the new Storstrøm Bridge: Status and potential with CVI 2917
T. Norsk

SS31: O&M of major bridges
Organizers: R. Percy & J.L. Jensen

Sustainability monitoring of cable systems 2927
J. Laigaard Jensen, J.F. Melén & I.F. Alcover

Tjörn bridge O&M challenges and mitigation 2935
J.L. Jensen, A. Larsen, A.H. Langager, S. Ussing, J.F. Melén & A. Maglica

Moisture monitoring in cable anchorages before and after dehumidification 2943
A. Parodi, J.L. Jensen, E. Stefansson, H. Sønderby, J.F. Melén & A. Maglica

Analysing ultrasonic testing data to optimise stay cable maintenance 2951
A. Boyez, R. Percy, J.L. Jensen & I.F. Alcover

The maintenance project of the special anti-seismic devices of the longest Italian bridge 2960
A. Greco & A. Lupoi

Experiences with repair of fatigue cracks in an orthotropic steel deck, New Little Belt Bridge, Denmark 2969
P.L. Sørensen, N. Bitsch & J. Præst

The organization, O&M operations and inspections of the 1915Çanakkale Bridge 2977
F. Aytekin & A.M. Kızılkaya

Traffic wind hazards on the Storebælt East Bridge and mitigation 2984
A. Larsen, L.F. Pedersen, N. Bitsch & F.R. Gottfredsen

Fatigue crack propagation simulation of Haibach hole for orthotropic steel bridge deck 2992
Z. Kang, J. Kang, L.W. Xu, P.Y. Li & C.S. Wang

Digital fatigue test of steel truss girders in long-span suspension bridge with double-deck 3001
Q.L. Wu, T.K. Zhang, J. Xu, S. Liu & C.S. Wang

SS32: Data-driven asset management
Organizers: I.F. Alcover, M. Saberi & J. Winkler

Change detection using Bayesian multivariate linear regression 3011
R.J. Hollamby & I.F. Alcover

Scoring system for technical evaluation of technologies for remote monitoring of bridges 3019
M. Saberi, K. McPherson, F. Zhang, A. Arvidsson, S. Fjendbo, C.V. Geem, M. Kreslin & A. Anžlin

Regional impacts of natural disasters on road bridges in the Philippines 3027
M.J. Adarne & M. Henry

Improved structural assessment of Newport Bridge using smartphone-based technologies 3035
J. Winkler, N. McKay & C. Hendy

Artificial intelligence to identify defects on bridges inspected by drone 3041
S. Flawinne

Improved structural health monitoring of the Lincent Bridge using innovative camera-based system 3049
L. Rivituso, S. Flawinne & J. Winkler

SS33: Sustainability in bridge design, operation and maintenance
Organizers: M.H. Faber & P. Linneberg

Life-cycle assessment of RC trough bridges in Sweden and Colombia: A comparative Study 3059
S.L. Leiva-Maldonado, J. Gonzalez-Libreros, C. Wang , G. Sas, P. Simonsson & D. Sas

Reducing the climate impact (GWP) from bridges in a Danish highway project 3067
J. Olesen, P.G. Pedersen & C.V. Scholten

Static behavior of steel-concrete bridge under pier girder consolidation 3075
W. Xie & Q. Su

On CO_2 efficiency and trade-offs between safety and sustainability in concrete bridge management 3084
M. Liu, J. Olesen, P. Linneberg, D.G. Lu & M.H. Faber

Fatigue design of continuous thermite-welded rail 3092
Y.C. Park & J.Y. Lee

SS37: Nordic Operation and maintenance strategies for bridges: Pioneering a sustainable future
Organizers: T. Bangsgaard, D. Honfi & B.T. Svendsen

Risk-based evaluation of fire protection on cable-supported bridges 3101
N.P. Høj, M. Bjelkerud & H. Matre

Maintenance strategies by the Swedish Transport Administration 3111
F. Olsson

Evaluation of post-tensioned bridges by state-of-the-art techniques 3117
G. Rapaport

Development and implementation of digital inspection notebook for bridges 3124
M. Tai, H. Shirahata, T. Kawai, T. Aoki, H. Hara & S. Takagi

Towards a service life extension of the Øresund Fixed Link 3133
I. Björnsson, S. Thöns, S. Celati & B. Hergart

SS39: Digital enabled asset management of major bridges
Organizers: T. Friis & I. Gualtero

Extending great belt bridge bearing service life using mobile computer vision 3145
J. Winkler, M.D. Havelykke & F. Bormlund

30 years' experience of optimizing the use of corrosion sensors 3152
P.H. Møller & S. Gjerding

Digital technologies for bridge damage detection: Drones and AI for remote inspections 3161
D. Buggiani, M. Malavisi & A. Baldacci

Service life strategies on hanger cables of the Great Belt Bridge 3169
P. Holmstrøm, D. Lang, T. Friis, M.N. Svendsen & M.D. Havelykke

Data-driven maintenance of Bogibeel Bridge - large scale structural health monitoring 3178
H. Gjelstrup, T. Bangsgaard & F. Houseini

Digital health monitoring of the Great Belt Suspension Bridge 3187
T. Friis, S.S. Christensen, S.T. Nielsen, M. Lollesgaard, T.B. Bangsgaard & M.D. Havelykke

Data-driven preventive maintenance and service life extension of the Sunshine Skyway Bridge – Tampa FL, USA 3196
I.A. Gualtero, A.H. Alvi, S.D. Womble, J.J. Jacobsen & V.S. Collie

Sustaining structural bearings – assessment of renovation design on Storebælt West Bridge 3205
A. Smyth, D. Lang, J. Fogh-Svensson, N. Grønkjær Rasmussen, M. Duus Havelykke & F. Raun Gottfredsen

SS41: Management and maintenance of urban bridges
Organizers: D. Honfi, L. Dunai & J. Vig

Cause identification for uplifting behavior of truss bridges 3215
K. Suzuki, Y. Nojima, K. Takeya, A. Akutsu, K.K. Vankayalapati, Y. Ito & E. Sasaki

Aerial-demolition method for bridges above intersections with heavy traffic 3223
R. Nakata, T. Oike, K. Fujiwara, S. Watanabe, K. Mori, Y. Ninomiya, T. Shimada, D. Fujimoto & I. Tada

Risk assessment of the K-bridge over the Danube 3231
B. Kövesdi, D. Kollár, L. Dunai & Z. Hodik

Development of the maintenance strategy for Västerbron 3240
J. Sandberg, L. Steen & J. Hedenström

Enhancing Dybbølsbro Bridge – Refurbishment and expansion without new substructure 3249
L. Thormann, C. Pedersen & J.F. Svensson

SS42: Community resilience and decision-support systems
Organizers: N. Makhoul, R. Kromanis, J. van de Lindt, A.R. Barbosa & F. Schmidt

Dynamic traffic simulation for transportation system resilience assessment 3259
X. Wang, P. Bocchini, P. Venkitasubramaniam & S. Xie

Adaptive transition of critical transport infrastructures 3267
D.V. Achillopoulou, N.K. Stamataki, N. Makhoul & R. Kromanis

Machine learning improving seismic infrastructure recovery time estimation 3276
N. Makhoul & B. Derras

Information entropy-driven recovery strategies for systems' resilience 3286
A. Tzioutziou & Y. Xenidis

Physics-based earthquake-tsunami fragility surfaces for risk and resilience analysis 3295
M. Harati & J.W van de Lindt

Bridge maintenance methodology accounting for climate change dependent parameters 3304
S.A. Keo & N. Makhoul

Enhancing urban resilience and sustainability under wind disasters with carbon emission as an indicator 3311
T.-Y. Wang & C.-Y. Lin

Identification of a suitable case study for the development of accessibility based vulnerability score for bridge maintenance decision making 3320
M. Lydon, A. Vega, E. Fitzpatrick, R. Higgins & A. Fenerich

SS43: Responding to structural emergencies: Post-event inspection to restoring the structure to full service
Organizers: S. Alampalli & M. Maqbool

A plan for assessing the damage to highway bridges after an earthquake 3329
J.S. O'Connor & S. Alampalli

Rapid response for ensuring safety following bridge hits 3337
M.A. Mohammed

Critical role of the bridges ensuring emergency services and disaster recovery in Turkey 3343
N. Memişoğlu Apaydin & R.B. Sikar

Human-centered post-disaster inspection of infrastructure using augmented reality 3352
F. Moreu, C.-M. Chang, Y.-T. Liu, K. Malek & A. Khorasani

Condition assessment and repair protocols for dynamically impacted bridge girders 3359
W. Zatar

SS44: AI and optimization methods for bridge management under uncertainty
Organizers: D.Y. Yang, C. Andriotis & K.G. Papakonstantinou

Data-derived train classification and monitoring of masonry bridge 3371
J. Cheng, A. Chen, M.J. DeJong & S. Cocking

Deep reinforcement learning-driven life-cycle management of bridge and pavement systems 3380
A. Bhattacharya, M. Saifullah & K.G. Papakonstantinou

Analyzing uncertainty in strain estimation framework for bridge condition assessment 3389
S.S. Eshkevari, I. Dabbaghchian, G. Marasco, S. Pakzad & D. Sen

Intelligent automatic operational modal analysis: Application to a suspension bridge 3397
M.M. Rosso, G.C. Marano, A. Aloisio & G. Quaranta

Managing aging bridges under seismic hazards through deep reinforcement learning 3405
Z. Metwally, C.P. Andriotis & F. Molaioni

Objective risk assessment for bridge management 3414
S.A. Moayyedi & D.Y. Yang

SS46: BRIDGITISE an EU network on the digitalization of bridge integrity management
Organizers: M.P. Limongelli, J.H. Roldsgaard, J. Jordan & M.H. Faber

Drone-based photogrammetric indoor inspection of box girder bridges 3425
J.C. Avendaño, J. Leander & R. Karoumi

Decision algorithms for the managing of steel railway bridges 3433
J. Garcia, F. Javier & C.R. Iván

Lightweight vehicles in indirect structural health monitoring: Current advances and future prospects 3441
P.F. Giordano, S. Quqa & M.P. Limongelli

Simultaneous WET and WIT with Q-learning for wireless bridge sensors network 3450
M.T. Mushtaq, V. Giuseppe, N. Cordeschi, A. Grieco & G. Boggia

Probabilistic digital twin for continuous bridge performance modelling 3457
P. Darò, D.L. Mazza, F. Basone, G. Mancini, M.P. Limongelli & M.H. Faber

SS47: Life-cycle of RC/PC bridges: Advances on experimental testing and computational methods from the BRIDGE|50 research project
Organizers: F. Biondini, F. Tondolo, S. Manto & C. Beltrami

Nonlinear structural analysis of 50-year-old PC bridge deck beams under load testing 3467
M. Anghileri & F. Biondini

Corrosion investigations on PC deck beams of a 50-year-old decommissioned viaduct 3476
M. Carsana, E. Redaelli & F. Biondini

Load tests on dismantled 50-year-old prestressed concrete bridge deck beams 3484
P. Savino, A. Quattrone, D. Sabia, B. Chiaia, F. Tondolo, M. Anghileri, F. Biondini & G. Rosati

Dynamic response of damaged precast bridge girders 3493
D. Sabia, A. Quattrone, F. Tondolo & P. Savino

Integrating BIM in experimental tests on bridge beams 3501
D.R. Polania, F. Tondolo, A. Osello, C. Trincianti & M. Chiara

GENERAL SESSIONS

GS01: BRIDGE MAINTENANCE - Application of new tools

Super-resolution enhanced vehicle recognition method for long-span bridge 3513
X. Shan, J. Zhang, Y. Pan, Y. Ma & D. Wang

Bayesian non-linear load estimation in long-span bridges via physics-informed Gaussian processes 3522
G.R. Tondo, I. Kavrakov & G. Morgenthal

A multi-task deep learning-based framework for structural details and corrosion detection in steel bridges 3530
M.Z. Esteghamati, M.H. Ahmed, S. Young & M. Halling

Tests of TIG welded lap joint between Fe-SMA and steel 3538
Z. Zhang, X. Qiang, X. Jiang & P. Jin

A decision method for ship-bridge collision pre-warning based on vision and radar data fusion 3546
H. Zhuang, D. Wang, Z. Gu, Y. Dong & J. Wang

GS05: BRIDGE MAINTENANCE - Inspection and diagnostic

Utilization of soundness assessment of medium and small span bridges based the ML models 3557
Arong, G.Z. Wang, M.X. Gao, Dongmei, S. Bai & Yiliguoqi

AI for bridge inspection with IBM Inspecto 3565
A.C.I. Malossi, R. Assaf, N. Avogaro, A. Bartezzaghi, B. Ebouky, T. Frick, I. Giurgiu, F.M. Janicki, P. Kluska, M. Rigotti, F. Scheidegger, A. Simeski, C. Skura, D. Caraballo, Y. Cinar, F. Bormlund & S. Gjerding

A review of recent research on visual inspection processes for bridges and the potential uses of AI 3573
P.J. Vardanega, T. Tryfonas, G. Gavriel, D.T. Nepomuceno, M. Pregnolato & J. Bennetts

Performance evaluation of TMDs for a continuous steel box girder 3581
G.L. Liu, X.H. Hu & R.J. Ma

Improvement of thickness estimation model on a steel member using local vibration mode based on data augmentation 3590
S. Kato, K. Hisazumi, T. Tominaga, Y. Yang & T. Nagayama

Crack detection method for RC beams with an automatic hammering device 3599
I. Uchiyama, H. Naito, K. Inada, Y. Kuriharam & K. Matsuhashi

An attempt to improve the accuracy of 3D point cloud considering bridge vibration effects 3608
A. Akutsu, J. Lin & E. Sasaki

Scour detection method of bridge foundation based on pier vibration mode under vehicle braking action 3617
Y. Li, Z.H. Zhang, Z.B. Sun & H. Sun

Field test study of bridge scour diagnostic method based on time-varying frequency 3625
Z.H. Zhang, Y. Li, C. Yang & H. Sun

Accuracy of the pulsed eddy current thickness measurement for a corroded steel pipe 3633
Y. Kitane, Y. Shichijo & Y. Itoh

GS07: BRIDGE MAINTENANCE - Non-destructive testing

Ground Penetrating Radar (GPR) for bridge inspection 3645
N. Roumia & C. Mazzotti

Advancements in bridges NDT: National Highways' "Structures Moonshot" – Paper No. 1 3653
C. Mundell, C. Hendy, T. Argyle & C. George

Advancements in Bridges NDT: National Highways' "Structures Moonshot" – Paper No. 2 3663
C. Mundell, C. Hendy, T. Argyle & C. George

Advancements in Structural Health Monitoring (SHM): Deformation Area Difference (DAD) method and model updating 3673
T. Čamo, E. Apostolidi & D. Waldmann-Diederich

A study on hammering inspection for unreinforced concrete based on wearable microphone measurement 3681
K. Takeya, S. Kobayashi, A. Akutsu, Y. Ito & E. Sasaki

GS17: BRIDGE SAFETY - Advanced computer simulation

Simulation of cylinder impact damage by peridynamics 3691
J.J. Zhang, Z.C. Pan & H.C. Chang

Analytical evaluation of DBTT in Charpy impact test for structural steels 3698
A. Jamil, H. Tamura, H. Katsuchi & C. He

Elastic-plastic bearing capacity simulation of steel-concrete composite bridge tower 3706
S.D. Sun, L.H. Yang, Y.W. Wang, K.Q. Cheng & C.S. Wang

Structural behavior of steel truss girder with thick concrete deck in cable-stayed bridge 3715
Y.Q. Li, Y.C. Feng, X. Hou, S.L. Yan, H.J. Liu & C.S. Wang

Reasonable degree of shear connection for thick concrete deck in cable-stayed bridge 3723
Y.Q. Li, Y.C. Feng, X. Hou, H.J. Liu & C.S. Wang

GS19: BRIDGE SAFETY - Assessment and evaluation

Development of a new abutment connection for rapid construction 3733
F. Sigurjónsson, R.S. Smárason, O.S. Haraldsson, B. Bessason & C.Y. Tsai

NDT for damage detection in FRP reinforced/strengthened concrete elements 3740
A.B. Mehrabi, S.S.K. Dolati, P. Malla, J.O. Polanco & A. Nanni

Calibration of constitutive model parameters of bridge steels using particle swarm optimization 3748
Y. Zhang, C. Li & H. Huo

Modal identification for rapid assessment of short span reinforced concrete bridges 3757
S.L. Leiva-Maldonado & F. Consuegra

Retroreflective sheeting materials as SHM passive strain sensors 3765
H.M. Power & H.W. Shenton III

Assessment method for arch bridges affected by HS2 tunnel settlement, UK 3773
A.S. Justo, A. Bariyya, C. Brown, R. Lee & M. Gilbert

Parametric evaluation and design of prestressed concrete beam bridges 3782
V.N. Moraes, T.E.T. Buttignol & L.M. Trautwein

Bridge deterioration estimation for small zones considering chemical attack 3790
F. Obunguta, K. Kaito, K. Sasai, K. Kobayashi, K. Matsushima & H. Bakamwesiga

Assessment of shear capacity of bridge beams with non-standard anchorage - an experimental study 3801
E. Nuti, A. Darby, M. Evernden, J. Bennetts, J.D. Shave & P. Valerio

Deep learning for evaluation of girder rotation during bridge deck construction 3809
L. Hui & R. Hindi

FEM-based dynamic analysis of noise barriers under train-induced aerodynamic load 3817
D. Liu, C. Wang, J. Gonzalez-Libreros, Y. Tu, L. Elfgren, G. Sas, O. Enoksson, T. Höjsten & Y. Tu

Analytical evaluation of Hybrid Deck Bulb Tee for superstructure replacement 3825
P. Agüero-Barrantes & A. Hain

PCA-based technique to assess the modal properties of the Itacaiúnas bridge during flooding 3832
R. Lopes, J. Weyl, V. Barros & T. Bittencourt

Recommendations for structural assessment of RC slabs using the finite element method 3838
M. Plos, M. Johansson, K. Zandi & J. Shu

Behaviour & management of pre-tensioned girder halving joints 3845
N. Stevens, T. Heldt, C. Lin & R. Sampaio

The behaviour and management of post-tensioned girder halving joints 3854
N. Stevens, R. Sampaio, T. Heldt & C. Lin

Fatigue behaviour of reinforced concrete inverted T headstock halving joints 3863
N. Stevens, C. Lin, T. Heldt & R. Sampaio

Enhancing safety on timber bridges: Feasibility and risk assessment of bridge barrier implementation 3871
E. Chaw, G. O'Connor, D. Milling, A.D. Silva, R. Daley & B. Wiggins

Design curves for masonry arch bridges over rivers in the UK 3880
J. Liu, G.D.D. Dieco, F.D.D. Dieco, F. Ragone & S.L. Nunn

Seismic performance of highway RC bridges with corroded piers 3889
D. Cardone, V. Possidente, G. Perrone, A. Spica, D. Bernardini, D. Ruta, A. Paolone, F. Braga, F. Buttarazzi & A. Rossi

Identification of governing structural safety criterion for existing bridges considering costs, occupancy and conditional fatality probability 3897
F. Liljefors & J. Köhler

A review of design and assessment methods for skew concrete slabs 3904
A. Lipari

Non-destructive testing of a post-tensioned concrete road bridge in Norway 3913
B. Täljsten, C. Popescu & M. Holmqvist

Comparison of partial factor methods for existing concrete structures: Application to a cable-stayed bridge 3922
L. Casti, F. Schmidt, F. Biondini, N. Makhoul & R. Pittet

GS25: BRIDGE SAFETY - Extreme loads

Seismic design of cable-stayed bridges in high intensity areas 3933
B. Li, Z. Zeng, Y. He & Y. Xu

A coupled thermal-mechanical-phase field model for concrete under fire 3941
K. Miao, Z. Pan, X. Fang & A. Chen

Modelling of thermo-mechanical behaviour of tunnels under fire conditions 3950
R.A.S. Díaz, E.O.L. Lantsoght & M.A.N. Hendriks

An unconventional barrier design 3958
Z. Kamranian, D. Penate, G. Norlander & F. Oudah

GS27: BRIDGE SAFETY - Repair and retrofitting strategy

Anchored response tailored prestressed CFRP strengthening – preliminary long-term and temperature investigations 3967
J.W. Schmidt, C.O. Christensen & P. Goltermann

Analytical study on the effects of flange size on the axial force introduced in the rivet 3976
K. Yamamoto & K. Nozaka

Novel Fe-SMA bonding method for repair of U-rib butt welds in OSDs 3985
Z.L. Lv, X. Jiang, X.H. Qiang, H.L. Wu & J.M. Ding

Experiment research on fatigue cracks at diaphragm cutouts reinforced employing Fe-SMA in steel bridge 3992
Y.P. Wu, X.H. Qiang, X. Jiang & Z.Y. Yang

Experimental study on seismic performance of different failure modes of RC shear keys 4001
H. Mei & A.X. Guo

Progressive failure analysis of strengthened masonry arch bridges 4010
T. Kamiński & C. Costa

Rapid repair of bridge beams and decks with prefabricated FRP panels 4019
M. Ehsani

Incremental repair method for corroded bolted connection 4027
E. Yamaguchi, N. Tamada, U. Agvaanluvsan, T. Takai & M. Wada

GS28: BRIDGE SAFETY - Safety and serviceability

A 2D TBI model to study lateral dynamics in ship impact event 4035
D. Riboldi, L. Bernardini & A. Collina

Energy absorption of bolted connection up to tensile ultimate state 4043
T. Takai, K. Tanii & S. Masudome

Effectiveness of geotechnical seismic isolation for post-tensioned rocking piers 4052
A. Contento, B. Briseghella, A. Di Egidio, A. Aloisio, H.-H. Tsang & P. Gardoni

Flexural behavior of concrete- steel composite girders with tubular flanges 4060
Y.R. Liu, B.Q. Gao, X.B. Qu, J.W. Zhang, Y.W. Wang & L. Duan

Flexural behavior of high strength steel-UHPFRC composite girders 4069
J.W. Zhang, F. Li, X.B. Qu, S.J. Li, W.T. Liu & C.S. Wang

Preface

The world economy is changing rapidly. On the one hand, issues like health and safety, quality, resilience, sustainability, climate change, social justice, and the environment are increasing their weight for decision-makers compared with traditional financial considerations. On the other hand, the advent of cheap, powerful computers, smartphones, and robots is changing society and economic interactions drastically.

However, one thing that seems stable in this turmoil is the importance given to maintenance and life-cycle evaluation in any infrastructure, making IABMAS (International Association for Bridge Maintenance and Safety) goals more and more relevant for the engineering community. In this context, academics and practitioners are rising to the challenge with research and practice focusing on innovative approaches to identify problems and implement solutions. IABMAS conferences bring together academic and technological developments in bridge safety, maintenance, management, life-cycle, resilience, and sustainability, among others, to solve new and old problems with innovative solutions. The most recent developments in the field are expected to be discussed at the 12th International Conference on Bridge Maintenance, Safety and Management (IABMAS 2024), held in Copenhagen, Denmark, on 24–28th of June 2024 (https://iabmas2024.dk/).

The First (IABMAS'02), Second (IABMAS'04), Third (IABMAS'06), Fourth (IABMAS'08), Fifth (IABMAS'10), Sixth (IABMAS'12), Seventh (IABMAS'14), Eighth (IABMAS'16), Ninth (IABMAS'18), Tenth (IABMAS'20) and Eleventh (IABMAS'22) International Conferences on Bridge Maintenance, Safety and Management were held in Barcelona, Spain, July 14–17, 2002, Kyoto, Japan, October 18–22, 2004, Porto, Portugal, July 16–19, 2006, Seoul, Korea, July 13–17, 2008, Philadelphia, USA, July 11–15, 2010, Stresa, Lake Maggiore, Italy, July 8–12, 2012, Shanghai, China, July 7–11, 2014, Foz do Iguaçu, Brazil, June 26–30, 2016, Melbourne, Australia, July 9–13, 2018, Sapporo, Hokkaido, Japan, April 11–15, 2021 (online) and Barcelona, Spain, July 11–15, 2022.

In this edition, the Conference will be in Copenhagen, Denmark, and IABMAS Denmark looks forward to celebrating the 12th edition and 25th anniversary of IABMAS. Again, face-to-face after some challenging years with COVID.

IABMAS 2024 is organized by IABMAS (https://iabmas.w.waseda.jp/) in collaboration with IABMAS Denmark (https://iabmas-danmark.dk). IABMAS encompasses all aspects of bridge maintenance, safety and management. Specifically, it deals with bridge repair and rehabilitation issues, bridge management systems, needs of bridge owners, financial planning, life costing and investment of the future, sustainability, bridge-related safety and risk issues, and economic and other implications.

The objective of the Association is to promote international cooperation in bridge maintenance, safety, risk, resilience, sustainability, and management to enhance society's welfare (www.iabmas.org). The interest of the international bridge community in the fields covered by IABMAS has been confirmed by the significant response to the IABMAS 2024 call for papers. The Conference Secretariat received 680 abstracts, 676 of which were selected for presentation at the Conference within mini-symposia (MS), special sessions (SS), and general sessions (GS). Finally, 480 papers were accepted for publication in this Open Access book. Contributions presented at IABMAS 2024 deal with the state-of-the-art and emerging

concepts and innovative applications related to the main aspects of safety, maintenance, management, life-cycle, resilience, sustainability, and technological innovations of bridges.

Significant topics include advanced bridge design, construction and maintenance approaches, safety, reliability and risk evaluation, life-cycle management, life-cycle resilience, sustainability, standardization, analytical models, bridge management systems, service life prediction, structural health monitoring, non-destructive testing and field testing, robustness and redundancy, durability enhancement, repair and rehabilitation, fatigue and corrosion, extreme loads, needs of bridge owners, whole life costing and investment for the future, financial planning and application of information and computer technology, extensive data analysis and artificial intelligence for bridges, among others.

Bridge Maintenance, Safety, Management, Digitalisation and Sustainability contains 480 contributions, including the T.Y. Lin Lecture, 9 Keynote Lectures, and 470 technical papers from 44 countries. This volume provides an up-to-date overview of the field of bridge engineering and significant contributions to making more rational decisions on bridge safety, maintenance, management, life-cycle, resilience, sustainability and bridge innovations to enhance the welfare of society. The Editors hope that this book will serve as a valuable reference to all concerned with bridge structure and infrastructure systems, including engineers, researchers, academics, and students from all areas of bridge engineering.

Acknowledgements

The Editors are extremely grateful to everyone who contributed to the scientific program and organization of the IABMAS 2024 Conference. The Editors would like to express their sincere thanks to all authors for their contributions, to the members of the International Scientific Committee and the Local Scientific Committee for their role in ensuring the highest scientific level of the Conference, and to the members of the Local Organizing Committee for their time and efforts dedicated to making IABMAS 2024 a successful event.

Moreover, the Editors thank all organizations, institutions, and authorities offering sponsorship and support. A special acknowledgement has to be given to the International Association for Bridge Maintenance and Safety (IABMAS) and IABMAS Denmark for endorsing and supporting the conference organization.

The conference organizers want to thank the following companies and institutions and their personnel sincerely: The Danish Road Directorate for a visit to the Nordhavnstunnel and the Storstrøms Bridge, Femern and Sund & Baelt for a visit to the Femarnbelt Tunnel, Storebaelt and Sund & Baelt for a visit to the Great Belt Bridge, Oeresundsbron for a visit to the Oresundsbridge, Copenhagen Municipality for a visit to Copenhagen Bridges, Rail Net Denmark and Bridge walking Lillebaelt for the visit to the Lillebaelt Bridge, By og Havn for a boat tour round Nordhavn and Lynetteholm and the Danish Technical University for a visit to the structural and materials testing facilities at the Technical University of Denmark (DTU).

The Editors are also highly thankful to Mitsuyoshi Akiyama, Sreenivas Alampalli, Nurdan Apaydin, Tulio Bittencourt, Eugen Brühwiler, Joan Ramon Casas, Necati Catbas, Airong Chen, Ranjith Dissanayake, Reed M. Ellis, Michel Ghosn, Pier Giorgio Malerba, Jens Sandager Jensen, Ho-Kyung Kim, David De León, Nigel G. Powers, and Matías A. Valenzuela co-chairs of the International Scientific Committee.

Finally, the Editors wish to express their sincerest appreciation to Helle Klestrup and the team at DIS Congress Service A/S, who professionally managed the Organizing Secretariat with outstanding expertise, patience, energy, and commitment, which have been very important for the successful organisation of this Conference.

Editor Biographies

Mr. Jens Sandager Jensen is Project and Market Director in COWI's Transportation Division, which services the Danish market and provide O&M (Operation & Maintenance) specialist services in connection with Transportation projects in Scandinavia and Internationally.
Mr. Jens Sandager Jensen graduated from the Danish Engineering Academy in Denmark in 1982 with a BSc in Civil and Structural Engineering. Specialist knowledge areas are management, life cycle analysis, design of bridges and tunnels and asset management.

In 1982 he joined the Danish company Christiani & Nielsen working with design of marine and tunnel structures, before coming to COWI in 1988, where the first assignment was to be part of the design team for the Eastern Railway Tunnel under the Great Belt in Denmark.

Mr. Jens Sandager Jensen has been the project manager responsible for O&M activities on several major Danish infrastructure projects, amongst others the Eastern Railway Tunnel and the West Bridge of the Great Belt, the land works for the Øresund Bridge and the Copenhagen Metro. He has also worked as project manager to Rail Net Denmark with the responsibility of bridge maintenance in East Denmark.

During many years he has been responsible for Design Build projects for Contractors in the Scandinavian Infrastructure Market with high focus on time and cost savings for the Contractor Clients and at the same time fulfilling the requirements of the Public End Clients.

Mr. Jens Sandager Jensen has been involved in innovation and development within the field of O&M and has in COWI been responsible for major international research and development projects, amongst others the comprehensive EU projects "Sustainable Bridges; Assessment for future traffic demands and longer lives" and "MAINLINE – MAINtenance, renewal and Improvement of rail transport iNfrastructure to reduce Economic and environmental impacts".

Mr. Jens Sandager Jensen is furthermore active in IABSE and in IABMAS since 2002, including a member of The Executive Committee of IABMAS since 2016 and Chairman of IABMAS Denmark since inauguration in 2023. Finally since 2006 he has been a member of the organizing committee for yearly Danish Bridge Day and he has since 2011 been active in the Danish group responsible for defining the policies and regulations to be used in connection with transportation infrastructure structures and civil works.

Dan M Frangopol is the inaugural holder of the Fazlur R. Khan Endowed Chair of Structural Engineering and Architecture at Lehigh University. He is recognized as a pioneer in the field of life-cycle engineering of civil and marine structures under various types of hazards. Dr. Frangopol is the Founding President of the *International Association for Bridge Maintenance and Safety* (IABMAS) and the *International Association for Life-Cycle Civil Engineering* (IALCCE). He is the Founding Editor of *Structure and Infrastructure Engineering*. Dr. Frangopol is the recipient of several honors and awards from ASCE, IABSE, IASSAR, ISHMII, SAE and other professional organizations. He holds 4 honorary doctorates and 14 honorary professorships from major universities. In 2023 ASCE established the Dan M, Frangopol Medal for Life-Cycle Engineering of Civil Structures. Dr. Frangopol is an Elected Member of the US National Academy of Construction, and a foreign member of the Canadian, Japan and Mexican Academies of Engineering, Academia Europaea (London), Royal Academy of Belgium, Romanian Academy, Romanian Academy of Technical Sciences, and a Distinguished Member of ASCE.

Jacob Wittrup Schmidt is Associate professor at the University of Aalborg. His primary field of research concerns the assessment, upgrading, and service life extension of existing structures, focusing on bridges. In this regard, he has published significantly in the field of structural strengthening using Fiber Reinforced Polymer (FRP) materials and multidisciplinary approaches combining structural evaluations, probabilistic assessments, and testing in all scales. Jacob Wittrup Schmidt, a member of the IABMAS Technical Committee on bridge load testing, has performed several national in-situ bridge tests and pilot projects within his field of expertise and has authored an upcoming national proof loading guideline. In addition, he participates in national- and Eurocode standardization- and several international scientific committees.

Aesthetic value of bridges

Man-Chung Tang
T. Y. Lin International (China), Chongqing, China

ABSTRACT: In his book, *The Bridge and the Tower*, David Billington of Princeton University described bridge design as "structural art," which can be equated to architecture in buildings. However, in his opinion, bridge aesthetics should not be handled by architects but by engineers. He listed the three characteristics of a well-designed bridge as having "efficiency, economy, and elegance." He especially emphasized the virtue of efficiency. In Billington's opinion, an efficient structure would naturally look "better." This is in contrast with architecture, wherein decorative elements oftentimes have no practical purpose in and of themselves. Billington's criteria are certainly true for long-span bridges, which are situated far from a city and nowhere near any buildings. City bridges, however, are typically juxtaposed with many buildings or other types of structures. In such cases, being harmonious with the urban surroundings is just as important. Such a bridge can be less efficient and more expensive. Then the question becomes, "What should the acceptable added cost be for such a bridge?" This question can be applied to the maintenance of such bridges as well. Sadly, there are many beautiful bridges in disrepair.

1 INTRODUCTION

The objective of a bridge design is to produce a safe bridge that looks good and satisfies all functionality requirements at a cost acceptable to the owner. This means that a bridge must be safe, functional, economical, and beautiful. The safety of a bridge is guided by the applicable design specifications, while functionality is determined by the traffic requirements; they can be achieved by strictly following codes and specifications. There are no codes or specifications for economy and aesthetics. Whether a bridge is economical or not is typically measured by comparing it to other similar bridges. On the other hand, there are no specifications or rules to judge the aesthetics of a bridge. Then, how do we determine the aesthetic value of a bridge?

This is important because there are always various alternatives for any given bridge. Each alternative may have a different price tag. Should we choose the least expensive bridge concept, or should we build the more expensive one that people may find more beautiful?

2 STRUCTURAL ART

In his book, *The Bridge and the Tower* (Billington, 1983), David Billington of Princeton University described bridge design as "structural art," which can be equated to architecture in buildings. However, they are different! He listed the three characteristics of a well-designed bridge as having "efficiency, economy, and elegance." He especially emphasized the virtue of efficiency. Billington believed that an efficient structure would necessarily look better. This is in contrast with architecture, wherein decorative elements oftentimes have no practical purpose in and of themselves. Therefore, in his opinion, bridge aesthetics should not be handled by architects, but by engineers.

But, in the real world of bridge design, this assertion by Billington may not be true all the time. It is common that by emphasizing elegance, the bridge design may give up some

DOI: 10.1201/9781003483755-1

efficiency and/or to increase cost. Bridges are public facilities almost exclusively paid for by public funds where value must justify cost. But then, again, how do we determine the value of aesthetics?

Moreover, Billington's criteria are more suitable for long-span bridges, most of which are situated far from a city and not close to any buildings. City bridges, however, are typically juxtaposed with many buildings or other types of structures. In these cases, being harmonious with the urban surroundings is just as important. Such a bridge can be less efficient and more expensive in some cases. Then the question becomes, "What should the appropriate added cost to achieve beauty be for those bridges?"

There can be other factors that can be considered too, such as a city may want to build a bridge to commemorate a certain event or person, or to act as a signature of the city, etc.

Engineers like simple rules, such as the allowable tensile stress of high-strength steel used for cables is a certain percentage of its yield stress. Engineers would like to put the appropriate cost of aesthetics as a percentage of the construction cost. This kind of rule would make the choice simpler. But the problems with such a simple approach are twofold: first, this would necessitate that every bridge spend additional money just to show that the design has considered the aesthetics of the bridge. Otherwise, the designer may be criticized for not paying sufficient attention to bridge aesthetics. Obviously, richer localities are willing to pay more for aesthetics, while poorer localities may not. And secondly, how to calculate this percentage is a problem too. Nevertheless, without considering the value of aesthetics, we may end up with some really ugly bridges.

A bridge is a part of a city. An ugly bridge is equivalent to a pollution in the city. Once completed, it could be there for hundreds of years. We have no way to avoid seeing it. Therefore, people have attempted to introduce aesthetics as one of the design criteria. But, how?

3 EXAMPLES

Following are several examples of how people have put a value behind the aesthetics of bridges.

3.1 *Denny Creek Bridge, State of Washington, United States*

This bridge is near a ski resort area in the state of Washington, which is not far from Seattle. It is in a very scenic setting. The total length of the bridge is 1,203 m, with a regular span length of 57.3 m. The bridge, which was designed in 1978, was constrained by several severe restrictions in the design:

1. The bridge is in a high seismic zone and is located at the bottom of a hillside with relatively unstable rocks. Therefore, no blasting was allowed during construction. This means that the pier footings had to be hand dug with relatively small equipment;
2. The piers are 10 m to 49 m tall. They had to be able to resist possible rockslides;
3. After the piers were completed, falsework support was not allowed for the construction of the bridge girder; again, this avoided the danger of causing a rockslide;
4. The main reinforcement and all longitudinal prestressing steel were placed at least 20 cm below the girder surface to avoid corrosion due to salts being used to melt the snow and ice on the deck in winter;
5. Only trees that were in direct conflict with the bridge body were allowed to be cut; and
6. Aesthetics was one of the selection criteria. This is the first bridge in the US in which aesthetics was given a monetary value.

In the 1970s, this type of long viaduct in the US was built exclusively with precast I girders (Figure 1) or steel girders supporting a cast-in-place deck slab. The State of Washington even had standard precast girders named after the state. A citizen's group, after visiting some new bridges in Europe, requested that the state offer an alternative design that would be more aesthetically pleasing to match the beautiful surroundings of the area. DRC was one of the firms requested by the State to prepare a new design.

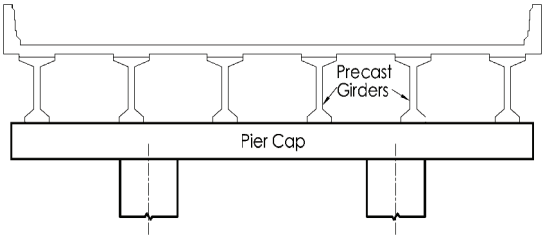

Figure 1. Bridge with precast girders.

Here is how we conceptualized our design to satisfy all requirements listed above and produced a beautiful bridge structure:

- First, to increase the resistance against a possible impact force from the rockslide, I used single-column piers instead of the double-column piers popular at the time. The stiffness (Moment of Inertia) of a single-column pier with the same quantity of material (cross sectional area) as two columns is about 6.36 times larger (Figure 2). Therefore, the safety against a possible rockslide is much higher.
- Second, I used a single-box cross section with tapered webs for the girder. This drastically reduced the chance of the bridge girder being hit by the rocks during a rockslide (Figure 3). Had we used the conventional precast beams, the bridge would have to be raised higher to avoid the sliding rocks.
- Third, the single-box cross section has much thicker webs, especially at the top portion, so prestressing tendons and reinforcement can be easily accommodated inside the webs and 12 cm below the deck surface (Figure 4).
- Fourth, because only trees that were in direct conflict with the bridge body could be cut, we proposed to build the bridge using the span-by-span method with a gantry so the construction did not touch the ground after the pier was built.
- Fifth, the box girder cross section with long cantilever overhangs looks very elegant along the valley full of trees. This was the first box girder in the US with such long cantilever slab overhangs (Figure 5, 6).

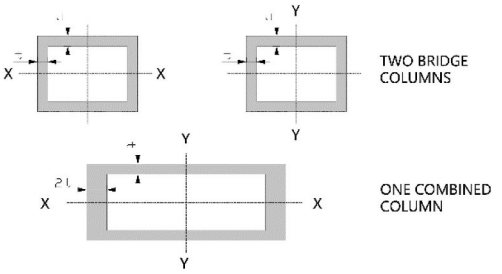

Figure 2. Single versus twin columns.

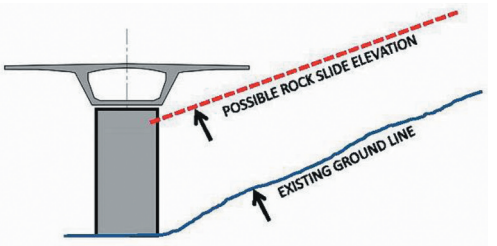

Figure 3. Rockslide protection.

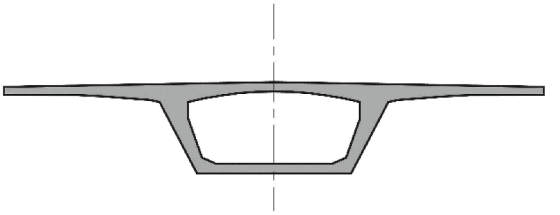

Figure 4. Girder cross section.

Figure 5. The Denny Creek Bridge – among trees.

Figure 6. The Denny Creek Bridge – trees under bridge protected.

People liked the aesthetics of this design so much that they offered a US$300,000 incentive for this bridge scheme, which was a first in the US. This was about 3% of the estimated construction cost. But it was not necessary. The bid price of this design was about 10% lower than the other two alternate schemes. This is a proof that a more beautiful bridge does not necessarily cost more.

The horizontal segmental method I developed for the construction of this bridge was one of the reasons why this alternative was so competitive. In the US, bridges are built by general contractors. For a general contractor, bridge building is only one part of their business. They also build roads, high rises, dams, or any other type structure they can contract to construct. This means that a general contractor may build a bridge only occasionally. Therefore, to save on costs, they will try to limit the use of any special equipment to a minimum because special equipment, such as gantries, or form-travelers, are usually scrapped after the project is finished.

Because we were not allowed to touch the ground anymore after the piers were done, we had to build the bridge girder from the top using a gantry that supports the entire span. Such a gantry would have been very heavy and expensive. Saving in the cost of the gantry was important.

Figures 7a and 7b present a schematic showing how the bridge was built. In Figure 7a, we divided the girder cross section into three parts and built the girder in three stages:

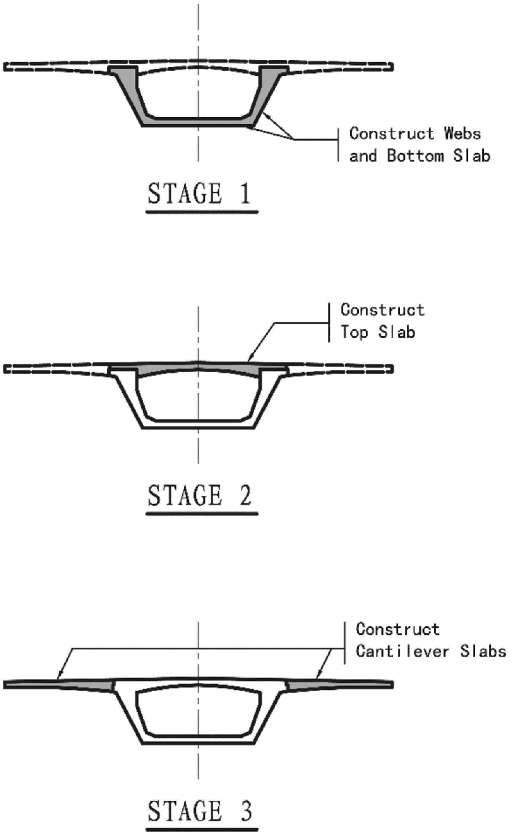

Figure 7a. Dividing the cross section into three parts.

The first stage consisted of the bottom slab and the webs. It was supported by the gantry during construction. The weight at this stage is about 1/3 of the total girder. That means that

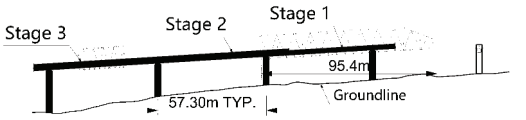

Figure 7b. The three stages of construction.

the gantry had to support only 1/3 of the total weight of the girder; therefore, it was less expensive. After the first stage was poured, stressed, and gained sufficient strength, the gantry was moved ahead for the construction of the next span.

The second stage consisted of the middle part of the top slab. The formwork for this portion of the top slab was supported directly by the completed U-shaped first stage of the girder. Its construction was very simple, and it was not on the critical path.

The third stage consisted of the two wing slabs. It was constructed using a simple formwork suspended from a steel frame running on top of the middle slab. Again, it was not on the critical path.

The advantage of this construction scheme is twofold: first, the main gantry for the first stage was very light because it only supported 1/3 of the weight of the girder; second, by dividing the girder into three sections, we provided three work areas, so it was easier to rotate the workers. This has to do with the US labor regulations: each worker belongs to a specific union; each union does only those type of work that is legally assigned to that union. For example, workers from Iron Workers Union are not allowed to do concrete work, which can only be done by Laborer's Union; the electricians are not allowed to do any steel work, etc. Having three work areas made the planning easier. The construction was very successful. The completed bridge is very well-liked by the citizens.

The design and construction of the Denny Creek Bridge was done specifically to meet the requirements of that project. Each bridge is unique. If the same bridge were built in another country today, without those labor union regulations and design requirements, it could be built differently.

In this case, we can assume that, from the owner's point of view, the aesthetic value of the bridge is at least $300,000.

3.2 *Eastern spans of the San Francisco-Oakland Bay Bridge, San Francisco, United States*

The replacement of the Eastern Spans of the San Francisco-Oakland Bay Bridge, or simply called the Bay Bridge, was a seismic safety project. For a seismic safety project, the government pays for whatever is necessary to sufficiently upgrade the structure to withstand the current design earthquake in the area. Anything beyond that will not be paid for by the government, which means, no money for aesthetics!

The old Eastern Spans of the San Francisco-Oakland Bay Bridge was opened to traffic in 1938. It was one of the world's most significant bridges at that time. "*This marks the physical beginning of the greatest bridge yet erected by the human race,"* said US President Herbert Hoover at the groundbreaking ceremony in 1933. But, the bridge was found to be incapable of withstanding earthquakes that could happen in this area, so it had to be upgraded. This is mainly because when this bridge was designed, the knowledge of earthquakes was still too primitive. Fortunately, no major earthquake had occurred in this area up to 1989; it had previously safely carried traffic up to that point. The Bay Bridge lies between the Hayward and the San Andreas faults, which can produce magnitude 7.5 and 8 earthquakes, respectively. The proposed bridge alignment is underlain by variable subsurface conditions. This is a location with the highest seismic activities and the worst soil conditions. The state of California's study found that a retrofit of the old bridge was not worthwhile, so they decided to build a new replacement bridge instead.

The total bridge is over 4 km long (Figure 8) and consists of four major sections, from left: (a) the Yerba Bueno Approach that transitions the girder configuration from a single two-

level girder in the tunnel to a two side-by-side deck configuration of the new bridge, (b) the self-anchored suspension bridge, or the main spans, (c) the Skyway, or the high-level viaduct, and (d) the Oakland approach. Even though the aesthetics of the entire bridge is important, the main spans are the most visible portion of this bridge.

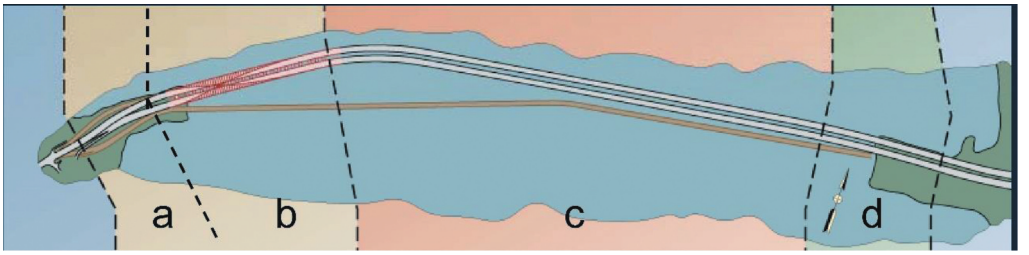

Figure 8. The New San Francisco-Oakland Bay Bridge eastern spans.

Bay Area residents were very concerned about the aesthetics of this bridge, especially the main spans. They did not like the scheme originally proposed by the California Department of Transportation (Caltrans). However, this was a seismic retrofit project for which no money could be spent for aesthetics. To make sure that the new bridge would be an aesthetically pleasing addition to the beautiful San Francisco Bay, Bay Area communities were willing to put up US$230 million to improve the aesthetics of the bridge. Representing the citizens of the area, the Metropolitan Transportation Committee established an Engineering and Design Advisory Panel (EDAP) to help select a signature bridge. EDAP had 34 members: approximately 1/3 were engineers, 1/3 were architects, and 1/3 were local San Francisco community stakeholders. EDAP established 17 rules for the design of the main spans, such as the bridge tower must be a vertical single tower not taller than 160 m and the deck girder must be separated into two 5-lane decks with a space of minimum 15 m in between. This formed part of the state Senate Bill authorizing the bridge replacement.

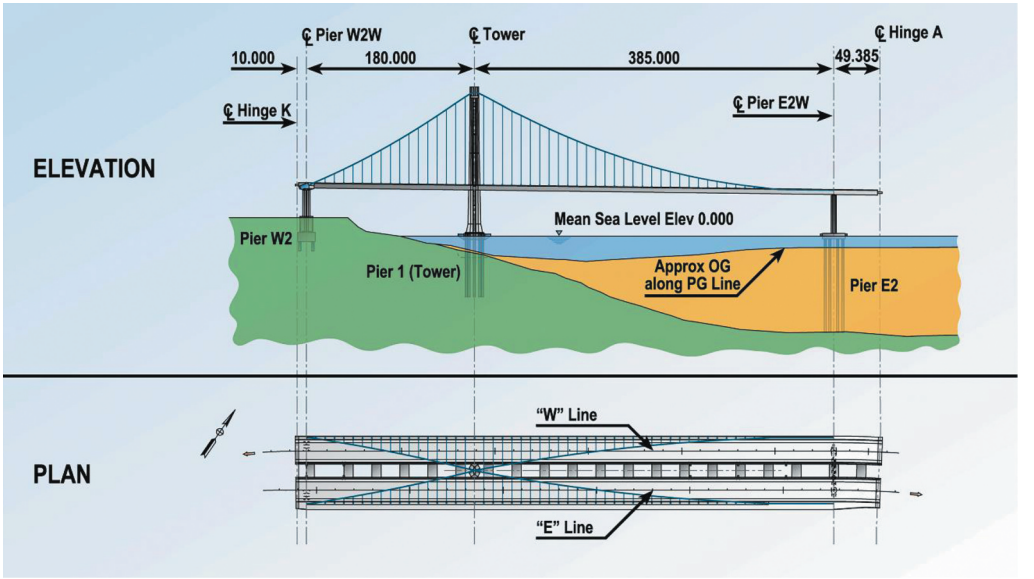
Caltrans selected the Joint Venture of T.Y. Lin International and Moffatt & Nichol from an international competition to design the bridge. Weidlinger Associates was a major subconsultant, and Donald MacDonald was the architect. I was the technical director of this joint venture and oversaw the conceptual design and preliminary design.

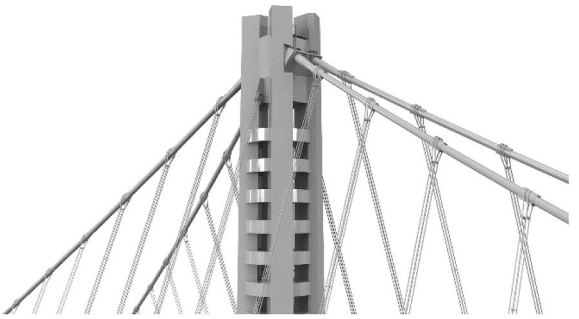
The very soft bay mud along the bridge alignment cannot resist large horizontal force, so both the earth-anchored suspension bridge and true arch bridge would not work. We proposed two alternative concepts: a cable-stayed bridge and a self-anchored suspension bridge.

These two bridge types do not need any anchorages in the ground. EDAP voted to select the single-tower self-anchored suspension bridge (Figure 9). The majority of the EDAP members felt that a suspension bridge would be more harmonious with the two existing suspension bridges already in the Bay—the Golden Gate Bridge and the Western Spans of the San Francisco-Oakland Bay Bridge. They also increased the main span of the bridge from 285 m to 385 m to make it more spectacular.

The bridge has been declared as part of the lifeline to transport first responders and emergency supplies in case of a seismic event. The design criteria specified that the bridge must provide the following:

1. Full service after a functional evaluation earthquake (450-year return period), showing only minor inelastic response, narrow cracking in concrete, and no apparent permanent damage; and
2. Be almost immediate serviceable after a safety evaluation earthquake (1,500-year return period), allowing only limited yielding of structural steel, some spalling of concrete, some yielding of steel reinforcement, and damage to expansion joints.





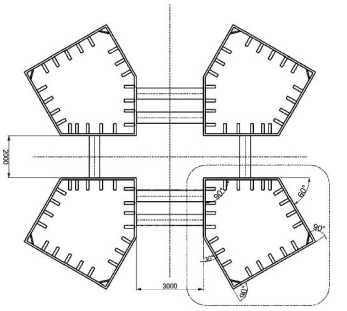


Figure 9. The San Francisco-Oakland Bay Bridge final selection – orange indicates young bay mud.

This is a very severe demand for a bridge located in an area with a thick layer of bay mud, especially for the design of the bridge tower. In addition, as most suspension bridges have a portal-shaped tower, the Bay Area residents preferred a single-pole tower. Because San Francisco is in a high seismic zone, a single-pole tower was deemed not allowable because it is not a non-redundant structure. But a single-pole tower really looks much better at this location. To solve this problem, we created a tower that consisted of four poles connected transversely by short shear struts (Figure 10a, 10b). Thus, under a severe earthquake, the shear struts may yield while keeping the vertical poles in elastic condition. The four poles are very close together, so they look like a single-pole tower.

Figures 10a and 10b. The tower configuration views.

Coming back to our question of aesthetic value: The Bay Area communities put up US$230 million to change the bridge from a design they did not like to a more beautiful design they preferred. Then we should be able to assume, at least for them, the aesthetic value of this bridge was US$230 million? Then, what percent of total cost does the $230 million represent?

The aesthetic improvement is mainly on the main spans, which cost US$2.1 billion. If we only count the main span, the $230 million amounts to 11% of the construction cost. But the bridge is actually very long. The construction cost of the entire bridge was US$4.1 billion; therefore, the $230 million is 5.6%. The official total cost of the bridge, including all other expenses such

as management, land acquisition, etc. as announced by Caltrans was about US$6.5 billion, so then the $230 million should be only 3.5%. Each of the three methods of expression can be justified: the 11% seems rational because the improvement was mainly on the main spans; the 5.6% seems rational also because this was one bridge, while the 3.5% also seems rational because from the Owner's point of view, that was the money it had paid for the bridge project.

The fact that the community was willing to put up $230 million to get a better-looking bridge is certainly a very special occurrence. But in San Francisco, just one of those tall buildings in the city may cost that much. If we had built a bridge in the Bay Area that people did not like, wouldn't that have been very regrettable?

If people are willing to pay so much money for the aesthetic of the bridge, then aesthetics must have a value!

3.3 *Sundial Bridge, Redding, California, USA*

The Sundial Bridge is located in the Turtle Bay Exploration Park in Redding County in northern California, about a four-hour drive north from San Francisco. Redding has a population of about 90,000. The bridge crosses the Sacramental River and connects the hiking trails on both sides of the river. At this location, the river is about 100 meters wide. In 1990, Redding County allocated US$3 million to build this bridge. In 1993, as I remember, the County asked two design firms, T.Y. Lin International and DRC Consultants, to submit a proposal for this bridge. The design requirements were as follows: (1) no pier in the river, (2) construction must not disturb or pollute the water, (3) aesthetics must be compatible with the local area, and (4) cost should be about US$3 million. TY Lin proposed a stress ribbon bridge and I, at DRC, proposed a deck arch. Both schemes would have fully met the requirements. They are both very low key and compatible with the tranquil surroundings.

The bridge is about 7 m wide and 210 m long, so the $3 million total cost would result in a per square meter price of about $2,040, which was quite reasonable for such a bridge at that time.

However, a local group, McConnell Foundation, which is a well-funded organization with affluent members such as lawyers and doctors, suggested that these two bridge schemes were not "outstanding enough." The Foundation preferred a spectacular bridge that could make Redding a global attraction so that many tourists would come to Redding, and in turn, help the local economy. In 1996, the Foundation hired Santiago Calatrava to design the bridge. They must have known that a spectacular design would definitely be more expensive. But they were willing to subsidize the project if it costed more than the US$3 million budget.

After Calatrava started to work on the bridge, the estimated cost of the project increased sharply as the design progressed. The call for tender was in 2000. The bridge was completed in 2004 (Figure 11). At the end of the project, the bridge had cost US$23.5 million, which is about eight times the original budget. The McConnell Foundation paid US$15.5 million for the overrun, while Redding County had to pay an additional US$5 million beyond the original budget of US$3 million. The unit price was US$15,220 per square meter.

Figure 11. The Sundial Bridge.

As a structural engineer, I can see why the bridge was so expensive. In order to create a unique form, practically every member of the bridge structure is eccentrically loaded. There are also curved surfaces that are very difficult to fabricate. For instance, it was said that *"More than 1,200 different plates each required 3-D calculations to determine the irregular polygon shape. Each plate edge had to be cut at a different angle to prepare for full penetration welds"* (Melnick, 2004).

The high cost caused a lot of discussions after the bridge was complete. Many criticized the high price, and many others lauded its beauty. One of the serious criticisms came from Professor David Billington. In a paper, "*Aesthetics and Economy in Pedestrian Bridge Design"* Woodruff & Billington (2007), authored by him and his graduate student Shawn Woodruff, Billington lamented: "Engineers have a duty to provide designs with a reasonable cost. The drive toward landmark pedestrian bridges or unique forms does not excuse us from the ethic of economy. Signature structures do not require extreme cost as proven by some of the examples of the national study. It is our duty to inform the public and to let them know other options exist."

On the other end of the criticism spectrum, the bridge was lauded as an engineering wonder. And it does attract more tourists to Redding as the McConnell Foundation had hoped for, even though no one had calculated whether the additional cost is economically worthwhile or not.

The bridge can also serve as a sundial. I do not know when the concept of the "Sundial" came to be used for this bridge. Sundials were used before clocks were available to find out the time of the day. The Sundial Bridge does look like a huge sundial, and it is lauded as the largest sundial in the world. Certainly, this proclamation attracts visitors too. Actually, this big sundial is accurate only one day a year, on the summer solstice, and only between 11:30 to 15:00. At all other times, people have to do some guessing!

4 SCULPTURING OR ENGINEERING

When people think of beauty, they will first think of "pure" art such as painting or sculptures. While sculpture is pure art, bridge engineering is also art, but it is applied art. The only purpose of a sculpture is to achieve beauty. The cost of the material of the sculpture itself is comparatively small and irrelevant. The sculptor can spend whatever time he wants to achieve perfection in a sculpture because a sculpture's sole purpose and value is in its aesthetics. The main purpose of a bridge is to carry traffic, so a bridge project must satisfy the safety and functional requirements at a predetermined cost within a predetermined time. Therefore, it could be catastrophic if an engineer treats his bridge project as a sculpture.

I visited the Sundial Bridge not long after it was completed. I recall seeing a plaque at the base of the tower stating that the bridge was "*sculpted by Santiago Calatrava*" and not the usual "*designed by Santiago Calatrava.*" Maybe this was the problem: Calatrava might have believed he was doing sculpture instead of designing a bridge! (Note: I understand this plaque was moved to a different place near the bridge).

Sculpture is pure art, which is priceless! Figure 12 shows a painting by the Dutch American Painter Willem de Kooning called "Interchange." (Burgess, 2023) It is one of the 10 most expensive painting in the world. In September 2015, collector Kenneth C. Griffin paid US$300 million to purchase it from the David Geffen Foundation. That is 12 times more than the total cost of the Sundial Bridge in Redding! Is this reasonable? Is this worthwhile? No one can say, because pure art is priceless!

Coming back to our discussion of the Sundial Bridge in Redding, the main point of contention is whether we should treat the bridge as a sculpture that *also* offers the function of a bridge or as a bridge that is artistic. As a bridge, the price is too high; as an art piece, price is irrelevant!

Figure 12. "Interchange" by Willem de Kooning.

It is also important to know about the McConnell Foundation. Its website states that *"Today, the Foundation's asset base is nearly $500 million"* (McConnell Foundation 2024).

Therefore, its payment of US$15.50 million for the Sundial Bridge was rather insignificant indeed!

Now the question becomes, *"If the party who pays the bill is happy with what it gets for the money, why are the bystanders complaining about the price?"*

Billington states that *"Engineers have a duty to provide designs with a reasonable cost."* Yes! But if the engineer is not only designing a bridge, but a monument, does he still have to be restricted by this rule?

5 OTHER EXAMPLES

Let us look at a few other expensive bridges:

The Sundial Bridge, at US$15,220 per square meter, was not the most expensive bridge in the world. Several bridges were more expensive (Figure 13). The first that comes to mind is the London Millennium Bridge. Its unit cost was US$32,600 per square meter of deck area (Note: cost figures may vary depending on exchange rate). The Peace Bridge in Calgary, Alberta, Canada, was US$20,000 per square meter. The Gateshead Millennium Bridge in Scotland, which cost about US$30,100 per square meter, is the champion! But the Gateshead Millennium Bridge is a moveable bridge that can be opened to allow ships to pass beneath, so its cost may not be comparable to the rest of the bridges.

It should be noted that almost all these expensive bridges were financed by some kind of foundation, just like the McConnell Foundation in the case of the Sundial Bridge. Usually, these foundations are quite wealthy, so paying for such a bridge is not a big deal for them. Compared to paying a huge sum for a painting that most people would never see, paying for a nice-looking bridge is by far a more meaningful thing to do.

Figure 13. Clockwise from top left: Gateshead, Grand Canal, Sun Dial, London Millennium, Peace (cross section), Peace (elevation).

By the same token, if a relatively wealthy community wants to build an artistic sculpture that can also serve as a bridge to make the area more attractive, is there anything wrong with that?

6 CONCLUDING REMARKS

What makes a bridge beautiful? I believe a beautiful bridge must be natural, simple, original, and harmonious with its surroundings. Looking at recent city bridges in the world, many of them may seem more suitable for Disneyland than in a working city—a phenomenon we may call the "Disneyfication" of cities. To attract attention, many bridges have such strange forms that they really do not look like or work like a bridge. Some of them, because of their unconventional shape, may even become a hindrance to pedestrians. As to the Sundial Bridge, besides being inefficient, does such a bridge really fit into the very tranquil surroundings of the Tuttle Bay area?

The main purpose of a bridge is to carry traffic and let people commute conveniently. They are not just decorations!

Assessment of post-tensioned bridges in Norway

L. Bathen
Norwegian Public Roads Administration, NPRA, Norway

ABSTRACT: Norway has a high percentage of bridges compared to the total road length. Several bridges are exposed to extreme weather conditions. A considerable number of bridges was built in the period of 1960 – 1990 and among these, several bonded post-tensioned, which potentially had issues during execution. There were no explicit requirements for the inspection and assessment of post-tensioned components in bridges until 2021.

Post-tensioning concrete has been considered as a reliable and efficient construction method, demanding little maintenance in comparison to traditionally reinforced concrete. The awareness of the possibilities of severe damage on post-tensioned bridges built has increases considerably during the last years. The lack of systematic inspection routines was realized, and the Norwegian Public Roads Administration therefore initialed an activity on assessment and inspection of post-tensioned bridges The paper will present the results from the R&D projects and todays approach for assessing and inspection post-tensioned bridges in Norway.

1 NORWEGIAN POST-TENSIONED BRIDGES IN A HISTORICAL PERSPECTIVE

1.1 *Introduction*

It is essential to understand the historical development of construction methods for post-tensioned bridges and by that the potential risk of damage that may have resulted from them. Post-tensioned concrete bridges are susceptible to deterioration over time, and assessment to maintain their structural integrity and to prolong their service life is vital. Bridges need inspection and evaluation of corrosion of post-tensioned strands, wires, and bars, the remaining post-stressing forces, and eventually concrete deterioration. It is essential to understand the level of safety, reliability, and robustness. Errors during execution and construction are a significant reason why constructions are damaged at an unexpectedly young age. Correspondingly, insufficient maintenance is a contributing factor to accelerated damage development. This also applies to post-tensioned system. There are currently around 20.000 bridges and ferry quays in the national and county road network. Approximately 10% of bridges are prestressed (NPRA BRUTUS) (1). About 40 % of the prestressed bridges are post-tensioned, 800 -850 bridges in number. There are currently around 20.000 bridges and ferry quays in the national and county road network, of which over 2,000 bridges are built with prestressed concrete, both post- and pretensioned. The first post-tensioned bridges in Norway were built during the period 1958 -1960.

The building accelerated throughout the 1960s and reached a tentative peak in the early 1980s. A large proportion of the bridges are beginning to reach an age where extensive maintenance is expected:

- 22% of the bridge area is over 50 years old.
- 38% of the bridge area is between 30 and 50 years old.
- 40% of the bridge area is younger than 30 years.

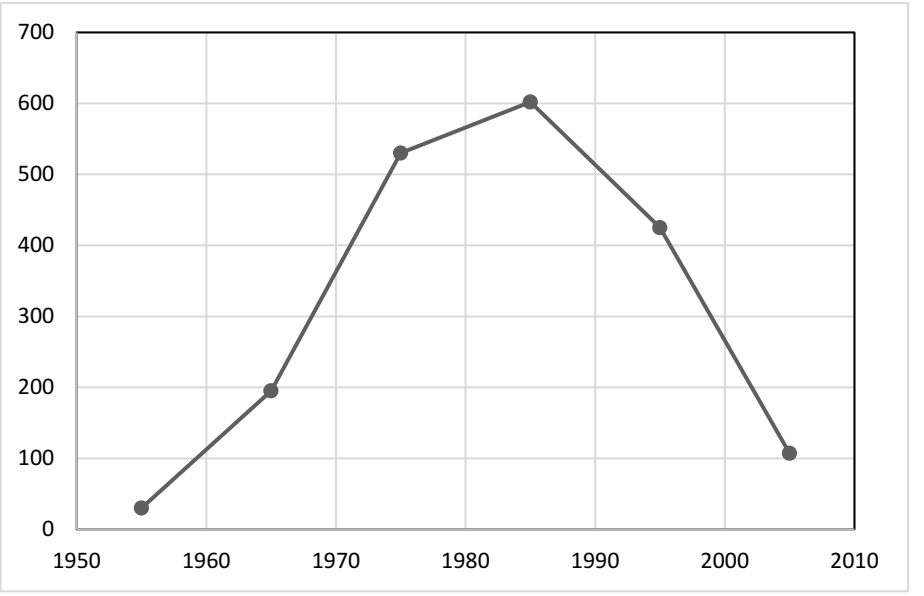

Figure 1. Prestressed bridges in Norway, year of building (NPRA, BRUTUS) (1).

Service life of post-tensioned structures is largely dependent on the service life of the post-tensioning components. It was a massive investment in roadbuilding and most needed bridges to districts and especially islands along the coastline in 1960-1990. This was a result of political and strategical decisions to connect small urban areas to the mainland and main road network. The industrial development and fishing industry needed transportation corridors to link to a market for their products. Also, it was a willingness to make it possible to live and flourish in districts of Norway. The necessity to guarantee a functional public transport infrastructure has led to the construction of many bridges, several of which are exposed to extreme weather conditions.

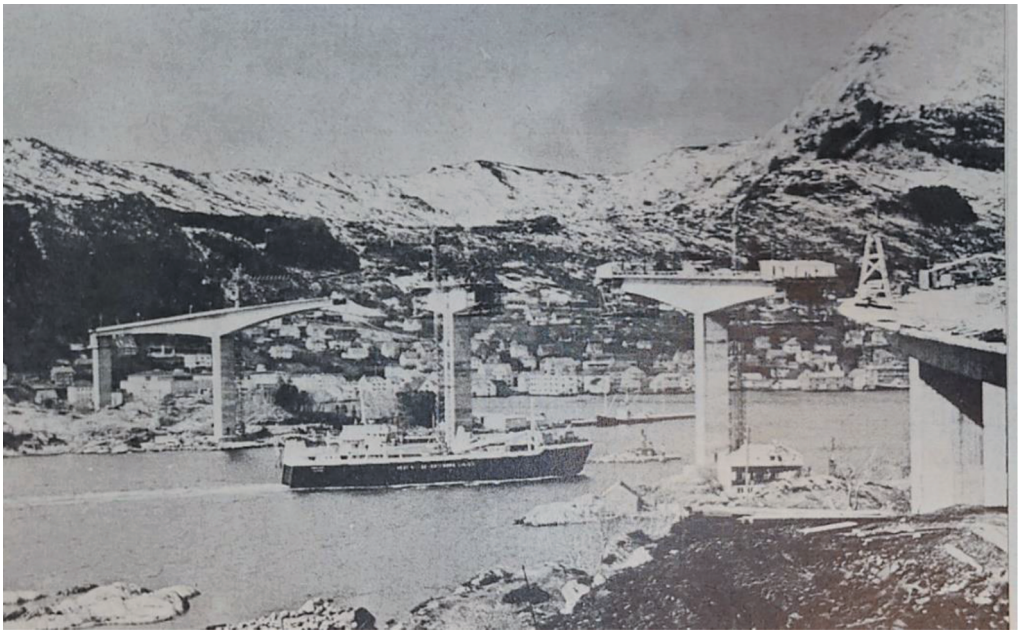

Figure 2. Måløy bridge during construction, 1973 (Photo; Byggeindustrien nr.1/1974).

Many bridges had been planned and fought for in many years before they came to realization. As an example, Måløy bridge was built during 1972–1973. The first plans for a bridge came as early as in 1918 (Ese) and the last decade before the building there was huge local engagement to raise financing. It was with its 1224 m, by the time of finalizing, the longest bridge in Norway and it is still one the biggest bridges in the country.

1.2 *PT- installation from the late 1950's until today*

Post-tensioning concrete has historically been considered as a reliable and efficient construction method, demanding little maintenance in comparison to traditionally reinforced concrete. Materials and methods for installation have changed over the years. When assessing any corrosion damage on post-tensioned components, it is important to establish the era in which the bridge was built. The constructions method has changed over the years with considerably more focus on execution and durability since the years between 1982–1986. In Norway we expect no damages due to corrosion on strands if requirements regulated by today's standards and regulations are followed. However, damages on post-tensioned bridges, especially those built prior to the revision of construction practice and standards, have been reported world-wide. In Norway damages are found occasionally as well, mainly coincidental during maintenance work.

The constructions method has changed over the years with considerably more focus on execution and durability since the years between 1982 - 1986. During these years the first regulation on grouting and properties of grout was introduced. Later the practice has developed, and both the quality of the grout and the grouting has improved significantly since the early 1980s. The first post-tensioned bridges in Norway were built during the period 1958 -1960, using prestressing bars. Later in the 1960s and 1970s, post-tensioning systems with wires were commonly used (widespread use of BBRV). During the 1970's post-tensioned bridges with high utilization of materials were executed. Prestressing strands gradually took over from wires in the early 80s. In Norway we can roughly divide practice for installation and grouting techniques in 4 periods based on the year of construction and thus which standards and common practice existed at the time. (Bathen & Nordbotten 2023) Table 1 shows the common practice and development for installation practice.

Table 1. Development of common installation practice in Norway.

Era	Common practice at the time
Late 1950s 1982.	A common practice during this era was that equipment for installation and grouting was sent to the construction site and the main contractor carried out the work. There is documentation from building periods of several bridges that there where issues with both installation and grouting practice.
1982–1997	NPRA changed its practice and introduced regulations. Post-tensioning companies had to execute prestressing and grouting on site instead of the main contractors. That changed focus a lot on installation of post-tensioning. Because of the high activity at the same time building condeeps for the North Sea it was considered a necessity to improve grouting practice in the industry. In 1982 and 1986 the Norwegian Concrete Association publishes NB13 Grouting (NCA 1982) (5) and NB14 Post-tensioning work (NCA 1986) (6) respectively. Procedures were improving, but there was still a risk of defective grouting. Standards for grouting and grout properties together with test-methods were developed in Great Britain 1992-1996. They became quickly adopted as Common European standards in 1997 and, also adopted in Norway. In Norway despite these standards there are some years where grouting had issues and can be deficient.
1997–2005	The industry began to adapt to NB14 (6) and the common European regulations. In the early 2000s, solutions for water management (joints, links, drains & pipes etc.) were improved.
2005–>.	It was introduced an additive, in 2005, which made the grout thixotropic, increased flow properties and made it easier to inject. That gave less chance of voids in ducts. There were no major changes in standards, regulations, or procedures. The era is considered as a relatively safe period in terms of cavities in the post-tensioned installations.

Figure 3 shows typical findings during maintenance work. Ducts are empty or partly filled with grout and the ducts in bridge decks get destroyed when using water chiseling. This is a typically result from the period between 1960 – 1980, maybe even some places until mid-1990´s.

Figure 3. Common finding during maintenance work, lack of grout inside ducts. (Photo; NPRA, BRUTUS) (1).

1.3 *Development of commonly used post-tensioning systems in past eras*

From the NPRA database BRUTUS (1) it has been possible to find what type of post-tensioning systems were commonly used in which era. In Table 2 it is listed what type of post-tensioning system that was commonly used in what era. There are three main groups that divides the practice; bridges prestressed whit single bars, a couple of years later tendons made of parallel wires and finally tendons made with multiple strands. The common use of multiple strands came first in the 80´s, but there are some bridges produced with that type of tendons from late 70's.

1.4 *Development of required cover thickness for bridges*

The required cover thickness for bridges has varied over the years since the first regulations in 1926. In the years from 1973 until 1988 it was at its lowest; 25 mm – 30 mm. Due to corrosion on rebars, the cover thickness for bridges changed in 1981, made stricter than common national standards. From 1997 the required cover thickness has been significantly more for bridges and ferry quays than common concrete structures in Norway. In 1994, rules for the provision of concrete cover were introduced. For reasons we don't fully understand today there was in 1973 an optimistic belief that required concrete quality combined with low concrete cover thickness gave enough durability and sustainability. The NPRA followed the national standards for concrete cover thickness more in general until 1988. Since 1988, requirements from NPRA for bridges have been stricter than for other structures. (Bathen & Nordbotten 2023). Table 3 gives an overview of the era for the required concrete cover thickness at the time. Table 4 gives an overview of the other national regulations, such as acceptable content of $CaCl_2$ in

Table 2. Commonly used PT-systems in Norway.

Era	Post-tensioning systems	Post-tensioned reinforcement type
~1955-1966	Dywidag	Single bars
Late 60's	Freyssinet (wedge cone system)	Tendons made of parallel wires.

1.5 *Development in design through standards and regulations*

Standards, national regulations, and inspection procedures regarding the construction of post-tensioned bridges are still under constant development. In 1969 and 1971, stricter requirements were introduced regarding design traffic loads compared to the regulations

from 1958. Concrete and reinforcement were more strongly utilized (NS 3473) and optimized regarding the use of materials. There are some bridges built in that era were material are strongly utilized. A significantly number of bridges has developed heavy corrosion on the ordinary reinforcement because of chloride ingress. Concrete and reinforcement were less utilized and changed in the revision of this standard a couple of times until the early 1990s. Comprehensive change in building practice was implemented from early 90´s. Since 2011, design loads from NS-EN 1991 have been used.

At the same time as the practice developed for grouting and tensioning of bridges, national rules and regulations have been developed under the auspices of The Norwegian Concrete Association. Publication no.14, post-tensioning work has since it was published in 1986 focusing on all parts of post-tensioning work at site. NCA, publications no. 13 (5) and no. 14 (6) have been important for the development of NS-EN 13670, Execution of concrete structures, in the sub-chapter on post-tensioning. Through NS-EN 13670, concrete contractors and contracting clients have been purposefully trained for post-tensioning work.

The use of waterproofing is difficult to track. In some places waterproofing was added when de-icing of roads was introduced locally. Waterproofing on post-tensioned concrete bridges has been a common practice since some time in the mid-1990s. Splicing tendons at the same cross-section was allowed until 1996. In the early 2000s, solutions for water management (joints, links, drains & pipes etc.) were improved. Before this, several unfortunate solutions were designed. From 1997 there was a requirement for waterproofing if de-icing of bridges and roads was frequent and AADT > 2000. The requirement was in force until 2015, when a requirement for waterproofing on all post-tensioned concrete bridges was introduced. On a significant number of existing bridges, the concrete wearing course has been replaced by waterproofing. Requirements related to details for waterproofing at bridge ends, along concrete edges, around drains and at joints were heavily revised in 2007 but took a few years to implement. It is highly likely that recommendations and requirements relating to details introduced in 1997 were not followed. Regulations that existed in the early 80s and up to 2005 prevented unfortunate execution, but there were still challenges when it came to grouting. On the contrary, it is interesting that we had to go all the way up to 2005 before we got a stable grout that is used without concerns about separation and lack of stability (Bathen & Nordbotten 2023). during the R&D-project Improved Bridge maintenance (2017-2022) (2, 3) which was later followed up by the R&D-project VESPA (2021-2024). The main goals for these projects have been to establish routines for systematical and periodical inspections of post-tensioned bridges. In addition, the projects aim on establishing routines for prioritizing order of inspections by a risk-rating tool adjusted to Norwegian conditions and traditions in building-technics. Also, the potential of repairs and strengthening are investigated. The methods developed within the projects are and will be implemented in the NPRA through regulations and guidelines, courses, and by practical training. Through these activities we are aiming to get a better overview of the condition of post-tensioned bridges in the road network and contribute to a forward-looking strategy for safe management of existing bridges.

2 THE R&D PROGRAM IMPROVED BRIDGE MAINTENANCE 2017-2021

2.1 *Introduction*

In 2017, the Road Directorate started the R&D program Improved bridge maintenance (2, 3). One of the activities in the program investigated damage of post-tensioned bridges.

Inspection of post-tensioned construction systems is difficult because tendons, anchorages and ducts are embedded in solid concrete. Indirect methods for locating voids in cable ducts are used to locate corrosion on tendons, because voids are locations where

corrosion can occur on tendons. In Improved bridge maintenance, among other things, inspection methods have been investigated to identify voids in tendons, possible corrosion mechanisms in non-grouted or poorly grouted ducts, and constructive consequences of damage to the post-tensioning. The activity was established due to well-founded suspicions of poor execution practices, especially in the 1970s and 1980s, before changes in practice in the industry from the late 1990s. Poor control and lack of quality at several points in the grouting process may have resulted in voids, poor adhesion, and corrosion. Corrosion of tendons results in a loss of load-bearing capacity.

The R&D program was carried out in the period 2017-2021. The program has consisted of the following 4 projects:

- Management tools for bridges,
- Reinforcement corrosion in concrete,
- Alkali-silica reactions in concrete and
- Rehabilitation of steel bridges.

The purpose of the program was to optimize the use of resources related to inspection, maintenance, and management of bridges, and to ensure that NPRA takes the right measures at the right time to ensure that the bridges are and remain safe. (Norwegian Public Roads Administration 2022) (2)

2.2 *Activity 2, reinforcement corrosion in concrete*

In 2018, NRPA, issued a request for a study of methods, possibilities, and restrictions for inspection of post tensioned concrete bridges as a part of the activity Reinforcement corrosion in concrete (NPRA 2022) (3). Various methods have been developed over many years to assess corrosion on ordinary reinforcement in concrete structures. Corrosion is a complicated mechanism affected by many factors. Surveying the extent of corrosion and its causes is challenging. Pre-tensioned reinforcement can be inspected to a large extent as ordinary reinforcement, but for constructions with post-tensioned reinforcement placed in ducts, corrosion measurements and assessments of the significance of this are more complicated. Tendons are placed within ordinary reinforcement in the concrete cross-section, and thus at a great depth from the surface. This makes it challenging to interpret results from non-destructive methods. (Karlsson et.al 2020)

Normally, the tendons are perceived as well protected against degradation as they are in grouted ducts, mounted with a good distance from exposed surfaces. The common opinion was that there are no issues considering post-tensioning as to severe damage and risk of failure. Experience has shown that corrosion occurs on post-tensioned tendons as well, and there are findings also in bridges in Norway. Post-tensioning components have to a small extent been inspected and examined for condition and function. Corrosion on these components is serious for two reasons:

- The damage develops hidden as the cables are inaccessible to visual inspection.
- Corrosion on tendons can in unfortunate situations lead to tendon failures with possible deformations and reduced load bearing capacity, without warning signs.

During repair work at the bridge in Herøysund in 2019, at the northern west coast of Norway, voids and severe corrosion were found inside the ducts. There were no outward signs of the damage to the post-tensioning. There were no chloride quantities in the grout that would indicate corrosion, and there was no damage to the concrete in the areas where we found severe damage to wires. NPRA experienced that damage can develop in post-tensioning systems and there is lack of obvious reasons why the damages have developed in such a scale. Figure 4 shows the condition inside a duct at Herøysund bridge. The finding was a result of a random opening along one of the tendons. This was the first time these types of severe damages were found in Norway, and it confirmed that it is a need for systematically inspections and a routine based assessment of post-tensioned components as well as other structural elements.

Figure 4. Severe corrosion on a tendon. Photo: Lise Bathen, NPRA.

Based on damages that was discovered, the ongoing activity in the R&D program was extended to investigate corrosion mechanisms in post-tensioned reinforcement, as well as to investigate the reason(s) for corrosion of the pre-stressed reinforcement. It has been investigated whether calculation models can be established for the constructive consequences of various types of breaks in the PT-system, and whether it is possible to establish a methodology on a general basis to investigate what the critical sections are for the individual bridge type. To be able to examine bridges with post-tensioned structures in a targeted manner, it is important to be able to examine the structures in the sections where tendon failure has the greatest impact. The results and findings in the R&D-program are reported and can be read at NPRA 2021 (2).

3 THE R&D PROGRAM VESPA

Experiences from Herøysund bridge and the knowledge from the R&D program Improved bridge maintenance (2, 3) are taken into the R&D program "VESPA" (maintenance of pre-stressed reinforcement), which is led by the Operation and Maintenance division, DoV. Through its activity, the R&D program VESPA will improve NPRA's overview of the condition of post-tensioned bridges and contribute to a forward-looking strategy for safe management of existing bridges. Post-tensioned concrete bridges form an important group of bridges, and they need assessment in a systematic way to ensure longevity and safety during the period of use. In VESPA, further development of research results from Improved Bridge Maintenance is being done. The objectives for VESPA are:

- To establish professional management by further developing of methods for inspecting post-tensioned concrete bridges, and by establishing routines for prioritizing inspection order of them.
- To contribute to a safe and secure assessment of damage of post-tensioned bridges, methods are developed to be able to make capacity and durability assessments for post-tensioned concrete bridges.
- To reduce the need for new construction and thereby contribute to the fulfillment of Norway's climate and environmental targets, tools and methods for remedial measures are developed when damage is found to the pretension system in existing bridges.

The purpose of VESPA has been to further develop inspection methods and maintenance strategies, as well as to implement the results in management routines and processes. Strategy

and methodology for inspections are developed. Routines for inspection are now implemented in NPRA´s inspection-program. VESPA is organized in four sub-projects:

- Inspection
- Case studies
- Mapping of consequences and remedial methodology
- Training of staff

Based on foreign experience and assessment-standards NPRA is developing a tool for prioritization of inspection order based on the knowledge of known issues in the era the bridges were built, reported issues during installation, the bridges importance in the road network and the possibilities or difficulties for driving detour if the bridge must be closed. These factors are the baseline for how to sort the order of inspections of our post-tensioned bridges. In addition, tools and methods for possible remedial measures will be mapped.

The R&D program will be finalized by the end of 2024. Routines and procedures for inspection of post-tensioned bridges are now implemented in NPRA regulations and results from ongoing investigations will be as well when it is finalized.

4 TODAY'S ASSESSING AND INSPECTION OF POST-TENSIONED BRIDGES

Inspection of post-tensioned reinforcement is carried out as needed, either as a routine based on vulnerability analysis, or in case of suspicion of poorly injected cable ducts and/or other damage to the post-tensioning. NPRA now recommends carrying out a special inspection of post-tensioned reinforcement before major maintenance is planned

Control of post-tensioned reinforcement is carried out with NDT methods, combined with some destructive, visual openings. Methods used in investigations will be selected based on local conditions. Current NDT methods are the use of cover meters, GPR, ultrasound and impact echo. The methods are used in combination with each other and provide information on cable location, extent of cavity and degree of grouting. Control of the degree of grouting with NDT, followed by visual inspection of individual tendons is therefore used to find voids in post-tensioning systems, which can give an indication of areas where corrosion may develop.

Choice of locations for control of tendons shall be based on preliminary investigations of documentation from the construction period, drawings, assessments, and visual observations. Suitable inspection areas can be high points of the duct-curvature, where ducts cross over supports, couplers and areas near anchorages. Critical areas for the bridge's carrying capacity shall be mapped. (NPRA 2023) (4).

There is a growing backlog on maintenance on bridges also in Norway. When it comes to post-tensioned structures it may not actually be a backlog since the common opinion up to today has been that there are no issues as to detoration of PT-systems. That has changed by the activity in the last couple of years in both Improved bridge maintenance and VESPA. The routines for doing inspections on the PT-system on a regular and systematic level will contribute to a well-functioning road network for the next generations.

ACKNOWLEDGEMENT

This is a presentation of work done and implementation of routines in NPRA from the two R&D programs "Improved Bridge Maintenance" and "VESPA" (maintenance of prestressed reinforcement) established by the NPRA respectively in 2017 and 2021. The work and findings presented are results of a cooperation work between the Operation and Maintenance and Legislation and Regulatory Authority departments of NPRA. I will especially acknowledge Karla Hornbostel, Magdalena Jadwiga Osmolska and Oliver James Hooper, for lifting assessment of prestressed systems to be a part of today's bridge management in Norway.

Sustainability and digitalization in bridge management: How far we are?

J.R. Casas
Universitat Politècnica de Catalunya, UPC-BarcelonaTech, Barcelona, Spain

ABSTRACT: Sustainability and digitalization are two main topics in many research programs in Europe and worldwide. It seems that bridge managers can largely benefit from the current digital transformation where processes using digital technologies are able to create new or to enhance existing bridge management systems (BMS). The concepts of sustainability and digitalization are very different in essence and, therefore, the tools needed for their fully adoption in the bridge management environment have to be also different in their basis and formulation. For an optimal adoption and development of both topics, also the actual trends in the bridge management policies, as performance-based decision making and adaptive BMS should be considered. This paper analyzes the actual bridge management policies, trying to evaluate their actual level of sustainability and digitalization. It is shown that although in the technical aspects the final goals are not so far, the human factor (educational and organizational aspects) remains as the critical factor for a full and optimal implementation.

1 INTRODUCTION

Bridge management was born and has evolved in the last decades with the main objective of providing serviceability and safety to bridge users by allocating in an optimal way the limited allocated resources from the managing agencies. Using just two words, we can say that safety and economy have been the driven concepts for an important number of years. The concepts of sustainability and digitalization were never introduced with emphasis in the development of the management policies. However, although not explicitly mentioned, we should think whether those concepts were not implicitly hidden in most of the actual bridge management systems.

In developed countries, sustainability and digitalization have emerged with force and are nowadays overrunning all aspects of daily life. The first is acknowledged in the formulation of the United Nations Sustainability Development Goals (UNSDG) in 2015 (UN 2015, OECD 2016). Sustainability and digitalization are two main topics in many research and innovation programs in Europe and worldwide. It seems that bridge managers can largely benefit from the current digital transformation where processes using digital technologies are able to create new or to enhance existing bridge management systems (BMS). Being the budgets for bridge maintenance also scarce, sustainability is a must to be implemented in bridge management (BM) for a proper use of limited resources.

According to the UN mandate, sustainability must become a basic concept for efficient performance-based operation of any structure throughout its service life. Therefore, from the structural management point of view, sustainability is an objective, while digitalization is a tool/method/technique. Even more, some people think that digitalization is also a powerful tool to improve sustainability. Therefore, the approach of bridge management to these topics must be different: dealing with sustainability the correct question is: how to emphasize sustainability in actual bridge management objectives and optimization procedures? However,

DOI: 10.1201/9781003483755-3

dealing with digitalization a more appropriate question would be: how to introduce digitalization in actual bridge management tools to become more efficient?

This paper aims to analyze the actual bridge management policies, trying to evaluate their actual level of sustainability and digitalization and seeking to their level of accomplishment in relation to an optimal implementation (where to go and how far we are?), analyzing possible causes of the actual distance from that optimum and proposing possible actions to decrease it.

Both previous questions can not be answered independently one of the other as the proposed solutions (if available) have to be implemented is a common framework, which is the BMS itself. Also, some boundary conditions that are guiding the development of advanced BMS should be considered when seeking for an answer to the above stated questions, these are: the management of existing bridges based on performance-based criteria and the need for adaptive BMS. There is an agreement among the experts, that future and more advanced BMS should be based on performance-based criteria, being Key Performance Indicators (KPIs) and their evolution over time the basis for management decisions. Therefore, a performance-based approach seems to be the most appropriate way of advancing in the embedding of sustainable concepts and in providing digitized tools in actual and future BMS. Also, the concept of adaptive BMS, able to adapt to changing loads and environmental conditions as a result of the climate change, is emerging with force among the bridge community. Therefore, also this boundary should be considered when facing the sustainability and digitalization improvement of actual BMS.

2 BRIDGE MANAGEMENT SHOULD BE SUSTAINABLE: HOW ?

Being sustainability an objective of actual engineering policies, BM has to be sustainable. Sustainability of bridges has mostly been considered in design and construction stages, but less attention was given to sustainability of bridges during the in-service stage. Although sustainability in bridge management is also influenced by the design and construction decisions (for instance, the maintenance will be influenced by the type of material or bridge configuration chosen at the design (Balogun et al. (2018)) or by errors or mistakes during construction), the subject of this paper is focused on how to enhance the sustainability of the decisions taking during the bridge management itself.

Sustainability in the built environment is founded on 3 interdependent and interconnected sustainable pillars: economic, social and environmental (Hajek (2023)). Are these pillars found in the actual bridge management (BM) policies? Clearly, this happens with the economic one and to some extent to the social too. In addition, we should start from the basis that bridge management is sustainable by itself due to its definition and objectives. In fact, clear objectives of BM are:

- **Extension of service life of assets**: extending the life of existing bridges is a real direction towards sustainability
- **Optimal interventions**: The interventions should be decided with the objectives of minimizing cost and environmental impact and maximizing availability and safety (social pillar). And the tool to achieve this is the life-cycle assessment (including cost analysis).

In both objectives, we can find embedded performance indicators in relation to the 3 pillars of sustainability. The first objective is clearly in the direction of strengthening the economic (reduction of costs associated to failure, reduction of demolition and re-construction works), social (extending the life of landmark or heritage bridges) and environmental pillars (reduction of the use of natural resources and energy). The second one comprises all 3 pillars as well: economic (reduced costs of maintenance and interventions), social (guarantee safety, functionality, comfort and availability to the users) and environmental (reduction of gas emissions and energy).

BM is already based on Life-cycle assessment (LCA) principles. Therefore, the basics of sustainability are already there, but relevant applications are not yet available. In fact, BM has well adopted the economic and social aspects of sustainability. However, there is still a long

way to go regarding the environmental one. This requires adoption of a complete LCA and not just a life-cycle cost analysis (LCCA), although some environmental indicators could be also monetized to some extent.

Advanced BMS should be based on quality control specifications and performance-based criteria, being Key Performance Indicators (KPI) and their evolution over time the basis for management decisions. As concluded in the works carried out in the COST Action TU1406, KPI´s related to safety, serviceability, availability and cost have been clearly identified in most of the running BMS. But appropriate sustainability KPI´s are still missing and we are still far to achieve a satisfactory solution for them. Performance indicators related to more global KPIs should be observable, quantifiable and provide valuable information for decision making. Therefore, one existing gap is to identify which are the performance indicators most sensitive to the potential sustainability effects, the ones that provide most valuable information and those which are most observable. Failing to identify such relevant sustainability indicators, one cannot quantify a level of sustainability performance (and even less its evolution) within a decision-making process.

Therefore, the framework and architecture to emphasize sustainability in BM is already there: LCA. Life-cycle approaches offer bridge managers a practical predictive view of cost, safety, and condition, the goal being to limit economic and environmental impacts. But the input is still missing. It is necessary to establish the system boundaries and to collect appropriate data for the life-cycle environmental analysis. One can be the introduction of CO2 calculators in the BMS, but others have to be investigated (energy savings, re-use of materials in interventions,. . .).

BM is still a little far from the optimal situation. But the way to become closer has been identified. The future direction is to introduce better performance indicators for sustainability. In many cases, actually, LCA is mainly reduced to a life-cycle cost analysis. In some countries, life-cycle cost analysis has been used for decades, where discounted maintenance costs over a certain time period are compared for different intervention strategies. But LCA does not fit into normal asset management procedures as applied now by most of the stakeholders. Apart from finding the appropriate sustainability performance indicators, it is essential to give more weight to sustainable criteria in the life-cycle approach. In fact, recently, Strauss et al. (2023) published the results of a survey carried out on implemented decision-making models among 23 infrastructure managers from 20 countries worldwide. In the implemented survey, the importance of different KPIs in the scheduling of maintenance and repair of structures was queried. The interrogated stakeholders were given the chance to indicate a level of importance between 1 (not important) to 5 (very important) regarding the following criteria: reliability, availability, safety, economy, environment, special/extreme cases of loading or any other criteria to be described by the respondent. The results are shown in Figure 1.

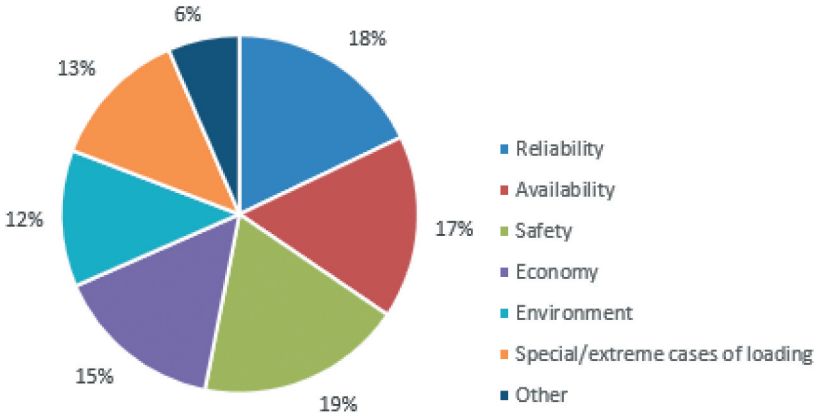

Figure 1. Importance of KPIs for scheduling of maintenance and repair of structures (Strauss et al. 2023).

The criterion given higher importance was safety, closely followed by reliability. In both cases, 15 out of 23 of the answers gave a ranking of 5 to these criteria. The third criterion considered most important was availability, followed by economy and special/extreme cases of loading. From the given choices, environment was considered the least important, although in two cases, stakeholders gave a ranking of 5 to this criterion. Another result from the same survey is that no one selected demands associated with climate change when asked about the incorporation of risk as a PI. Therefore, risk assessment incorporating climate change effects seems to be still in its infancy in practical BMS. For this reason, adaptive BMS has been hardly considered up to now.

Few, but some, realizations have been already done in this direction, however, still in the realm of academic research more than in practical applications. Xu and Guo 2022 have developed a condition-based maintenance approach for highway bridges, aiming to minimize the total carbon emissions of bridge networks subject to maintenance budget constraints. A two-dimensional Markov chain model is applied to predict the deterioration processes of bridges, and a Q-learning algorithm is proposed to determine the maintenance strategy for a single bridge. However, they are more interested on the environmental impacts of a bridge network than of a single bridge, which was the most analyzed until then. Contrary to the actual BMS, they propose a bridge deterioration model that contains the time factor to develop a sustainability-oriented maintenance management approach based on reinforcement learning with a target to minimize carbon emissions of bridge networks. The method is applied to the concrete bridges in New York state. The results of the study show the impacts of budget levels on maintenance plans and total carbon emissions. 10% drop in budget level results in 30 additional bridge repairs delayed as well as 39 tons extra annual carbon emissions.

3 BRIDGE MANAGEMENT SHOULD BENEFIT FROM DIGITALIZATION: HOW ?

To properly answer the question, we have to define what "digitalization" means. According to Callcut et al. (2021) "digitalization is the process of collecting information on physical assets and packaging them into a digital representation of these assets that can be processed automatically". According to this definition, we can understand that digitalization presents many opportunities to benefit BM, among them:

1. Improving and converting in more efficient the available methods and tools used in BM by digitalization: new data gathering techniques based on low-cost techniques, image processing, remote sensing, digitalization of visual inspection, automatization of the whole BM process.
2. Helping to move from "data" to "meaningful information". Probably, one of the main gaps identified by owners regarding inspection, non-destructive testing and SHM is that their main interest does not lie on gathering extensive amounts of data, but on how to use these data to assess the existing/remaining capacity of the bridges in their stock, which is generally not directly provided by just recording data from in-situ measurements. The question that defines the need for a full digitalization of the processes involved in BM is whether a full digitized approach will allow to transform the results from inspection and monitoring into information that can be used for optimal decision-making. The key point that a new tool as digitalization must help to solve is how to translate "data" into meaningful "information" and further into knowledge for appropriate decision-making. The definition and use of relevant Performance Indicators (PI) and Key Performance Indicators (KPI) is the right direction. Key performance indicators (KPIs) are used as metrics to monitor the performance of infrastructure and ensure the effectiveness maintenance and repair activities. Once the KPIs have been identified infrastructure, managers and asset owners can use data monitoring and condition assessment tools to collect the necessary data to measure and track these KPIs along time (Matos et al. (2016)). As an example, the paper by Stipanovic et al. (2023) presents PIs and KPIs for the assessment and monitoring of the following aspects: Productivity, Resource Efficiency, Cost, Health & Safety during

the operational life cycle stage. In the paper, quantifiable and measurable PIs and KPIs are proposed and applied on a highway bridge. Although digitalization by itself is not able to propose and define the most suitable PIs and KPIs, it can certainly help to automatize, facilitate and make more reliable the process of gathering the raw data, to extract and quantify the relevant PIs from it and predict their future evolution. Therefore, if correctly guided by engineering expertise, digitalization can be a useful tool to transform data into meaningful information through the use of KPIs.

In this sense, bridge managers can largely benefit from the current digital transformation where processes using digital technologies are able to create new, or to modify existing methodologies. Therefore, the integration of digitized structural health monitoring (SHM) systems, building information modelling (BIM) and other digitally-based tools into existing BMS is of interest. Being a tool more than an objective, digitalization can be seen more as a societal trend or an opportunity for better efficiency (in the same sense as performance-based decision making and adaptive BMS) than a requirement of future BMS. Digitalization with more or less intensity is already incorporated into actual bridge management. How far beyond the actual status of digitalization should BM move?

The maximum expression of asset digitalization is a Digital Twin (DT). Therefore, we can see DT as the most far away point we can go concerning digitalization. As a concept or idea, DT is something not completely new in structural and bridge engineering: All basics and elements of DT (data gathering, data analysis, model up-dating and prediction model) were already immersed to some extent into the so-called structural/system static or dynamic identification disciplines in application since many years ago, but, of course, dealt in a more primary way from the digital point of view: data gathering was achieved by analog sensors, rudimentary digital sensors and/or visual inspections, data analysis was carried out with limited digital tools, model up-dating was based on defining a numerical model (normally a FEM) that better reflected the recorded data. The up-dated model was afterwards used in the performance prediction. The only difference between this well-known procedure in bridge management and the actual DT paradigm is found on the level of digitalization and automatization of both approaches. The improvement in the automatization allows a faster prediction and intervention if needed.

Table 1. Comparison between BMS and DT frameworks.

BMS	**DT**
Inventory and data collection and management: based on drawings, sketches, pictures,..	Inventory: Based on BIM, image processing, remote sensing
	Artificial Intelligence and IoT technologies specifically tailored to bridges to process and share information (interoperability)
Diagnosis: Actual condition of the assets: mainly based on visual inspection (condition index) and limited NDT	Actual condition: based on Structural Health Monitoring
Fixed time for inspection intervals	Advanced analytics, driven by the integration of Geographic Information Systems (GIS) and
Condition-based diagnosis	Machine Learning (ML), allowing to optimize inspection schedules based on real-time traffic data, environmental conditions, historical bridge performance and risk
	low-cost and automatic technologies to collect bridge information
Prognosis: Performance prediction by proposed deterioration models based on deterministic or probabilistic approaches (Markov chain models).	Data analytics and predictive modeling.
	Model up-dating and damage detection
	Physical-based models
	Data-driven models
	Supervised and non-supervised machine learning
Optimal decision-making and intervention strategies: today still mainly periodic-based (fixed time interval)	Decision making: digital decision supported tools that allow preventive maintenance based on future performance, condition-based or risk-based

As noted, a clear analogy is seen between old structural identification techniques and modern DT. But this analogy is even more evident when comparing the framework of actual BMS and current DT, as presented in Table 1.

The tools (BMS and DT) are different, but the steps in both cases look very alike, comprising 4 main modules: data gathering, post-processing of data for performance up-dating, prediction of feasible future performance and consequent decision making.

Since actual BMS and DT present evident similarities, as shown in Table 1, and DT represents the higher level of digitalization, a relevant question to know how bridge management can benefit from digitalization is: **How far are actual BMS from DT?** In order to find an answer, let us look first to some general definitions:

A **Bridge Management System (BMS) is an** automatized tool that based on the identification of the bridges (**inventory**), their actual condition (**diagnosis**) and defined deterioration processes (**prognosis**) provides a decision-making framework to optimally allocate intervention operations to have safe bridges, preserve bridge capital and maintain their function (**optimal decision making**). The adopted decision shall ensure reliability, safety and functional, economic and environmental optimality.

A **Digital Twin (DT)** is a dynamic virtual representation of an object or physical system (**inventory**) throughout its lifecycle, that uses data in real-time to enable understanding, learning, and reasoning about the asset (**diagnosis**), allowing for a reduction in the total cost in bridge management processes, as it allows predictive and proactive maintenance (**prognosis**), avoiding unnecessary interventions and improving system availability (**optimal decision making**) (Bado et al. (2022), Massao et al. (2022)). Digital Twins require the use of scans, sensors, remote monitoring and automated computation models among others. Specific requirements of contact sensors, data images and remote sensing should be accomplished for an adequate connection between the physical and the digital assets (Casas et al. (2022)).

A main advantage on the use of a digital twin framework for existing bridges allows full interoperability: the integration of multiple simulation models and multiple data resources under a unified data structure to enable visualisation and prediction of bridge performance, something that is also done by BMS, but in a more rudimentary and slow way.

BMS and DT are not so far in some special cases. In fact, some long-span bridges are already digitally twinned to optimize their management and performance during service-life. However, this is not the case for the majority of bridges and we are still far in the case of standard bridges. How far? Several questions remain open: How to proceed with more standard bridges, how to digitalize their management? Is the methodology developed for landmark and iconic bridges valid for a huge number of standard bridges in a network? How to develop a network-based DT? Let us see if the answers can be obtained by analyzing one by one the steps involved in the DT paradigm.

-Inventory/BIM. 3D digital representations combined with BIM technologies are now widely used for new design and construction, but still need further development for existing assets. If available, digital models of existing bridges can be obtained from design drawings and quality control during construction. In their absence, digital-based techniques as photogrammetry, Lidar, terrestrial laser scanning (TLS) and others can be used to create a digital model of the bridge. However, requirements of accuracy, long-term reliability, format (an approach relying on big data implies to deal with both structured and unstructured data) are mandatory as the accuracy and relevance of data are crucial to ensure the validity of the datasets. Structured data is highly specific and is stored in a predefined format, where unstructured data is a conglomeration of many varied types of data that are stored in their native formats. This variety of structures is complemented by the variety of formats that can be found: text, image, audio, video, and also all sensor data. The use of digital twin tools can help improve the management of such heterogeneous information, storage (the increase in the number of structures requiring increased monitoring, coupled with increasingly numerous measurement devices on the structure, leads to new needs in terms of management and archiving of increasingly voluminous data), interoperability and data sharing.

BMS need to overpass the gap between static information, such as 2D drawings that often are incomplete and only reproduce the "as-design" version of the bridge, and a dynamic

digitized information represented by a BIM. Although the tools to evolve from actual bridge inventories to BIM models are already here, obtaining a BIM model for existing bridges in a standard format (usually Industry Foundation Classes (IFC)) is still particularly challenging due to their complex geometry. The final goal is the digitalization of the whole bridge inventory owners without the need to construct BIM models with a lot of manual effort. To reach this goal, there is still a way to go. However, initiatives are already in progress. The main difficulties in the field of scanning applied on bridge point clouds are encountered in how to obtain semantically meaningful bridge information models in an automated way. As an example, Hajdin et al. (2023) present a novel modular framework with procedures for the automated provision of BIM models from 3D point clouds for existing road bridges. The method is based on artificial neural networks (ANN). The work presented is a starting point for a comprehensive digitalization campaign of the whole bridge inventory in Germany.

-Data gathering/Monitoring. What distinguishes a DT from any other digital model or replica is its adequate real time connection to its physical counterpart. This is achieved by an appropriate monitoring system. Therefore, digitalizing the data gathering necessary for the management will highly improve its efficiency. This digitalization can be oriented in 2 main directions: the digitalization of the visual inspection and the incorporation of new digitized monitoring techniques. The first one is of paramount interest. In fact, visual inspection is still nowadays the most widely used technique to get required data to derive the condition state of existing bridges. The results of the survey presented by Strauss et al. (2023), show that all the respondents (23 infrastructure managers from 20 countries) to the questionnaire answered that they use condition rating based on visual inspection in their inspection and assessment procedure. Most of the limitations of visual inspection can be solved by the support of digitalization: use of un-maned aerial vehicles (UAV) equipped with cameras and videos, analysis of satellite images, virtual inspection using 3D models established by UAV and photogrammetry and other data-driven methodologies are on the way, avoiding costly access equipment, enhancing safety for workers and providing a basis for performance prediction.

A step forward towards digitalization is using inspection and monitoring tools that allow to reproduce the "as is" condition of the bridge and not the "as design" condition.

How far we are? The step forward requires proper instruments and expert inspectors. Moreover, the amount of information needed requires that several of these steps are made semi or completely automatically. Nevertheless, automated systems for bridge maintenance have always been of concern within a bridge management process, especially those that involve a large stock of older bridges where information is not easily available. Although following an appropriate monitoring policy should allow managers to get the best information about the maintenance and operation of their asset, the implementation of bridge monitoring systems in regular bridges remains a significant investment compared to the current inspection strategies. The use of high-tech monitoring constitutes a paradigm shift in surveillance strategies since it involves supplementing periodic (or non-periodic) visual inspections carried out by an operator, by some advanced monitoring frameworks. In practice, the use of long-term monitoring systems remains practically exclusive to major or landmark bridges or to special bridges. However, some pioneering experiences in short and medium-span bridges have already appeared recently. Hou et al. (2022) present a data-driven Load and Resistance Factor Rating (LRFR) framework that is empowered by a cyber-physical system (CPS) architecture that uses Internet connectivity to integrate measured bridge responses with truck weights measured by a weigh-in-motion (WIM) station. The CPS architecture uses computer vision of camera images to confirm trucks observed at a WIM station are identical to those observed at a bridge and correlates the monitored response and the load in the bridge.

This existing gap on SHM in the case of standard bridges can be closed by implementing digitalization in monitoring. How digitalization can help in this aspect? In several ways:

– By introducing cheaper sensors that allow to deploy permanent monitoring in a higher volume of bridges in the network (Komarizadehasl et al. (2022a,b)). Alternatively, the use of smartphones. Smartphones can provide crowd-sensing data. They may include several sensors as accelerometer, gyroscope, cameras, microphones, proximity sensors and GPS,

which could be used in the monitoring of different structural parameters (Mei & Gül (2019a), Morgenthal et al. (2018)). Several studies have shown that smartphones could be used as reliable sensors to collect acceleration data and apply them into indirect health monitoring techniques to assess structural condition (Feng et al. (2015)).

- By digitalizing the visual inspection: Using drones+images and remote sensing by satellite images. InSAR is a remote sensing technique that uses the phase information of radar signals emitted by Synthetic Aperture Radar (SAR) sensors mounted on satellites and backscattered by the Earth's surface to measure the displacement of reflective targets along the Line of Sight (LoS) of the satellites (Perisin (2018))
- By the use of the so-called drive-by bridge monitoring in which sensors are installed on vehicles and used to infer information about the condition of a bridge as they pass over it. A unique vehicle can inspect many bridges in a short period of time (Malekjafarian et al. 2022, Mei & Gül 2019b)
- By the implementation of Transfer Learning (TL) methodologies. These new methodologies will allow transfer of diagnostic information of one bridge across a population of similar bridges, augmenting SHM capability beyond that applicable to an individual element of the bridge network. TL is seen as a strategy enabling population-level bridge SHM. The training of an algorithm in the damaged situation of a fully monitored bridge can be extended to infer early-stage damage detection capabilities across a population of bridges with similar characteristics (Giglioni et al. (2023), Gardner et al. (2020,2022))

The reliability of the monitoring system and digitized data requires the implementation of cybersecurity solutions to ensure the integrity and confidentiality of the transmission of data and diagnostics. The requirements and needs that the gathered data should fulfill in order to be practically implemented in a DT are heterogeneous, some of them general and other case specific. A summary of a set of identified challenges and requirements for a seamless infusion of well-established SHM systems within DT platforms is available in Chacon et al. (2023). In addition, SHM-enabled DT must provide monitoring data in a way that can be integrated within data models that can guarantee interoperability (ability to effectively, accurately, and consistently communicate and exchange information, within different information technology systems) among digital systems

-Deterioration models/Model up-dating and prediction. Physical models need continuously up-dating for reliable prediction. Up-dating is carried out by the post-processing of the recorded data. This is probably the aspect where actual BMS and DT are more distant as the former are still far from what a DT uses for prediction of future performance. BMS perform prediction based on static or quasi-static deterioration models mainly based on Markov chains to deal with the inherent uncertainty. Up-dating of the transition matrices involved is not carried out automatically and on-line. However, in DT prediction is based either on physical models that can be automatically up-dated or data-driven algorithms that can react almost in real time thanks to the advantages of IoT. However, while UAVs provide detailed digitized visual data and monitoring acquires digitized sensor data almost continuously, interpreting this information requires expertise, emphasizing the importance of a harmonious blend of digital technology and human judgment. To digitize everything and provide capacity for on-line reaction does not mean that the problem is completely solved. Accurate and reliable post-processing of digital information is very important.

In this sense, it is worth mentioning the recent case of the Interstate-40 Mississippi River bridge in Arkansas. A visual inspection carried out in May 2021, detected the presence of a tie-beam fracture that forced and emergency shutdown of the bridge (Figure 2 left). Although state officials initially stated that the fracture in one of the 50-year-old bridge's two tied-arch truss navigation spans was not present during its most recent inspection in September 2020, a May 2019 drone video that was revisioned after the incident occurred, clearly shows the break already beginning to form (Figure 2 right). According to Arkansas DOT officials, the five-hour drone video was focused solely on assessing the 50-year-old structure's rods and connectors. Although the crack was already present in the video image, nobody took care to check for fatigue cracks in the main members, as this was not the basis of the inspection and the contract.

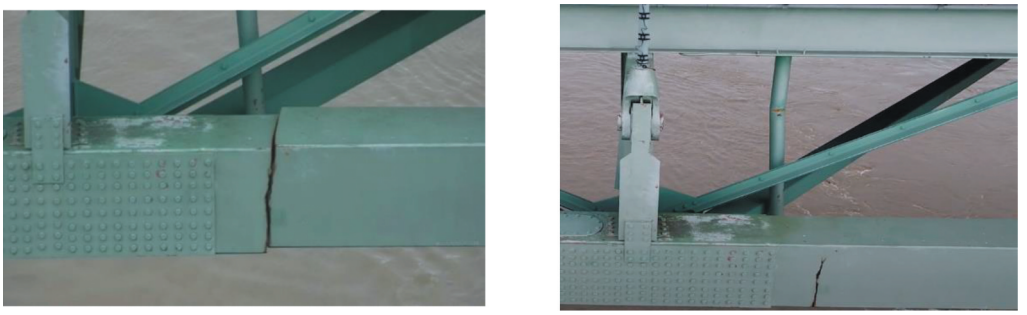

Figure 2. The crack as discovered in 2021 (left) and drone footage from 2019 showing the crack already existed (right). (Photo courtesy of Arkansas DOT via YouTube).

This example points the fact that SHM is not just deploying sensors or gathering images or cloud-points accurate enough to record the damage, but also the post-processing techniques should be as automatized and reliable as possible to proceed with a full analysis of the recorded data, something that relies on the availability of AI techniques and not only on human capacity.

-Decision making. Based on the interview with 9 infrastructure stakeholders from Europe and South America (Strauss et al. (In prep.)) is evident that the digital tools are seen by them **as decision-support** and not **decision-making tools**. Experienced engineers who have knowledge of the bridge stock make the decisions, supported by relevant evidence. The same interview revealed Strengths, Weaknesses, Opportunities and Threats (SWOT) related to digitalisation of decision-making in bridge management, summarised as follows:

Strengths:

- Consistency and traceability
- Enables working with complex contexts
- On demand evaluations based on the existing digital data
- Save time and increase objectivity and transparency
- Allows better control of assets and communication between stakeholders.
- Quality of data – completeness, structured, timeliness and accuracy
- Flexible to changing business needs
- Customization of the platform to operators and/or country specific needs
- Integration of data from various sources

Weaknesses:

- High investment requirements in software and operation, including IoT specialists. Sometime difficult to evaluate the gain of implementation
- Working with systems with automatic analytical capabilities requires data with a high accuracy
- Challenges related to data sharing, security, and standardization
- Employees who do not have a high affinity for digitization are difficult to get on board
- Inspection tools do not make you an inspector. Inspectors must have prior knowledge of bridges
- Integration with other IoT-infrastructure such as monitoring platforms and other platforms is needed
- Validation of data is an important task and a source of inconsistencies and errors

Opportunities:

- Recognize complex relationships based on a continuous data analysis
- Valuable as a tool to better use of resources and resource planning (budget and employees)
- Use of data analytics to get a better insight into a large variety of infrastructure problems

Threads/risks:

- Infrastructure managers become dependent on purchase of external services including but not limited to dependency of a particular software provider
- Different access to IoT and certification of the inspectors and professionals could lead to different response of damage index or base line, between regional and national level management
- Lack of expertise and inadequate use of software or other tools
- If change is not supported/anchored at executive board level, the implementation process becomes (too) complicated. A strong management mandate is needed.
- High costs
- Experts who may not be available on the job market are needed to meet future challenges

As presented in Table 1, as a concept/framework, digitalization is already within actual BMS and also in the next steps to follow in the thoughts and will of bridge managers. It seems that the future road to increasingly digitalization on the actual BMS is already paved. In fact, the results of a recent survey (Strauss et al. 2023) indicate that data-driven asset management is high on the agenda within owner/operator organizations. This comprises the application of BIM and AI, among others. However, as a tool, there is still a long way to go if the final goal is to incorporate all available digital technologies. However, at this point another questions arises apart from the original question **how far we are** from digitalization of BM, which is **how far we should go or we need to go?**

We know the actual trend, that is bridge management is evolving from reactive response to data-centered and performance-based predictive and preventative measures. This is partially due to costly consequences (societal and economical but also environmental) of un-planned maintenance, but also due to the new possibilities appeared by embracing new capabilities in value-generation through data exploitation. Then: a performance-based (condition-based, risk-based) maintenance requires a full DT or it is enough and better with less digitalization effort?

In fact, there are gaps in the actual bridge maintenance and management-related data collection, processing, analytics and simulations and is time to investigate the barriers to exploiting the value and potential offered by growing data and emerging technologies. One of these barriers is their lack of flexibility in fully digitized the systems to allow adaptability to change and account for human interaction. This needs to be considered on designing new management tools based on available digital technologies, by recognizing and anticipating components that may change in future and may difficult to establish a multifaceted (real-time, automated, secure, future-proof, resilient, precise) preventive and adaptive system for bridge decision support. For instance, climate change induces changes in load and environmental conditions, thus imposing adaptive strategies in existing bridge management tools. Digitalization can be a key component when facing future adaptive BMS. It becomes evident that digitalization should be the skeleton of future BMS, but the level of this digitalization should be decided according to specific needs. Probably a DT can be the answer for a manager taking care of a complex and extensive stock of bridges, but not for a medium or small stock. Different DT for different purposes and taking into account the size and complexity of the bridge stock, the feasible sources of data and other specific requirements can be the best solution to the need of adaptive BMS.

4 EDUCATIONAL AND ORGANIZATIONAL ASPECTS: THE HUMAN FACTOR

As mentioned before, one of the threads in relation to the introduction of digitalization in decision-making in bridge maintenance identified by the stakeholders is: “experts who may not be available on the job market are needed to meet future challenges”. There exist limitations in educational background of personnel with fundaments on civil and structural engineering know/how in regards with data acquisition, data processing and data analytics, i.e. in digitalization processes. This makes difficult to incorporate new techniques and tools developed in the research field to the standard management practice.

Therefore, a relevant issue, after responding where we want to go and how far we are from there, is to know **who** should lead the process. Is a bridge engineer the best suited for it? Is a bridge engineer with some complementary education the appropriate solution? Are actual academic CV in civil engineering bachelor and master programs appropriate for the implementation of sustainability and digitalization into the bridge management practice? Are there other best prepared professionals? According to the opinion of the stakeholders, presented as a weakness of the digitalization in BM: "Inspection tools do not make you an inspector. Inspectors must have prior knowledge of bridges".

Sustainability and digitalization offer significant advantages. However, their integration into routine bridge management practices presents important challenges. The implementation of the process of using digital technologies to optimize the management of bridges is not always straight-forward. Practical hurdles such as regulatory constraints, the requirement for skilled operators, and concerns over data privacy among others can impede widespread adoption. Additionally, while digitalization provides lots of raw data, interpreting this data and convert it into information requires expertise in the field of bridge engineering, again emphasizing the importance of a harmonious blend of the technology provided by the tool (digitalization) and human judgment provided by the education and expertise (professional background).

Practical implementation of research results achieved in both sustainability and digitalization fields, into bridge management practice is highly required. Which are the facts limiting the practical implementation? One of them is the different points of view and objectives between researchers and practitioners. For instance, in the case of digitalization one important advance emphasized by the new research developments (easier to carry out inspections, possibility to post-process results of inspections almost on-line, …) is the possibility of changing the schedule of basic inspections and move it from a periodical inspection schedule to a risk-based time inspection interval (Yang & Frangopol (2022)). As an example, in the case of USA, a gap between researchers and practitioners becomes evident in the field of bridge inspection planning. In fact, a 24-month inspection cycle is normally stated according to FHWA. However, some researchers argued against this fixed inspection interval showing that in some cases can derive in too-early or too-late inspections, compromising funds in one case or safety in the other (Nasrollahi & Washer, (2015); Washer et al. (2016)). According to this, FHWA now recognizes the possibility of risk-based interval inspection (FHWA (2019)). However, a recent survey carried out to twenty-six bridge personnel from state Departments of Transportation (DOTs) across the United States (Abdallah et al. (2023)) discovered that 24% of the participants agreed with the research proposal, while surprisingly 44% of participants supported the 24-month inspection cycle, and the remaining 32% stated that it has some advantages and some disadvantages. The main reason was that: "…. participants found that one of the main problems to apply a variable inspection planning framework is managing bridge inspectors, since a variable inspection schedule will lead to downsizing or hiring new inspectors, which is not an easy task in public organizations".

5 CONCLUSIONS

In the process of implementation of sustainability and digitalization into BM, two aspects are of importance: the technical and the human factor. Concerning the technical factor, full implementation is not so far. In fact, we have the tools (BIM, DT, VR,. …) and methods (performance/condition/risk-based maintenance) in one side, and the framework in the form of BMS in the other. Practitioners from bridge owners recognize that implementing novel methodologies or technologies often demands significant financial investment, be it in new equipment, training, or restructuring of existing frameworks. The main work is, therefore, to introduce these new tools and methods into the framework. However, the way to go looks longer in what concerns the human/organizational factor.

The literature review performed in Jiménez-Rios et al. (2023), examining a total of 76 relevant studies from 2017 up to 2022 shows "a consensus toward the future adoption of DT for bridge design, management, and operation among the scientific community and bridge practitioners. The main gaps identified are related to the lack of software interoperability, the

required improvement of the performance of anomaly detection algorithms, and the approach definition to be adopted for the integration of DT at the macro scale". The adaptation of data analytics methods and tools (software) is happening at a slow but regular pace. Particularly, there are limitations in training of personnel in regards to the digital aspects.

In summary, an adaptation rather than a revolution is needed. In any case, adaptation, as revolution, also requires leaders. The main findings of the work developed by Cortellazo et al (2019) show that: "leaders are key actors in the development of a digital culture: they need to create relationships with multiple and scattered stakeholders, and focus on enabling collaborative processes in complex settings, while attending to pressing ethical concerns"

In addition, adaption requires organizational changes, and these require enough resources and trained manpower to sustain these changes. Digitalization of the decision-making process has been identified as having many advantages, even by the practitioners. However, it has also been identified that employees from bridge owners who do not have a high affinity for digitalization are difficult to get on board

This is probably one of the main challenges that owners and DOTs face when incorporating digitized and sustainability-based planning approaches. Training is vital, ensuring that staff members are equipped with the necessary knowledge and skills to embrace new technologies or processes. Managing the workforce, and ensuring there is a sufficient number of skilled workers, is essential, as is securing adequate funding to support the implementation phase.

Bridge management – past, present, and future

Reed M. Ellis, Ph.D., P.Eng.
Stantec Consulting Ltd., Edmonton, Canada

ABSTRACT: The history of bridge engineering is a story of human innovation. As long as humans have existed there has been a need to bridge gaps such as streams, gullies, canyons etc. The history of bridge management and bridge management systems (BMS) is also a story of innovation as bridge owners eventually began to be responsible for many structures, constructed using various materials, exposed to varying demands. BMS are powerful computer solutions that help bridge owners responsibly manage lifecycle costs, risk, determine optimized priority programs, report current and forecasted condition and other performance measures. Today BMS help sustainably maintain the inventory while considering a variety of socio-economic factors and are proving instrumental in helping owners manage the effects of climate change and extreme weather.

In this lecture, we will take a high level review of bridge management practices in the past, present, and postulate where bridge management might be heading in the future.

1 BRIDGE MANAGEMENT - PAST

As long as humans have existed there has been a need to bridge gaps such as streams, gullies, canyons etc. The first bridge was likely made by nature - as simple as a log fallen across a stream. Nature can even create beautiful natural stone arches, examples of which we can see today. The first bridge ever built by humans is lost to prehistory and has long disappeared and no records exist. The moment the first bridge was constructed humans probably from a tree, or a stone slab (Figure 1), was most likely the moment bridge engineering first began and knowledge about durability and maintenance thus followed, whether it was understood or not at the time. We learned about forms and materials originally from nature, and then from experimentation. Which materials lasted longer, which ideas worked better, how to build would naturally lead to innovation. It may be said that the history of bridge engineering is a story of human innovation.

Although we do not know for certain, it is said that the oldest constructed bridge still in use today is the Arkadiko Bridge in Greece, the construction of which dates from the Mycenaean period, around 1300 BC. It is a stone arch bridge constructed using stone blocks fitted together without mortar. It is part of a road linking the city-states of Mycenae, Argos and Tirynthos, with the port of Ancient Epidavros (Figure 2). There were undoubtedly many such structures in the ancient world that have not survived or no longer in use.

Already we can see that the ancient engineers were using the materials available to them in designs well-suited to the material. They had learned lessons on durable construction methods as well as something about which designs best survived earthquakes; basic logs as beam elements spanning streams, stones arranged to form an arch similar to those provided by nature. Maintenance would have been very basic, keeping the bridge clean, removing debris from streams, replacing worn out materials, whatever was necessary to keep the crossing in service.

Over time, and of course in all parts of the world, innovation continued with larger and more complex structures. Kingdoms and empires evolved and through the centuries road

Figure 2. Arkadiko bridge, Greece c.1300 BC (Wikipedia).

networks were developed that became essential to commerce as well as serving military purposes. Maintenance of these structures was considered a requirement and important enough that it was written in deeds and planned for in the original construction. There are both ancient and medieval records of this. In his excellent treatise entitled *The Bridges of Medieval England – Transport and Society 400 – 1800AD*, David Harrison investigates the excellent

design and construction of bridges from Roman, Anglo-Saxon, and medieval times to the Industrial Revolution including the immense efforts of construction of small and very large multi-span structures using large skilled workforce and the planned upkeep of these bridges by the state, church, bridge trusts, charitable donations and sometimes even using resident hermits. There are even records of bridge maintenance being considered a chivalrous activity. The overall situation was similar in other parts of Europe. But consider this, provide for the maintenance and preservation at the time of construction - there is a novel idea! Clearly, we can learn from those that came before us. Although maintenance was very much reactive in nature, it was considered important and planned for at the time of construction.

In the modern era, advances in materials, mathematics, engineering, and construction methods, led to larger and more complex structures. The great railway bridge building boom occurred in Europe the early 19th century and the latter half of the century in North America. In the 20th century, the great road network expansion in the 1950s, 60s and 70s saw a great number of bridges constructed and of course large innovations in design and construction. Owners/transport departments became responsible for large inventories of structures, constructed using various materials, various designs in different exposures carrying different loadings. Maintenance was mostly reactive and not treated in any sophisticated way. And for the recently expanded road networks, the structures were fairly new and not yet at the age when rehabilitation and replacements would be necessary. This would change drastically in the coming decades.

The first use of computerized systems for managing bridges and culverts appear in the 1970s when many departments developed inventory or inventory and inspection management systems on mainframe computers. Very primitive by today's standards, these tools helped to store and manage basic data which could be retrieved to inform management decisions. The growing inventories and required investments in transportation networks started to present challenges. In December 1967 in the USA, a tragedy occurred which would lead to innovation and significant advances in the management of bridges. On December 15, 1967, the Silver Bridge, which carried U.S. 35 over the Ohio River collapsed under the weight of rush-hour traffic, resulting in the deaths of 46 people. The cause was a brittle fracture of a single eye-bar in a suspension chain, due to a small 2.5 mm defect that was undetected (US Federal Highway Administration, FHWA 2021). The end results included the formation of the National Bridge Inspection Standards to "establish national bridge inspection standards in order to provide for the proper safety inspection of bridges." The standards would detail the methods by which inspections were to be conducted, the frequency of inspections, and the qualifications of bridge inspectors. Many countries followed suit during the 1970s and inspection programs were mandated, and funding was allocated to formalize processes to manage bridges.

During the next decade it became clear that the significant expansion of road networks that had occurred in various parts of the world had created challenges for maintenance, repair, rehabilitation (MR&R) and replacement of bridges in terms of needs identification, prioritising, funding, and having resources to manage these challenges. There was a need to have methodologies and tools to help with these tasks and research efforts began in various countries in the early 1980s. It wasn't until 1987 that term 'bridge management system' (BMS) was first used. Incidentally, in the transportation world, pavement management and pavement management systems had been a focus of research and development more than a decade earlier c. 1970 and the first concepts in bridge management evolved from these systems. The formative summary of pavement management systems (PMS) is given in the book entitled Pavement Management Systems (Haas, R. C. G., Hudson, W. R., 1978). Examples of the earliest bridge management system research projects include the NCHRP Project 12-28(2) (Hudson, et al.,1987) and FHWA Demonstration Project 71 (O'Connor, et al., 1989). These reports defined the essential components of bridge management systems and documented techniques which could be implemented for BMS development. These initial research projects provided the basis for further BMS development. The NCHRP research continued with the

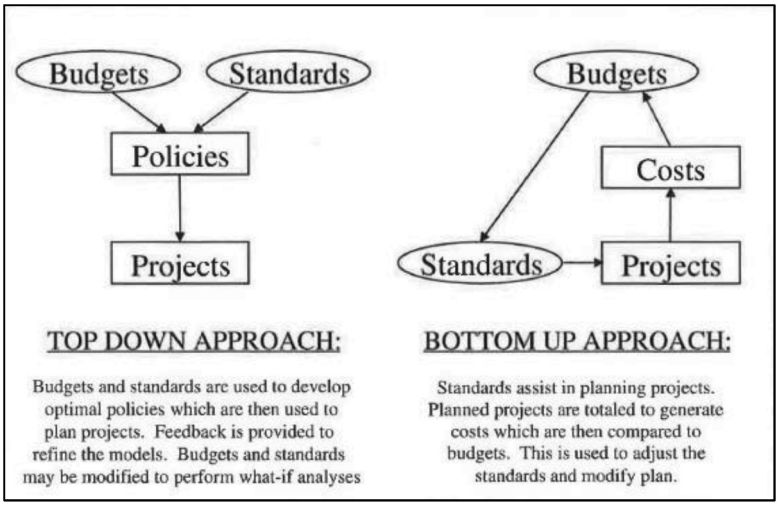

Figure 3. Alternative BMS development strategies (transportation research circular, 2000).

development of the BRIDGIT BMS. The FHWA project continued with the development of the Pontis bridge management system.

The BRIDGIT BMS was based on a bottom-up approach while the Pontis BMS was based on a top-down approach (Figure 3). A consensus was emerging on the required ingredients of bridge management systems (AASHTO, 1992) and these are still accepted today. Some of the key recommendations are that the BMS should help bridge managers manage the inventory data, the inspection program and all the data required, and ultimately make decisions about MR&R, improvements and replacements and do this within a financial framework that considers user costs, benefits, lifecycle cost analysis. Indeed, bridge management is defined in the 1992 AASHTO guideline as "*the process of combining management, condition assessment, engineering, and economic information in order to determine the best actions to take on bridges in a network over a specific time*". This requires a set of engineering and financial models such as cost, deterioration, user cost and safety models, and optimization algorithms. We will return to these requirements below, but it should be emphasized a BMS is more than an inspection and inventory database or repository.

Agencies and bridge managers continued to face challenges in managing large networks of aging and deteriorating bridges and require decision support tools for project and network level analysis that can help recommend MR&R strategies, improvement, or replacements under fiscal constraints (Transportation Research Circular 423, 1994). Research and development continued and not long after the early BMS, we see other systems developed in the early 1990s such as the Danish DANBRO, the Swiss Bridge Management System KUBA, and the Finnish Transport Agency SIHA. DANBRO originally focusing on inspection and routine maintenance and later added analysis modules. KUBA (Ludescher, H., & Hajdin, R., 1999) and SIHA (Finnish National Road Administration, 1991) were both originally based on many of the underlying concepts of the Pontis BMS but were adapted to suit local conditions. At the end of the 1990s we see the development of the next generation of BMS such as the new Ontario Bridge Management System (OBMS), Thompson et al, 1999. The OBMS followed a bottom-up approach as in the BRIDGIT system and expanded on many of the features from the other major systems listed above but had lifecycle cost and incremental benefit cost framework at three levels dependent on one another (element level treatments, project level strategies, and network level budgeting). The OBMS had a more detailed project-level capabilities than any existing system at the time (see Figure 4), and included a GIS

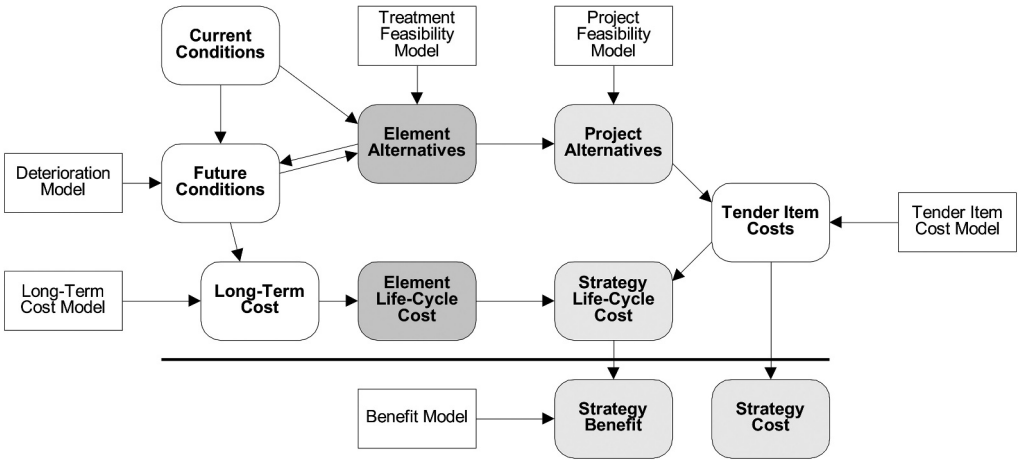

Figure 4. Project level models (Thompson et al, 1999).

interface that displayed bridge info on a GIS, together with image and document management capabilities (Thompson et al, 1999).

As with nearly all of the systems described above, in OBMS element level condition is expressed by recording the type, severity, and extent of deterioration of each major structural element. Condition is expressed as the percent or quantity of each element found to be in each of a number of condition states. As with most of the other systems described above, element level Markovian deterioration models were used. Various derivatives of this system are being used today by the majority of Transportation agencies in Canada (National Research Council of Canada, 2023).

In only a decade later, many other systems were under development in various parts of the world. Although each system has its own features, consensus was emerging on some common characteristics in these systems (Mirzaei et al, 2014):

a) The most common inspection and condition rating was element-level, condition state inspection recording severity and extent of defects.
b) The most common deterioration model being used was Markovian deterioration models applied to bridge and culvert elements.
c) Condition was the most common performance measure. Usually in some for of condition index.
d) The most common financial framework for decision making was minimum lifecycle cost analysis (LCCA), with benefit/cost (B/C) as ranking.

Bridges and Bridge Management came a long way from the earliest bridges to the modern era but it wasn't until the last few decades of the 20th century that bridge owners would have the technology to fully manage inventories of bridges and move from reactive maintenance to proactive maintenance. The age of BMS began roughly in the mid-1980s and the subsequent decades ended with systems that could help manage inventory and inspection information, perform analysis to calculate LCCA and B/C to develop prioritized MR&R activities, improvements, and replacements (Transportation Research Circular, Issue Number: 498, 2000). Bridge managers could now make informed decisions and create budgets and work programs along with forecasted condition depending on those budgets.

2 BRIDGE MANAGEMENT – PRESENT

With the framework in place for effective BMS, bridge management and BMS research and development continued throughout the first decades of the 21st century. Improvements in

bridge management/BMS have occurred in various countries. Today, in addition to the common characteristics described above, we can expect BMS to be able to perform risk analysis for risks associated with advanced deteriorated condition, vulnerability to scour, flooding, seismic, fatigue, and more (Mirzaei et al 2014, Sobanjo & Thompson 2013, Ellis et al 2012.). A few systems give the bridge manager the ability to consider multi-objective analysis (Patidar et al 2007). For example, BrM (AASHTOWare) includes an analysis that uses a utility function approach to allow the user to weight different objectives such as condition, lifecycle cost, and risk in the decision making process (Mirzaei et all, 2014).

The need for better performance measures for bridges led to research on best practices (e.g. NCHRP 2010) as to what should be reported and how performance measures can help understand effectiveness of design, construction, inspection, and preservation strategies thereby supporting good bridge management. Performance measures are being used such as condition (e.g. % bridge decks in Good or better condition by functional class, % of bridges posted weight restrictions). Vulnerability ratings for scour, flood, fatigue, fracture can be used as performance measures and many systems have this capability (Mirzaei et all, 2014). Also in the last decade, there has been increased emphasis on improving existing models such as deterioration models and treatment effectiveness. In many countries asset management practices began to place emphasis or requirements for industry accepted bridge management practices so agencies that have BMS are able to provide input into transportation asset management plans (TAMS).

Also during this time better field data collection tools such as field tablets etc. become available to improve the efficiency of inspection data collection. These tools are used on site but later synchronize the data collected with the BMS.

Building Information Modeling (BIM) has been widely applied in today's building construction industry for some time and the benefits of having a 3D model from conception, through design, construction and maintenance have been realized. In recent years we have seen BIM applied more commonly to bridges (BrIM). Linking BrIM to BMS is in the early stages but already seeing great possibilities to record inspection information such defects and maintenance issues on a 3D model. This will be particularly efficient when the models are created at the time of conception and used for the entire lifecycle including design and construction, inspection and maintenance.

Drones or Unmanned Aerial System (UAS) were first used in the last 10 years for bridge inspection purposes and the capabilities of these systems are continuing to improve with more automated flight capabilities, types of cameras, sensors etc.. Today we can use UAS to fly the bridge site in a pre-inspection to create a 3D model for BrIM and then superimpose inspection findings on the model which is then linked to a BMS. Examples of this are being presented in this conference (IABMAS '24 Special Session 9).

Increased awareness of the effects of climate change and extreme weather has emphasized the need for assessment of vulnerabilities to flood, scour, etc.. Various bridge management systems have this capability (Mirzaei et all, 2014). Recently an appraisal index, vulnerability rating and risk analysis is reported for wildfire (Ellis & Kamranian, 2023) and this is particularly of interest for the countries that were exposed to record wildfires in 2023 (Canada Natural Resources, 2023). The ways in which agencies can respond to the challenges of climate change vary for new design vs. existing infrastructure. In a recent survey and study commissioned by the National Research Council of Canada (NRC), it was determined that most of the advanced bridge owner agencies are aware of the challenges surrounding climate change and extreme weather (NRC, 2023). All Provincial government agencies responded that the effects of climate change and extreme weather events are being considered in the design of new structures. Most are using guidance from hydraulic studies, Environment Canada and other climatic data, and new Intensity-Duration-Frequency (IDF) curves to determine design flows and flood events, increases in scour potential, temperature range etc. In response to these challenges for new design, most have internal policies related to design requirements for increased freeboard, deck drainage, more stringent permafrost considerations, erosion and sediment control, river protection works, etc. The 2025 Canadian Highway Bridge Design Code will have specific climatic data to address the changing climate.

The situation is different for the assessment of existing structures when considering the impacts of climate change and extreme weather. Existing structures are generally designed to older standards. Most agencies surveyed indicated that they consider increased design storm events or temperature ranges obtained using updated climatic data. This generally translates into re-mediation such as increasing freeboard, river protection or training works, improved deck drainage etc.. Sometimes, hydraulic capacity can also be increased for example by constructing relief flow culverts beside existing structures.

Beyond the design parameters for mitigation of a particular vulnerability, the main challenge for agencies is to determine which structures should be prioritised and due to which vulnerability. Vulnerabilities and risks need to be identified and the need for remediation should be considered and prioritised over the transportation network, corridor, etc. Agencies identified that guidance would be useful in concepts such as:

a) what are the vulnerabilities to consider with respect to climate change and extreme weather? (e.g., types of extreme weather events, flooding, scour, seismic, wildfire, hurricane, tornados)
b) what analytical tools are needed to help determine and prioritise mitigation of these vulnerabilities?

These are areas of active and likely future work as agencies must manage risks and provide resilient transportation networks.

We have also seen increased use of non-destructive evaluation of bridges to determine for example crack detection and monitoring in steel bridges, or cracking, delamination and rebar corrosion in bridge decks. This information can feed level II decision making in bridge management although nearly all BMS continue to use visual inspection data. These tools continue to improve and there are robotic non-destructive evaluation and testing devices already in use. Artificial intelligence (AI) is being applied to damage detection using imaged-based methods and detection based on data from sensors and signals such as vibration or acoustic emission.

The use of sensors on bridges is far from new, having its origins along with structural health monitoring in the 1990s. Today sensors and instrumentation are miniaturized and inexpensive and easily installed for long-term monitoring of bridges or for load testing purposes. Bridge monitoring and bridge load testing can be very efficient and cost effective solutions for bridge owners. It is rare that these systems are directly linked to a BMS.

3 BRIDGE MANAGEMENT – FUTURE

Perhaps it is risky to try to predict the future, particularly when technology is involved, as it is in bridge engineering in general and specifically in bridge management/bridge management systems. Actually, prognosticators such as Shirole demonstrated impressive insights into the future that were remarkably accurate (TR Circular 423 Shirole, A.M., 1994). Writing in 1993, the author thought that the need for BMS development was great due to the increased demands, deteriorating structures, and shrinking budgets. It was suggested that improved decision support analysis would be needed, together with improved types of inspection data and collection of the data, significant improvements in computer power and storage, use of the new geographic information systems (GIS), and improved decision support for assessing vulnerability to flood, scour, fatigue and other hazards. These things would prove true within a decade. This author can only hope to do as well.

Looking to the future, is possible to foresee some emerging technologies and ways in which the challenges of effectively managing bridge inventories may be solved.

1. **Condition assessment and data collection.** We can expect to see improvements in condition assessment and data collection tools, and increased use of NDE. The promise of better data, collected in a more efficient way and populated into bridge management systems is ever appealing.

2. **Automated, Remote Inspection and Condition Assessment.** UAS technology has technology has improved incredibly in the last 5 years continued improvement in automated flight capabilities, payloads, types of cameras, sensors etc. will make this a regular part of the inspection program. Whether this is used for pre-inspection, on-site inspection, or live inspection to an off-site senior reviewer, this technology will move to mainstream, especially if linked to BrIM. AI plays a role in this area in the form of damage detection and model creation. Research is on-going in AI supported damage detection from images such as cracks, efflorescence and staining, exposed rebar, delamination, spalling, rust, repair areas and more. Research into acoustic sensors in combination with hammer sounding is showing promise in the ability to detect loose bolts and concrete delaminations. Once fully developed this will be truly revolutionary. Further improvements in efficiency will occur when these tools are linked directly to bridge management systems which can then provide decision support.
   The situation for robotic inspection and condition assessment is similar.
3. **3D models, BrIM, Digitization, Digital Twins and Extended Reality.** The use of bridge BIM or BrIM will continue to grow, not necessarily due to bridge inspection management needs, but because it makes the entire lifecycle management process more efficient including planning, design, construction, inspection and maintenance, and decommissioning. The growing trend towards digitization is driven by the improvement of technology including surveying, drone/UAS scanning, AI in processing, and computer and cloud hardware. AI will improve in the ability to detect structure elements from images (i.e. girders, bearings, cables, abutment walls etc.) and calculate quantities. Of course, big data, statistical analysis, and deep learning play a role in this, and these fields are evolving. Bridge managers will have real advantages as these tools are linked to BMS to provide informed decision support with the benefits of 3D visualization and reporting.
   We will see continuing research on, and increased application of digital twins in the bridge industry. A digital twin is a digital 3D replica of the physical bridge which models the behaviour of the real thing. The digital twin can connect to sensors and real time data from the physical structure. Before this is fully practical, we will have to solve the challenges associated with the immense amount of data to process.
   We will undoubtedly see increased development of extended reality (ER) tools in bridge inspection. These wearable displays will enable inspectors to interact visually and even physically (e.g. hammer sounding robot) with the physical bridge and maybe one day a digital twin. There are exciting possibilities in this area.
4. **Sensor, Structural Health Monitoring, Integration With Bridge Management Systems And Iot.** Inexpensive, miniaturized, low power sensors have been available for some time now, but improvements are likely to continue. The equipment and communication systems have become smaller and less costly, and we are finally seeing more application of sensors, structural health monitoring systems, live load testing, bridge weigh-in-motion (B-WIM). Personally, as an early adopter of some of these tools decades ago, it continues to surprise how slow general adoption and application of these tools has been. In future, I expect (and hope) wider use and direct integration with BMS and BrIM will become common. Sensors will one day be applied on most bridges. For example, perhaps every deck joint and large bridge bearing will be manufactured with sensors and all the owner has to do is connect them. Imagine if deck joint gaps and temperate were measured continuously and shared via the Internet of Things (IoT) directly to the BMS for monitoring and decision making, no longer requiring inspectors to take measurements in dangerous traffic situations. Imagine if bearings could share bridge bearing reactions continuously the same way thereby informing the bridge engineer of changes, potentially serious changes. In fact, deck joint gaps and bearing reactions can be an early indicator of issues before they become serious. It is an expectation and a hope that these things will become common in the future. As with all of these exciting technologies, it will reach full potential when bridge managers can access the information in their BMS in real time for decision support.

5. **Global positioning and satellite data.** Scientists have developed a technique for analyzing satellite data that can reveal subtle structural changes in bridges and other infrastructure. Using synthetic aperture radar (SAR) measurements from several different satellites and reference points, it is now possible to map relative displacement such as structural changes to a bridge. Using SAR and new processing, it has been possible to detect millimeter-sized changes to a bridge over time. A team from NASA, University of Bath, and the Italian Space Agency have successfully applied this technique to retroactively investigate the collapse of the Morandi Bridge, near Genoa, Italy in 2018. The researchers found there were subtle changes as early as 3 years before the collapse and significant increases in structural changes in the year prior to the collapse.

A new satellite NASA-ISRO SAR (NISAR) planned by NASA and the Indian Space Research Organization (ISRO) for 2024 is intended to greatly expand this coverage (Figure 5). This has promise in future to improve the safety of infrastructure globally.

Figure 5. Planned NASA-ISRO SAR (NISAR) (NASA, 2024).

5 SUMMARY

We have seen that bridge engineering, and the management of bridges has been linked to human innovation since the beginning of time, at least from the time of the first bridge. Through this journey, innovation has constantly occurred as the need arose that has enabled bridge managers to successfully manage this vital infrastructure whether this was a few bridges or the large complex inventories of today. The need drives the innovation and technology has contributed to the success. To the many bridge engineers out there have been privileged to have been part of this journey, you will have enjoyed the ride and no doubt feel confident about the future of bridge management. To those young aspiring bridge engineers, it's a great time to be a bridge engineer involved in design, inspection, preservation, and all the new technologies that comprise bridge management. Enjoy, you are in for an exciting ride!

Bridge engineering - Proving the sustainability case for refurbishment v replacement

D.K. MacKenzie
COWI UK Limited

ABSTRACT: The demands on our existing transportation infrastructure are growing as our cities increase in size. We are constantly faced with the need of increasing the capacity of our existing networks. So do we rebuild or refurbish? We live in a world of finite resource and the idea of simply knocking something down and rebuilding it afresh is counter-intuitive to a society that seeks sustainable solutions. So how do we assess the sustainable benefit of refurbishing an existing structure?

There are several tools recently developed to measure the extent of embedded carbon in new projects that help us compare the sustainability of new construction and determine the most effective scheme. However, the same tools cannot be used to assess the relative sustainability of refurbishment versus replacement and yet decisions on this critical point are having to be met by bridge owners worldwide.

1 INTRODUCTION

We live in ever developing societies and with that comes the need to update our infrastructure. We have been faced with both increasing the volume of traffic flows and the weight of the vehicles using our bridge networks. In the past, with a few notable exceptions, we have tended to replace existing assets with new assets and justified them on purely commercial and operational bases. The view was very much "out with the old and in with the new" as we tended to take the view that it was easier to build new rather than refurbish the existing.

Our mindset has naturally been cost and programme driven, as we have striven to get the best return when seeking to increase the capacity of an existing structure. However, we are now facing a global climate emergency and, as engineers, we must be at the forefront of reducing the carbon content of our projects. We therefore need to place a greater emphasis on making better use on our existing assets and when the call comes to increase the capacity of our network, we must take a hard look at the value and benefit of retaining and strengthening of what is already there.

This view is not new. It has been explored by researchers evaluating the changes to the state of the art. Mizra (2006) carried out a qualitative review of Canadian infrastructure to review the effects of poor maintenance on structures and the consequential cost that arose. His conclusions were that the approach taken by bridge designers and subsequently by funders of infrastructure maintenance were that the construction industry only tends to consider "first cost" and not whole life costing. This work was driven by the huge cost of failing to maintain infrastructure; it will be seen from this paper that the additional impact on sustainability through embedded carbon and a failure to redevelop existing infrastructure also has significant consequences for global warming.

When we are faced with evaluating the basis for refurbishment against renewal, we are presented with a number of challenges. The obvious ones are that:

- the existing load bearing capacity is insufficient,
- the bridge needs to be widened,

DOI: 10.1201/9781003483755-5

- the structure is in very poor condition through insufficient maintenance or from damage, and
- the existing alignment does not suit the increased demands.

These are the basic structural requirements that are the immediate concerns of the bridge engineer, but there are many other factors of equal importance that also need consideration. These include as a minimum:

- the effects of construction on traffic flow during the refurbishment or replacement,
- the loss of amenity to users of the structure, which broadly align with the traffic effects,
- the effects on local businesses and residents nearby the structure where temporary access will be required to the site and will affect local traffic patterns on neighbouring roads,
- the environmental effects during construction due to noise, alternative access, lighting, and out of hours working,
- those environmental and biodiversity efforts created by increasing the capacity of the bridge,
- the effects of loss of heritage,
- the ease of future operation, and
- the maintainability of the scheme

All of these will drive up the carbon emissions on a project and impact its sustainability. Special consideration will need to be given to the long term environmental and biodiversity cases; this paper does not set down methodologies for this as they are generally better defined and are usually part of the statutory requirements for a project. However, they need to be added into the mix to ensure that the overall balance of sustainability is assessed.

It should be noted that at present, there are limited means for carrying out a complete comparison of the long term benefits between refurbishing/strengthening a structure and building from new. This paper therefore sets out the steps needed to develop this process into a more quantifiable basis so that there is an effective means for assessing the merit of preserving our existing heritage. We know that it is a "good thing" to preserve existing infrastructure and not just rip it up, but when does it become too much of a challenge and how do we legitimately justify new construction? A means for comparison is required.

2 WHAT IS REFURBISHMENT?

This paper considers how the case for refurbishment instead of replacement can be justified when the existing bridge capacity is insufficient. It is a clearly understood premise of modern bridge design that all bridges will have components where there is the need for regular refurbishment or replacement. The designer is required to assess the effects of replacement, be they items, for example, such as bearings or stay cables. This is planned refurbishment. This paper is concerned with major refurbishment or replacement of the entire structure, which is very rarely contemplated in the design of bridges. Some legislations require designers to consider safety in demolition of an asset (HSE 2015) but this is not linked to a whole life cost approach.

It is considered that there are two forms of major refurbishment. The first is when there is an increase in traffic volume and there are an insufficient number of lanes to carry the increased traffic volume across the bridge. Typically, this requires major intervention as there is a requirement to provide more space for traffic on the deck. However, it is not always necessary to widen the running surface as it may be possible to use narrower lanes and make other changes to the hard-shoulders and barriers to accommodate additional traffic lanes.

West Gate Bridge and Gade Valley Viaduct stand out as particular examples of successful widening schemes where better management of the available deck space obviated the need for construction of additional deck space. In both these projects, this ability to use the same traffic corridor to carry a greater volume meant that the works mainly comprised strengthening of the primary structure to carry the additional loads, but no change to the overall width of the deck. It should also be recognised that providing additional volume does not always result

in significant force increases as most design codes will have small additional loadings for the additional load when adding a seventh and eighth lane to a six lane bridge.

Figure 1. West Gate Bridge before widening.

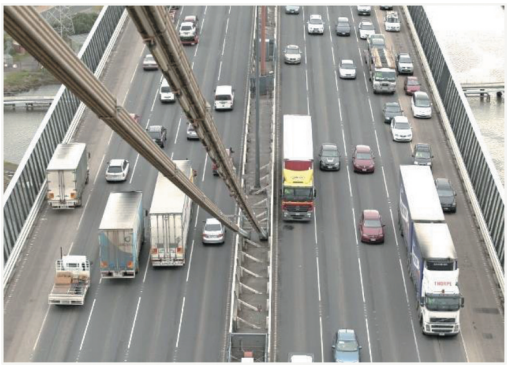

Figure 2. West Gate Bridge after widening.

The second form is when there is insufficient capacity to carry the traffic because either the traffic loads have gone up or the capacity has decreased due to deterioration. Here the refurbishment considerations will be driven by the ability to intervene to enhance the capacity of the deck. There have been some highly successful schemes where the bridge design engineers have demonstrated remarkable ingenuity to upgrade the structural capacity to the requisite level. These are presented in the case studies given throughout this paper.

There will of course be cases when the refurbishment needs to consider both a loss of capacity through deterioration as well as an increased demand for traffic flow and weight. Such cases are inevitable more challenging but, again, there have been some extremely impressive schemes (shown in the case studies) where the original structure has been enhanced with minimal interference and embedded carbon when compared with the alternative of complete refurbishment.

3 HOW DO WE MEASURE SUSTAINABILITY?

3.1 *Definition*

The starting point in any debate on sustainability is to set out some clear definitions of what we mean by sustainability. The United Nations (2021) offers "*Sustainable infrastructure systems are those that are planned, designed, constructed, operated and decommissioned in a manner that ensures economic and financial, social, environmental (including climate resilience), and institutional sustainability over the entire infrastructure life cycle*". The key message here is that sustainability is a whole life consideration and must consider all aspects of the lifecycle of a project. There are many definitions of sustainability that exist owing to the various nuances within the different types of infrastructure. The reader is referred to an overview carried out by Yanamandra (2020).

The challenge to the consideration of sustainability is that most bridges will have been designed on the basis of direct costs only with little or no direct calculation of whole life costs. Explicit consideration is required of the maintenance and depreciation of infrastructure over its service life. Such considerations will drive greater awareness at the design stage of potential limitations in bridges and their ability to accommodate changes in the future. It is appreciated that the foresight required to predict future change and to provide the means for upgrading capacity is not an easy subject. Some of the case studies considered in this paper show some remarkable foresight on the part of the bridge owners, which is to be commended, and should serve as a guide for all bridge engineers when considering the whole life value of either a new

or an existing structure. It is inevitable then that the sustainable design of bridges must be guided by overall socio-economic and environmental concerns which is inexorably linked to future use.

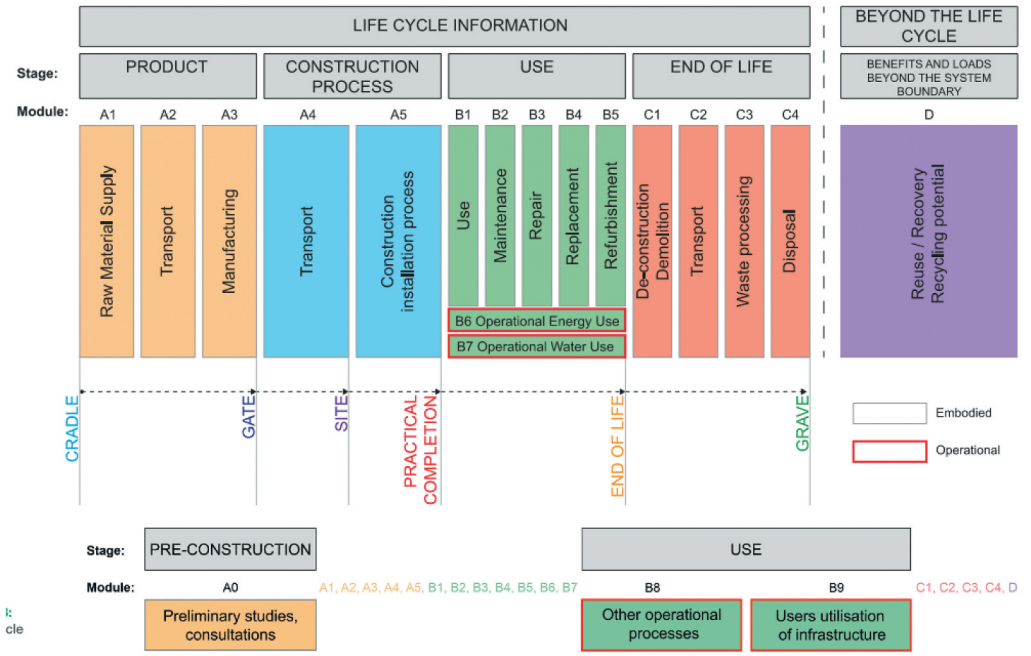

Figure 3. Lifecycle modules for construction projects.

Given the imperative to reduce carbon emissions, there has been widespread acceptance in the structural engineering community that the most appropriate role we can play is to reduce the embedded carbon in our structures and in the associated materials such as asphalt and barriers. The Institution of Structural Engineers has taken a particular lead here and through the work of Orr et al (2022) has set out a procedure for deriving the embodied carbon that is introduced into a structure over its life time. The process examines all stages of the structure which includes, importantly, the full operational and end of life stages of a project. These are necessary to assist in the comparative study of different schemes; if we simply limit comparisons to new build we cannot provide an accurate comparative assessment over the lifetime of a project and our comparison will fail.

Orr's work is used as the basic standard in the United Kingdom. He has developed a model to represent the full set of stages for the total lifecycle of a project. Figure 3 shows the stages for a typical construction project. Each stage broken down into a series of specific steps or modules which enables the means for assessing the embodied carbon at each stage of the lifecycle of an asset. It has been driven initially through the building sector but it is equally relevant to bridges.

It is worth also introducing some basic terminology around carbon. Figure 4 describes the various categories of carbon associated with an infrastructure project.

The emphasis on assessing embedded structural carbon was led initially in the building sector; further work carried out by Archer-Jones and Green (2021) and by Collings (2022) both provide the designer with some clear methodologies for the assessment of embedded carbon in bridges. They have been aided by the considerable work carried out by various contributors to develop databases for most construction materials and so the designer is well supported in the area.

Terminology

Carbon	=	Carbon dioxide equivalent emissions – a unit of global warming potential corresponding to 1kg of carbon dioxide ($kgCO_2e$)
CapCarb	=	Capital carbon associated with construction of the asset, the equivalent to upfront carbon for buildings (corresponding to lifecycle modules A1–A5). (Also referred to as embodied carbon)
OpCarb	=	Operational carbon associated with ongoing energy use, maintenance, refurbishment or replacement works (corresponding to lifecycle modules B1–B8)
UseCarb	=	In-use carbon associated with use of the asset by the public (corresponding to lifecycle module B9)

Figure 4. Carbon categories.

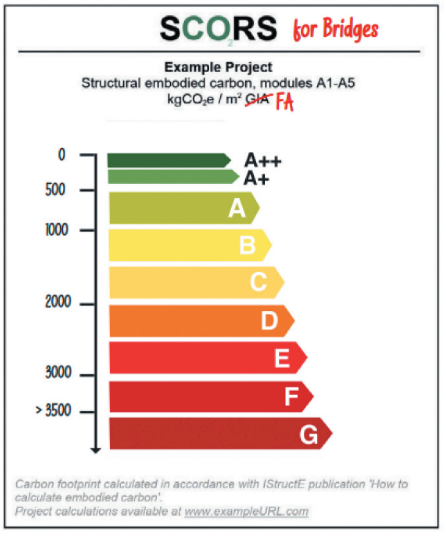

Figure 5. SCORBS ratings.

The work by Archer-Jones and Green is particularly useful as it extends the Structural Carbon Rating System Scheme (SCORS) for buildings with a similar system called Structural Carbon Rating System Scheme for Bridges or "SCORBS" (Figure 5). The rating is calibrated around the available deck areas as an appropriate comparative metric although the authors recognise that the form of bridge type does have an influence on the outputs. Nevertheless, the system provides designers with a clear relative scale for comparison of different schemes. Bridges can be rated against this scale with the intention that designs should seek the lowest possible rating.

3.2 *Calculating sustainability*

3.2.1 *Introduction*

The embedded carbon can be calculated for each module shown in Figure 3. The data that supports the calculations have been developed based on common industry databases. These are well developed for the Product and Construction Process modules but there is much less material available and increasingly less application of the modules as we move through the life cycles.

3.2.2 *Structurally embedded carbon*

Modules A1 to A5 relate to the embedded structural carbon and are the parameters that are most likely to be affected by decisions made by the design engineer. Many data sources are available Orr (2020) being an excellent starting point that provides guidance on the process. The process for calculating the specific embedded carbon content for modules A1 to A5, with advice on modules B, C and D has been set out by Archer-Jones (2023).

The embedded carbon for refurbishment can be calculated using the same processes as described in this document. It should be noted that the need for sophisticated temporary works is often a requirement for major bridge refurbishment. As such, special consideration is required to ensure that the embedded carbon employed in the manufacture and use and dismantling of the temporary works is included in the overall carbon accounting. Care must also be taken to use appropriate material indices such that any embedded carbon for the construction of those materials is not double counted.

3.2.3 *Carbon expended in use*

At present, the majority of the effort in calculating embedded carbon is in the Product and Construction Process Modules. However, for engineers considering the sustainability of existing bridges, the effort is required in the calculation of the operational modules, B1 through B9. There are considerably less data available for these assessments than for the A modules, where there has been, understandably, a greater drive to understand those design parameters which the design engineer can affect directly and thereby make the greatest initial contribution to reducing the amount of embedded carbon.

Wood and Archer-Jones (2023) have studied the B modules for the Clifton Suspension Bridge and set out a clear methodology for the assessment of the embedded carbon during operation. Their work has shown that the OppCarb (refer to Figure 4) for the operational phase (B1-B9) is relatively low per annum at 60 tCO2e. The key drivers here are operational energy costs and staff travel to the bridge to operate the bridge and the tolls. The cost of

Case Study – Clifton Suspension Bridge, UK

This heritage structure has been assessed for the operational carbon consumption which includes for major planned refurbishments such as deck replacement, resurfacing and painting. A notable outcome of this assessment is the was the disproportionate carbon cost of partial closures showing that maintaining traffic during refurbishment will have a significant effect on enhancing the sustainability of the works.

major maintenance over the years has be included based on the frequency of carrying out the works (such as painting, bearing replacement, resurfacing and deck replacement).

This annual carbon cost can be compared with an illustrative notional cost of a replacement structure of exactly the same form (but clearly not envisaged for this iconic structure designed by Brunel!) which would result an embedded carbon cost of 7800 tCO2e. This is a simplistic assessment as there are other parameters that need to be considered such as demolition costs of the old structure and the effects on traffic while the structures are changed. An outline assessment of this has been carried out and the cost of diverting traffic completely during a full bridge closure has been calculated at a carbon expenditure of 840 tCO2e so for an additional three-year closure of the bridge, the carbon costs would be of the order of 2500 tCO2e which needs to be added to the reconstruction and demolition costs. This needs to be assessed for all bridge refurbishments and replacements as part of the true carbon cost comparison.

The scope to reduce operational carbon is very much in the hands of the operator of the bridges. The work reported on Clifton shows the direct engagement of the bridge operator and owner, the Clifton Bridge Trust, and will enable it to set a proactive carbon policy in reviewing key items such as staff travel, the supply of electricity and better planning in the maintenance of components. This exercise is currently underway.

The Rochester Bridge Trust (2024) operates and owns two large crossings of the River Medway in south east England. In 2020 it carried out a major refurbishment of the bridges and calculated the carbon footprint of the project. It sought to offset the carbon through some direct tree planting in a new woodland plantation close to the site where it has direct control over the protection of this additional asset. Carbon offsetting has been used extensively in the past but is not generally considered to be genuinely sustainable as often the carbon creator has not control over the offset asset which means that the long term sustainability of the offset may not deliver the net carbon balance. This normally occurs long after a developer has taken the kudos for a net zero project! However, the Rochester Bridge Trust includes the management of the woodland as part of its total asset and so has protected the ensuing carbon savings.

The Trust has gone further in developing its net zero carbon approach by reviewing its maintenance strategy. Key findings from this are again the need to review all aspects of energy consumption. Staff travel and sequential planning of on-site bridge activities are key drivers here.

3.3 *Deferred carbon – the case of depreciation?*

There are several notable examples of bridges where the construction has been staged from the outset in recognition of the likely need for future expansion. Examples of this include the Auckland harbour bridge in New Zealand and the EJ Whitten bridge in Melbourne Australia. In both these cases the owners recognised that there would be future demand on the structures but that it was uneconomical to build the bridges with their full operational capacity from day one. As a consequence the designs were prepared in contemplation of the additional structure that might be required in the future but that the reduced plan area of the bridge was constructed initially. For both projects, the owners instructed the designers to include provision for the future works such that they could be incorporated with minimal intervention to what would become the existing structure. In both cases the period between the initial construction and that of the widened bridge was in excess of 10 years (over 20 in the case of E.J Whitten). Deferring the cost of building the full asset from day one meant that both bridges were affordable from the outset; in their full guise they were unaffordable. Naturally there is an additional initial construction cost for building in unused capacity from the outset, such as bigger foundations or stronger piers, but the costs for building these anew at a later stage will significantly increase the costs – this would be assessed using a net present value assessment to ensure it was value for money. Auckland Harbour Bridge was a major undertaking at the time of construction in 1960 so the foundations were built to provide additional capacity for a future deck that could be built at a later stage when funds were available. By making early provision in the foundations, the extensions required no costly new foundation work.

The question that arises is should we also discount future carbon against current carbon in the same way that we discount future costs? This question is currently under debate and is

Case Study – E.J Whitten Bridge, Australia

This refurbishment project was highly sustainable and showed a very strong client commitment to future proofing the structure. It was recognised that the major arterial route that crossed the bridge would promote reginal growth and so provision was made to build the foundations with sufficient capacity for additional loading. The site had poor access, so this extra commitment came at only a small incremental cost. Changes to design loadings meant that it was not feasible to construct the new deck from concrete and a lightweight steel box was inserted instead. The additional carbon cost of the new structure was considerably lower than would have arisen had the provisions not been made for future growth, justifying the effort and early commitment.

based around the premise that future construction will have to be more carbon efficient than at present having to general trends of decarbonization in the construction industry.

If we use E.J. Whitten as an example, the table below shows the cost of the original construction both with and without provision for adding an additional bridge deck to the foundations in the future. The carbon costs of the future works are then assessed, again on the basis that provision was or was not made at the time of initial construction.

Not surprisingly, the total carbon cost is significantly higher if provision is not made to incorporate the provision for future works at the time of original construction. However, if we were to achieve year on year savings of 4% in carbon efficiency then after twenty years it would appear that it is slightly more carbon efficient to defer the construction until later and it would be argued that no initial provision should be made or that it is entirely minimal. At 8% there is a large apparent saving in carbon if no provision is made.

This is a controversial point that is based on expectation that such improvement can and will be made if we are to achieve net zero targets by 2050 and so it leaves a conundrum that needs to be answered when we plan the development of new assets. Whether 8% is achievable

Table 1. Embedded Carbon in EJ Whitten with and without early provision.

	Embedded carbon (tCO_2e)		Total discounted carbon over 20 years		
	At first construction	At refurbishment	0%	4%	8%
Case 1: no early provision	6100	3000	9100	7426	6666
Case 2: early provision	7360	608	7968	7629	7475

or whether 4% to 5% is more likely, it is the author's firm opinion that the possibility of future expansion of all assets should be considered at the time of construction and a detailed review of how that would be achieved needs to be made. It should be emphasised here that the bridge was part of a much wider scheme and the alignment of the carriageways were arranged so that widening was into land that was reserved from the outset in between the carriageways. This means that the later works were much simpler and required no additional land take, resulting in significant overall project savings in embedded carbon. It was clear from this brief study that the information for the carbon assessments is not sufficiently mature for such a nuanced assessment and more data and research is required to assist in this important debate.

4 CHALLENGES TO REFURBISHMENT

4.1 *Heritage*

The consideration of the historical value of the structure will be an important feature in the decision on whether to replace or refurbish. These requirements will vary from country to country and depend on the strength of legislation that protects historical structures. In the United Kingdom, there is specific legislation to structures which have been "listed" and included on a register of historic monuments. Listed structures cannot be demolished without the direct approval of Historic England and such permission will only be granted for the higher level listed structures when all efforts to preserve the structure have been shown to be technically impossible by an independent body. Owners have a statuary duty to preserve and maintain such structures.

The justification for protecting historic structures is that the built environment contains a unique and dynamic record of human activity. The view espoused by English Heritage (2008) is that the built environment "has been shaped by people responding to the surroundings they inherit, and embodies the aspirations, skills and investment of successive generations. People value this historic environment as part of their cultural and natural heritage. It reflects the knowledge, beliefs and traditions of diverse communities. It gives distinctiveness, meaning and quality to the places in which we live, providing a sense of continuity and a source of identity. It is a social and economic asset and a resource for learning and enjoyment. Each generation should therefore shape and sustain the historic environment in ways that allow people to use, enjoy and benefit from it, without compromising the ability of future generations to do the same."

There are some very well known landmark structures in the UK that benefit from this protection. Structures such as Tower Bridge and Hammersmith Bridge in London are protected accordingly as national monuments. Hammersmith Bridge is presently closed to vehicular traffic due to defects in the pedestals and fatigue concerns over the deck. The owner has put in place strengthening schemes to restore the bridge back to an enhanced capacity while preserving as much of the original fabric as is possible. Where changes are required because they are life expired, sensitive treatment of the design of the new components is being applied to ensure that the structure is as little changed as possible while still delivering the required safety and durability. The process is still underway at the time of writing of this paper and the costs will be higher than replacing the bridge with a new structure.

Similar sentiments exist world-wide, albeit without the same level of protection. A notable case study is that of Lion's Gate Bridge where the challenge was to replace the deck of this aging suspension bridge.

4.2 *Traffic management*

Interruptions to the smooth operation of traffic across a network have a significant effect on the additional carbon produced. The case study with Clifton provides an interesting comparator of the cost of carbon from diverting traffic away from the bridge compared with the carbon embedded in the works.

It is self-evident that the most successful refurbishment works will be those where the traffic has minimal interruption. It will be difficult to avoid some delay to the traffic and therefore the cost of this impediment to free flow needs to be calculated and factored into the assessment of total carbon produced. The need to keep traffic flowing is likely to impact the programming of the works and so it will be necessary to establish the trade-off between a longer duration of limited interruption as opposed to the shorter duration of greater interruption. The need to apply intelligent engineering in developing innovative refurbishment schemes that do not restrict the traffic should be a worthy challenge for any talented engineer.

Case Study - Lion's Gate Bridge, Canada

This heritage structure opened in 1938 but with a deck design where the details were poorly configured that did not have the durability had the deck replaced and reconfigured to allow heavier vehicles to run on the new deck. The previous structure was life expired. Traffic disruptions were minimized by the innovative use of temporary works which also facilitated the replacement of the worn deck suspenders in a series of overnight operations where a complete section of deck was replaced. The structure is a landmark in Canada and this highly effective refurbishment allowed the preservation of the asset for minimal embedded carbon.

4.3 *Existing condition*

Much of our retrofit work is about keeping existing structures operating particularly where there has been absence of good maintenance or there have been poor design details that have led to a decrease in the capacity of the structure. The case for replacement of such structures can only be argued as being a last resort when there are no other means for enhancing the existing capacity.

The calculation for the embedded carbon in a refurbishment scheme can be determined using the data for modules A1 to A4. The data for A5 (construction installation processes)

may require some additional effort to piece together the enhanced construction activities. It is expected that there will be greater construction effort per tonne of material as the new material has to be fitted to the existing where there will be challenges of access, temporary loading and any reworking associated with unforeseen conditions in the original material. There is limited information on the impact of embedded carbon; it is proposed that in the absence of better information, rates should be increased by 50% to reflect the premium on handling and transport. This should not serve as being excessively penal – the example of Wye Bridge by Flint (1993) shows that the radical strengthening schemes of providing support from a new cable stay system reduced the internal deck stiffening to around 20% of what might otherwise have been achieved through deck stiffening alone.

4.4 *Increasing capacity*

The need for providing additional capacity will provide additional challenges owing to the need to either reconfigure the existing deck space or by adding additional decks alongside or above the existing running services. The expansion of the Gade Valley Viaduct and the West Gate Bridge were able to take advantage of the generous width of the existing structure. However, when there are significant increases in the capacity requirements, it is tempting to simply duplicate the crossing with a new structure alongside the existing. This becomes an expensive option in terms of cost and particularly of carbon because essentially a new independent structural system is being installed.

The primary cost in these instances is the addition of a new foundation. Depending on the form of deck this can add an additional 40% to the carbon cost of the structure and so it is

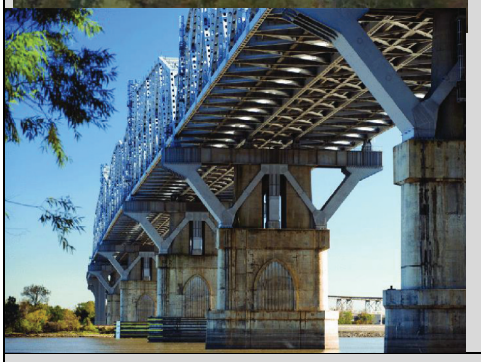
Case Study – Wye Bridge, UK

This first generation cable stayed bridge (and its grander neighbour, the Severn Bridge) had some serious shortcomings in its capacity, and was also subjected to significant increases in the demands on the structure. The application of some highly innovative engineering resulted in the doubling of the live load capacity for a very small fraction of additional steel tonnage. It was a highly sustainable refurbishment that allowed much heavier vehicles to use the bridge. Dramatic changes were made to the cable support of the bridge, which minimised the need for deck strengthening. Al of the works were carried out while the bridge remained open to traffic further contributing the overall sustainability of the project.

incumbent on the design engineer to examine the capacity of the existing foundations and to identify what additional capacity can be mobilised. The designer is of course helped here because of the observational data on the performance of the structure over its life to date and this, along with some enhanced site investigation, offers the opportunity for re use of the existing foundations. Even if some small additional capacity is required by means of local strengthening of the foundation, the overall carbon saving will be significant.

A particularly impressive example of how this works and can deliver a very carbon efficient refurbishment is the Huey P Long Bridge in the United States. Here there was a significant increase in the cross section of the bridge with minimal extension to the foundations. This was aided by a detailed investigation into the bearing strata of the bridge and a revaluation of the capacity.

4.5 *Programme and cost*



The design solutions for bridge construction are most usually determined on the basis of cost and time for construction. This becomes even more critical in a design and build project whether contractor is carrying the risk and will seek to develop the most efficient design from a cost perspective. Introducing some measure of carbon efficiency in terms of minimising embedded carbon should be an imperative on all projects. There is of course a fairly direct linkage between reduction in the use of materials and the reduction of embedded carbon. However on large structures the use of offsite fabrication at remote sites where construction costs are considerably lower means that this link between carbon and cost is broken. The construction industry and in particular its government funders is beginning to recognise that the reduction in embedded carbon needs to be a central part of the assessment of net value to society. At present in the United Kingdom, the National Highways, the government agency responsible for all major roads in England and Wales, is reviewing its procurement process is and will be including an assessment of social value which include an assessment of the embedded and operational carbon in all projects. At present it is proposed that 10% of the marks for the proposal assessment will be given to a social value rating which includes sustainability. It is the authors view that this proportion should be significantly increased.

This will greatly assist the fair assessment of refurbishment of existing structures. Refurbishment can be a complex operation and may take longer than, say, building a new bridge alongside the existing and then demolishing the existing. Such a replacement methodology can sometimes result in significant reductions in programme time and may not materially affect the traffic flow during the replacement period. However, it does represent a huge and unjustifiable increase in the overall carbon cost. In order to place a positive value of the reductions in embedded carbon, metrics such as those being considered by the National Highways will encourage the ascension of refurbishment over replacement.

There is a similar issue with encouraging private finance operations of bridge maintenance to also seek carbon reductions in the operation of traffic networks. The two examples described earlier in this paper of Clifton and Rochester show how bridge owners can make significant reductions in the net carbon emissions in the maintenance of bridges. To an extent, where the operator is also the owner of a publicly owned asset, there will be a much greater flexibility to drive down operational carbon emissions. However, many larger bridges are in the care of a dedicated asset manager who will be on a commercial setting where carbon optimisation is unlikely to have been a part of the original contractual set up. As willing as the concessionaire may be to make changes that cost slightly more, it is likely to be on a purely financially based reward system, thus a more nuanced approach will be required and it is likely to require some changes to the reward model for the concession.

Case Study - Huey P Long Bridge, USA

Case Study – Huey P Long Bridge was an existing mixed use bridge carrying road and rail. The demand for increased road traffic drove a major strengthening project which was complete in 2013. The designers reviewed the foundation capacity extensively and were able to determine that they could carry the additional weight of the new decks. Some additional strengthening was required of the piers to support the new decks. As a result, the cost and embedded carbon of the refurbishment was less than half that of a new crossing.

The decks were widened to provide three full size lanes each way with hard shoulders and to remove existing pinch points that seriously impeded traffic on the original road decks.

5 CONCLUSIONS

The construction industry is one of the greatest producers of greenhouse gases and it is incumbent on it to reduce this consumption at every opportunity. It is clear from the numerous examples of successful refurbishment of existing assets that need for greater capacity can be provided by some innovative engineering aided by forward planning at the time of construction. From society's perspective such projects will contribute to trying to achieve the goal of

net zero carbon industry. From the engineer's perspective such projects are uniquely challenging and offer some highly rewarding technical challenges.

The industry has developed some very good tools to assess embedded carbon but most of these are aimed at new construction and considerable work is required to ensure that we can use similar tools to justify the clear benefits of rehabilitation of structures. More work is required to collect information on operating processes and the cost of larger refurbishment projects. The work of client organisations such as the Rochester Bridge Trust is to be commended and encouraged.

It is the author's view, as expressed in this paper, that more needs to be done in the procurement process to ensure that embedded carbon is used as a metric for determining the overall efficiency of a project and as a basis for contract award. At present, most construction projects are effectively selected on a cost basis. A means for giving a much higher weighting to the embedded carbon in the development of options or in the development of tender submissions should be a direct requirement of every project.

ACKNOWLEDGEMENTS

The support of several leading industry specialist in sustainability is acknowledged. Particular support has been provided by Cameron Archer-Jones and Alistair Kean for proof reading this paper and for advising on the latest in current practice on achieving net zero bridges.

Thermo-mechanistic approach for evaluating service life of bridges and structural concrete

K. Maekawa
Yokohama National University, Yokohama, Japan, The University of Tokyo, Tokyo, Japan

T. Ishida
The University of Tokyo, Tokyo, Japan

ABSTRACT: To ensure the preventive maintenance of bridges, it is essential to assess both their current safety status and their remaining service life. To address this engineering challenge, a comprehensive approach that combines expertise in structural mechanics and thermodynamic materials science is proposed. This approach has been verified and validated across various scenarios as: (1) RC bridge decks under the high cycle traffic, (2) Long-term cracking and deflection in PC viaducts and pre-tensioned girders, (3) Remaining capacity of RC beams damaged by fire, (4) Ionic equilibrium and balance linked with steel corrosion, and (5) Remaining performance of rehabilitated bridges affected by significant earthquakes.

1 INTRODUCION

1.1 *Objective*

The assessment of the remaining lifespan of bridges in service is crucial for the effective management of road and highway infrastructures. This includes budget allocation, inspection programs, and technical training for engineers. There are two ways to meet the challenge. One approach involves a statistical analysis based on past records, data, and experiences from bridge inspection and monitoring, as well as the achieved serviceability and safety. Artificial intelligence technology (AI) is considered a promising tool for this purpose. Another method is behavioral simulation, which relies on the fundamentals of science and modeling of materials and structural members. This simulation begins with the current situation known from inspections. The first approach assumes that the future is an extension of the past, necessitating a substantial amount of reliable data. However, obtaining data related to the quality of construction is generally challenging, and the reliability of maintenance data cannot always be verified by AI.

On the other hand, the second approach relies on the soundness of the modeling and the use of appropriate indices to reflect the status. Through this method, we can assess the impact of construction quality, as it influences the current situations of bridges. Thus, the combination of these two approaches is considered to compensate for each other's strengths and weaknesses, and employing multiple methods may enhance overall reliability. Figure 1 illustrates the correlation between the first and second approaches across numerous bridges, including Tokyo Metropolis Highway Line #5 (Furukawa et al. 2019). Generally, the risk score, based on statistical survival analysis with maintenance data from the past 50 years, aligns with the remaining fatigue life of RC bridge decks computationally simulated with the current crack locations in concrete. This allows us to identify bridges that deviate from the correlation line. In the management of a vast amount of infrastructure, this approach can serve as a screening tool to identify problematic bridges that require careful examination and monitoring.

DOI: 10.1201/9781003483755-6

This paper presents the recent application of multi-scale, multi-chemo-physical, and mechanistic modeling of structural concrete to the life assessment of existing bridges in alignment with infrastructure management.

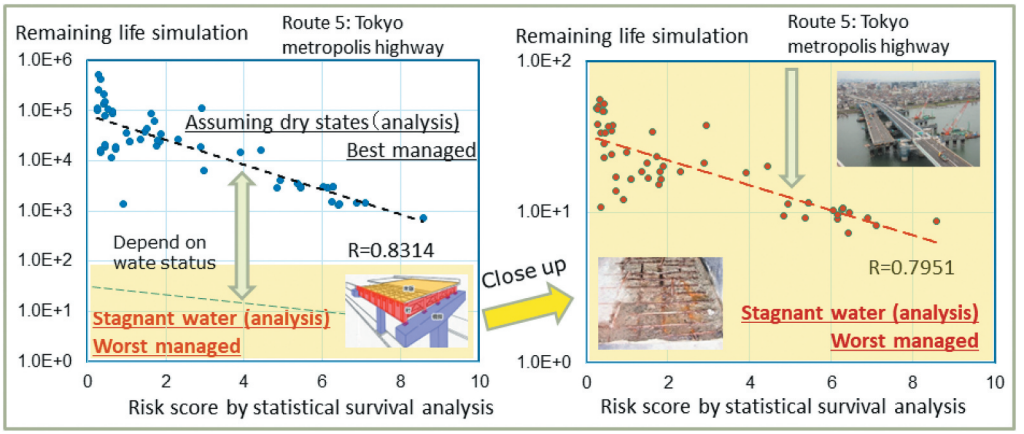

Figure 1. Combined statistical and scientific approaches to assess the remaining life of RC bridge decks in service under an estimated future large vehicle traffics.

1.2 *Electro-chemo-hygral and mechanistic multi-phase platform*

The evaluation of the service life of bridges requires a multifaceted understanding of 1) nonlinear structural mechanics, encompassing cracking and yielding of constituent materials; 2) the varying properties of solids, including erosion and aging; 3) the physical chemistry of substances and their transport and 4) the electric field within water in structural concrete. To address these complexities, referential volumes (REV) of different sizes are employed, each defining specific

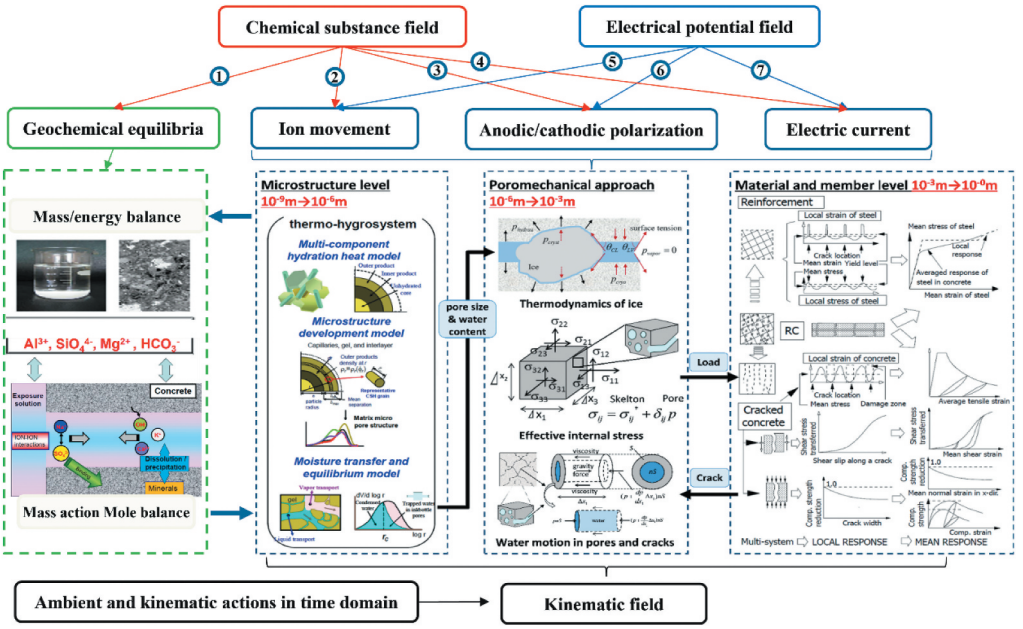

Figure 2. Electro-chemo-hygral and mechanistic multi-phase platform.

aspects of this multidisciplinary knowledge. For systematic utilization, a multi-scale view becomes essential for integration. The authors have developed a platform named *DuCOM-COM3* (dual concrete model) as a "dynamic library" of structural concrete (Maekawa et al. 2004,2008) applicable from the beginning of construction to the end of service life, as shown in Figure 2. Treating concrete cracking is crucial for evaluating the lifespan under ambient and mechanical actions. In reality, multi-directional cracking occurs due to ambient drying and wetting actions, as well as the complexity of applied loads during service, such as daily traffic and earthquakes as accidentals. The authors utilize REV with non-orthogonal multi-directional cracking, originally developed for the seismic analysis of reinforced concrete (RC), as shown in Figure 3.

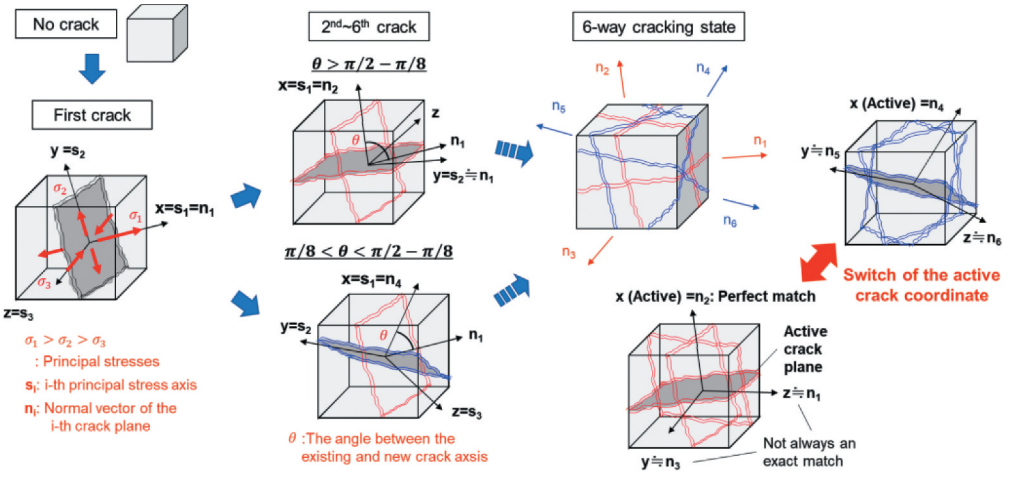

Figure 3. Referential volume of multi-directional cracking where stresses develop, and several substances are kept and in motion.

1.3 *Micro-meso-microscopic multi-scale platform*

As shown in Figure 4, substances related to durability may be contained in crack spaces, the orientations of which are described in Figure 3. These substances may be in motion under their partial pressure gradients. Within the multiphase platform, water with viscosity is present. Notably, the water pressure can rise when a crack rapidly closes, reaching the water in capillary pores. Additionally, alkali-silica reaction (ASR) and corrosion gels originating from aggregates, embedded steel, and reinforcing bars can be present. The crack space serves as a pathway for rapid migration and may influence the pressure, leading to further cracking.

This system has been successfully applied to pressurized gas and frozen ice (Gong et al. 2019) as well. The volume of crack spaces dynamically changes due to external forces, resulting in pressure that can contribute to the deterioration and aging of structural concrete with viods. Therefore, these meso-scale crack spaces play an extremely important role in integrating knowledge of structural mechanisms (macro-scale) and material sciences on the REV of micro-size (Maekawa et al. 2008, Wang et al. 2021 & 2022). The authors employ this meso-scale system for the evaluation of lifetime performance.

2 FATIGUE LIFE ASSESSMENT OF RC BRIDGE DECK

The direct stress-strain-path integral modeling has been commonly employed in the dynamic earthquake analysis of structural concrete, particularly under conditions of high nonlinearity but low cycles. Subsequently, this approach was extended to fatigue behavioral simulation,

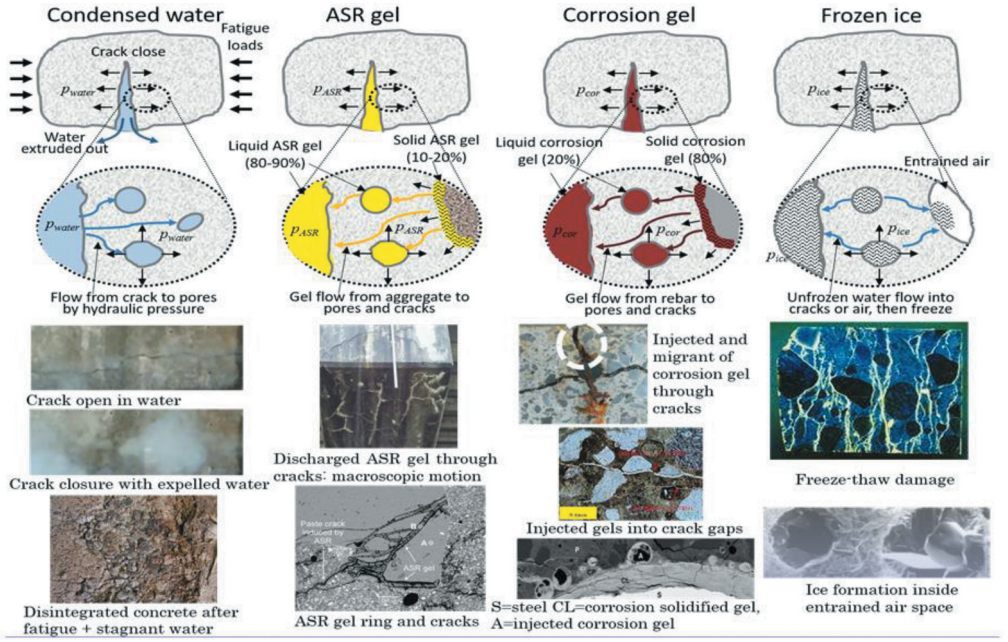

Figure 4. Meso-scale events related to durability and serviceability performance.

focusing on lower nonlinearity but higher cycles of loading, starting around the year of 2000. The extension became feasible through the enhancement of constitutive modeling, considering time-dependency and the accumulation of damages even under small amplitudes of stress and strains (Maekawa et al. 2006). Simultaneously, a high-speed computation algorithm was developed to address the highly cyclic repetition of loads, and successful experimental verification and validation were achieved. In particular, fatigue life simulation was examined using RC bridge deck slabs under moving wheel-type loading (Maeshima et al. 2014), as illustrated in Figure 5. Notably, moving traffic loads significantly deteriorate RC deck slabs due to the larger amplitude of shear along cracks and sections compared to fixed-point loading (Maekawa et al. 2006). This behavioral simulation was further extended to scenarios involving stagnant water (unsuccessful waterproofing) that may be set in motion by rising water pressure. The interaction of water kinetics with porous solids accelerates the damage to structural concrete, leading to a tremendously shortened service life. This mechanism is analogous to the liquefaction of saturated foundations.

This behavioral simulation was conducted using full-scale finite elements of a real bridge in service for about 50 years (see Figure 5), since the fatigue life of the deck slabs is also influenced by the boundary conditions with connected girders (Ishida et al. 2023). As mentioned earlier, the wet condition with stagnant water significantly impacts the fatigue life of slabs under moving loads. Hence, several ambient cases of wet and dry conditions were examined. For validation of the program *DuCOM-COM3*, inspection and monitoring data from the reference bridge were utilized as both ambient and structural boundary conditions, resulting in the evolution of damage, as illustrated in Figure 5. The computed loading cycles leading to deck failure were then converted to a service lifespan of 22 years, while the actual lifespan was 25 years, coinciding with the occurrence of bridge deck deterioration accompanied by graveling.

3 LONG-TERM SERVICEABILITY ASSESSMENT AT NORMAL TIMES

Although no corrosion of reinforcing bars or cracking/erosion by ASR is found, some bridges and viaducts exhibit excessive deflection compared to the design expectations over several decades (Wichukreangkrai et al. 2008). In such cases, it is crucial to assess

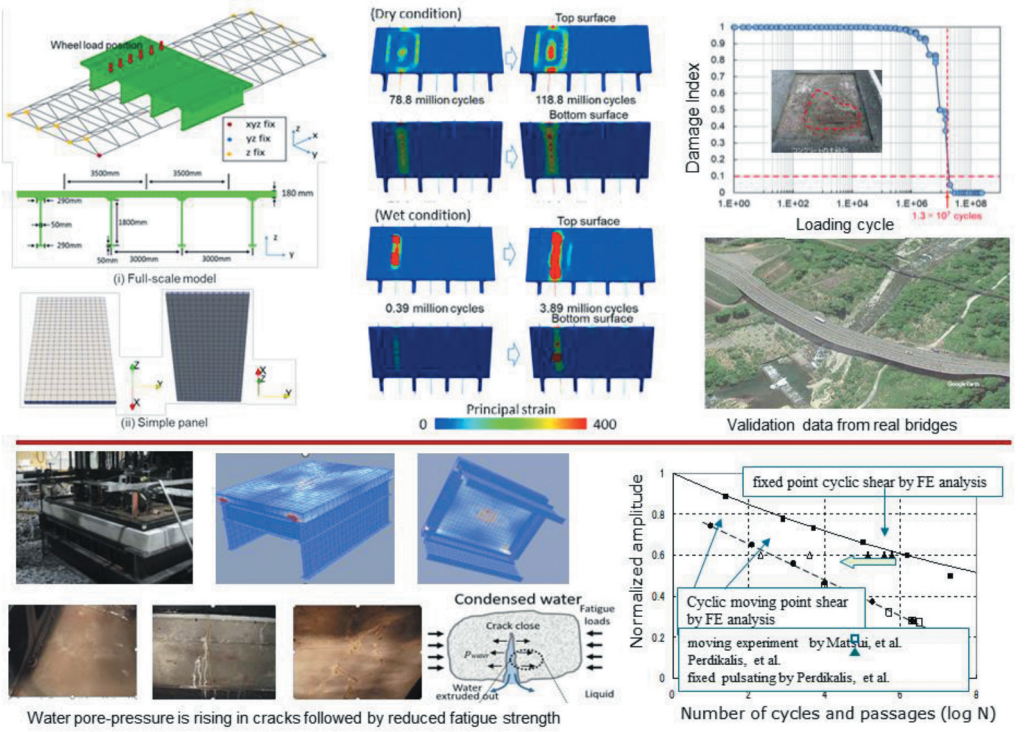

Figure 5. Fatigue life of RC bridge decks with and without stagnant water on the RC slabs.

the current safety level and consider possible future scenarios to prepare for potential risks. The multi-scale, multi-chemo-physics behavioral simulation was applied to long-span prestressed concrete hollow-type viaducts experiencing excessive deflection (Ohno et al. 2012), as shown in Figure 6.

Several years after the completion of these bridges, their deflections generally align with the estimates provided by design formulas. However, real deflections continue to increase and often surpass the initial design estimates. This excessive deflection, without noticeable damages to the concrete, is accurately reproduced in computational models and typically corresponds to the observed reality (Ohno et al. 2012). The substantial deflection over the service life is explained by locally different moisture contents within the structural concrete. The moisture state quickly equilibrates with ambient humidity if the thickness of webs and flanges is small, but it takes a longer time to achieve thermodynamic moisture equilibrium for larger-sized webs and flanges. This difference is closely tied to the size effect on deflection. The multi-scale platform can systematically handle these nonlinearities and provide a comprehensive understanding of future possible scenarios as an integrated knowledge of material sciences and structural mechanics.

We also observe excessive deflection in shorter span PC girders and viaducts, as illustrated in the bottom part of Figure 6 (Yoshino et al. 2023). Vertical gaps exist at the extreme edges of the bridges, between the pavement and the ground, as well as deflection at the span center. In computational models, both displacements at the center and edge are reproduced through the shrinkage of structural concrete. Deflections caused solely by ambient actions without loads and those induced by design loads alone are calculated. It is crucial to note that the deflection resulting from the combined influence of ambient and mechanical actions is greater than the simple summation of those caused by a sole action. This coupling nonlinearity is quite similar to the one of concrete material known as Pickett effect (1942). This is automatically considered without assuming the material parameters for creep and shrinkage.

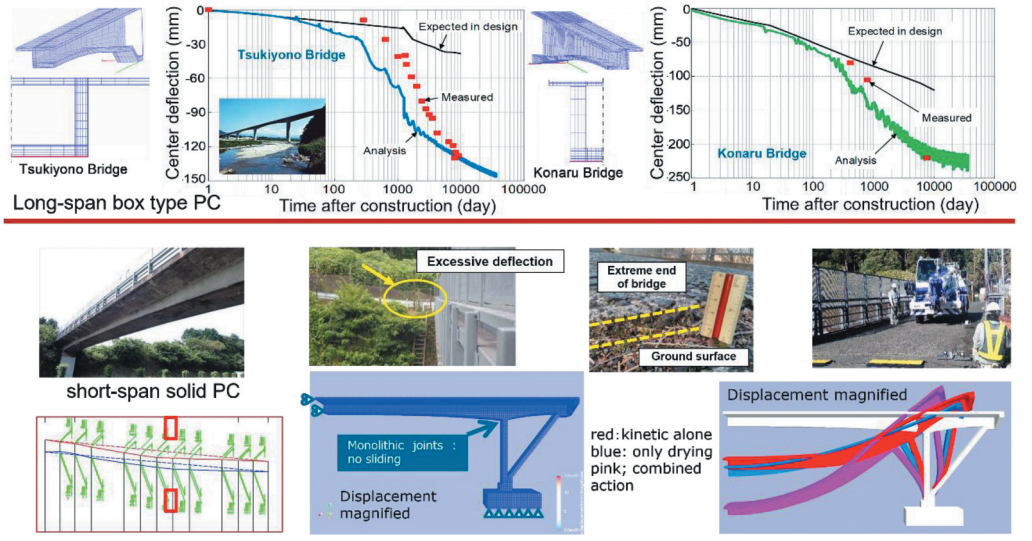

Figure 6. Excessive deflection of long and short span prestressed concrete viaducts.

The behavioral simulation was employed to investigate the cracking of pre-tensioning girders, as illustrated in Figure 7. It has been observed that cracking along the axis of pre-tensioning girders occurs long after production. Various potential causes, such as Alkali-Silica Reaction (ASR) and corrosion, were estimated, but the assessments were qualitative, lacking quantitative conclusions and waiting for the quantitative evaluation in order to evaluate the safety under the estimated scenario. The monitoring of emerging stresses in concrete computations indicates the possibility of cracking with the developed tensile strength of concrete (Tsuchiya et al. 2022). Similar to the case of long-span viaducts, local stresses around the surface of members and those at the core center vary repeatedly. The system records the accumulation of small damages estimated by

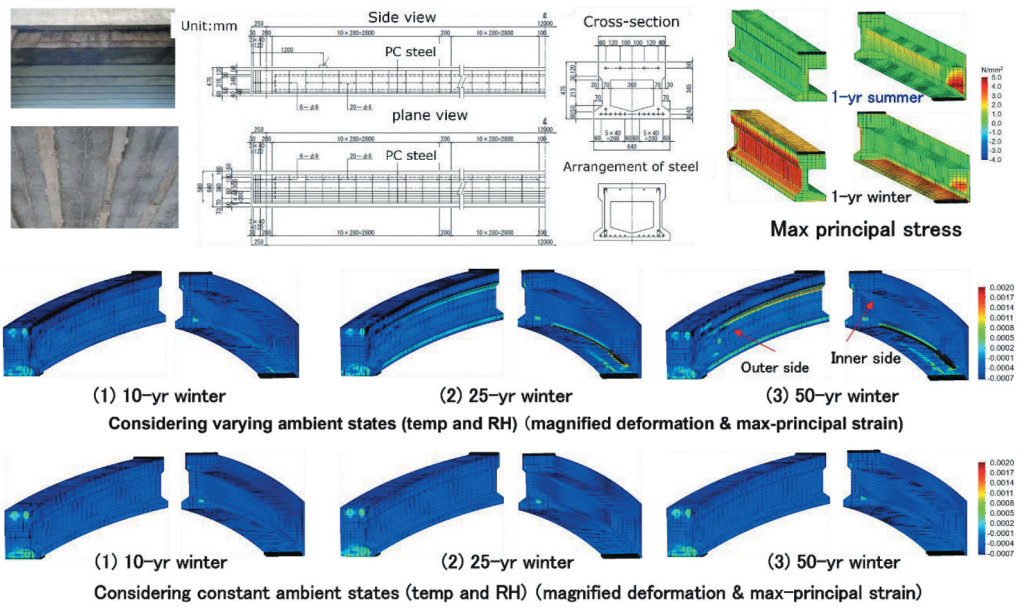

Figure 7. Cracking along the pre-tensioning girders long after construction.

the constitutive modeling (Maekawa et al. 2008). This new finding is reinforced by another trial simulation conducted under constant temperature and relative humidity. Under these fictitious ambient conditions, which do not promote cyclic stress paths, no cracking is reported. It can be inferred that varying ambient conditions are indispensable for long-term performance evaluation. Yearly averaged conditions alone may not capture the intricacies of the system effectively.

4 RESTORATION AND RESILIENCE AS EMERGENCY MANAGEMENT

4.1 *Damaged bridges after earthquake*

As for the crisis management of bridges, quick restoration of bridges and infrastructures damaged by earthquake is critical for resilience. Especially in urban areas, it is generally tough to have new reconstruction. For meeting the challenge at accidental events, we need a technology to trance and follow up collapsing processes beyond the design limit states on structural global safety.

Figure 8 illustrates an instance of damaged bridge abutments in railway infrastructures (Nishimura et al. 2024). This aging structure, designed over 45 years ago, had its seismic performance assessed as inadequate. Unfortunately, a major earthquake struck the abutment before the strengthening work could be carried out. One critical issue was the sinking of the column, leading to an excessive inclination of the rail track, as depicted in Figure 8. In fact, a significantly high compressive force was applied to the problematic column. To estimate the lift-up forces using hydraulic jacks and to examine the restored structure, it is imperative to computationally recreate the damage scenarios. This analytical aspect distinguishes the process from new construction, focusing solely on checking the limit states.

Figure 8 presents the actual lift-up force and its corresponding computational representation. At the onset of the lift-up operations, a notable stiffness was encountered and accurately replicated in the computation, despite the structural members already being damaged. It is crucial to note that even in the presence of pre-existing damage, structural members can still exhibit substantial tangential stiffness when the loading direction abruptly changes. This phenomenon is akin to pre-stressed cable trusses, where tensioned wires display high compressive tangential stiffness. The restoring force can be reasonably assessed to elevate the slabs to their original position. This assessment is critical to estimate how many jacks are needed for quick recovery. At the same time, some cracking and partial yielding may potentially occur. Thus, the evaluation of safety performance and serviceability after the crisis loads must consider the entire process of collapse beyond ultimate limit states and restoration.

Behavioral simulation of collapsing processes must account for extreme scenarios occurring at the meso-scale volume, where the cementing system linking sand and gravel particles is lost, as depicted in Figure 9. This situation cannot be accurately represented by reinforced concrete constitutive modeling, regardless of how many cracks are considered. Specifically, the strong anisotropy of cracked concrete is diminished to an isotropic granular assembly, wherein confinement critically keeps the remaining volumetric stiffness as well. In addressing this, we have applied the RC-graveling transition model (Yamanoi et al. 2020), which has been developed and successfully employed in the fatigue life evaluation of bridge slabs experiencing graveling in the presence of water (Maekawa et al. 2006). It is noteworthy that the shear resistance of graveling surpasses that of reinforced concrete under higher confinement. For bridge maintenance technology, confined disciplines may not exert a strong driving force.

4.2 *Damaged bridge after fire*

Road and railway bridges annually face fire incidents resulting from traffic accidents. In response, bridge managers must promptly formulate a restoration plan to facilitate the swift reopening of traffic. For both current and future evaluations of the performance of fire-damaged structural concrete, it is essential to consistently consider both microscopic and macroscopic events.

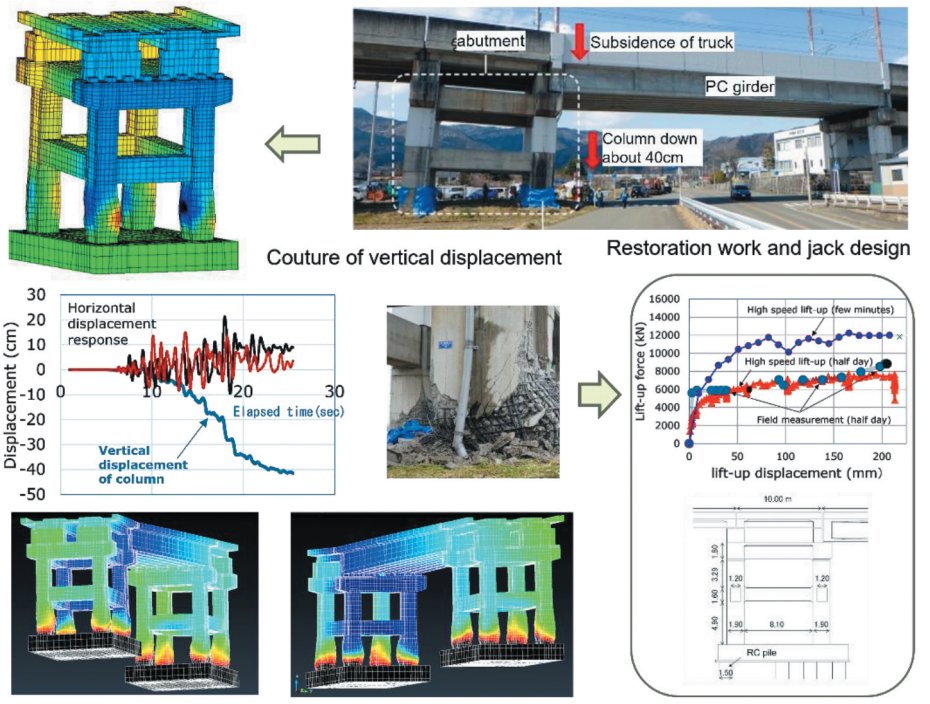

Figure 8. Restoration of railway bridges and abutments after great earthquake.

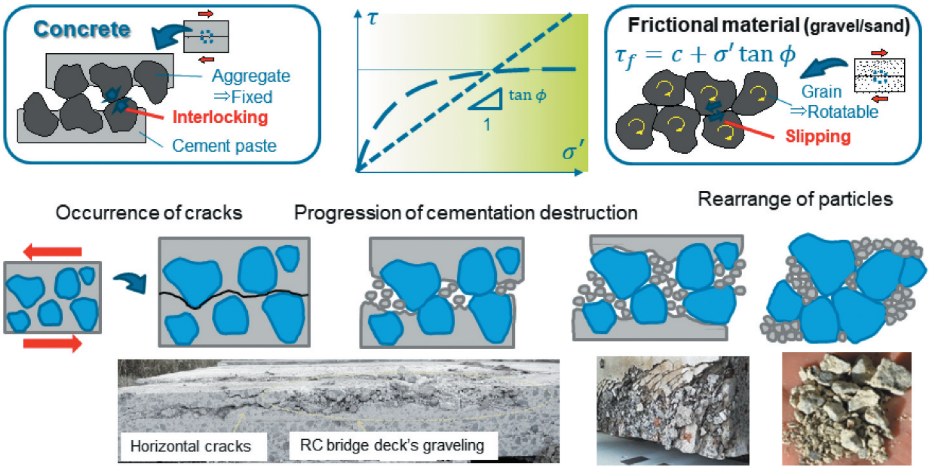

Figure 9. Graveling of concrete under large shear and erosion.

High temperatures can deteriorate crystallized solids, leading to changes in the micro-pore spaces lined with meso-scale mechanisms within the concrete composite. The elevated temperature can cause the release of chemically combined water in a gaseous phase, resulting in a rise in pore pressure. This phenomenon may occasionally lead to spalling of the surface concrete, followed by a deterioration in the axial capacity at the macro-scale.

Even after micro and macro-scale deterioration, a self-healing mechanism persists, wherein moisture and carbon dioxide in the air act as substances to fill up the void spaces, as illustrated in Figure 10. The recovery of the macroscopic performances and its scenario are welcome

especially for long-term performances even after fire accidents. Therefore, a multi-phase and multi-chemo-physics approach is deemed most suitable for this case (Iwama et al. 2020).

Figure 10 summarizes the chemical processes of non-organic substances with water and carbon dioxide under high-temperature conditions during a fire. Special attention is given to spalling in high-strength concrete concerning the risk assessment of macroscopic structural events. High-strength concrete, having fewer micro-pore spaces and lower permeability, can lead to vapor pressure confined inside the concrete. If this pressure exceeds the tensile strength, explosive spalling may occur. The interconnected events, evolving across varying sizes, are illustrated in Figure 1.

Figure 10 illustrates post-fired reinforced concrete beams in flexure and shear, clearly estimating the change in failure mode (Iwama et al. 2020). Fire action results in a loss of member capacity but an increase in ductility with higher fracture energy. In both reality and digital simulation, numerous smaller cracks near the surface of members are generated, interlinked with each other. Subsequently, discrete crack propagation is halted by the dispersed multi-directional cracking formed beforehand by fire. As a result, macroscopic performances are enhanced in terms of overall fracture energy.

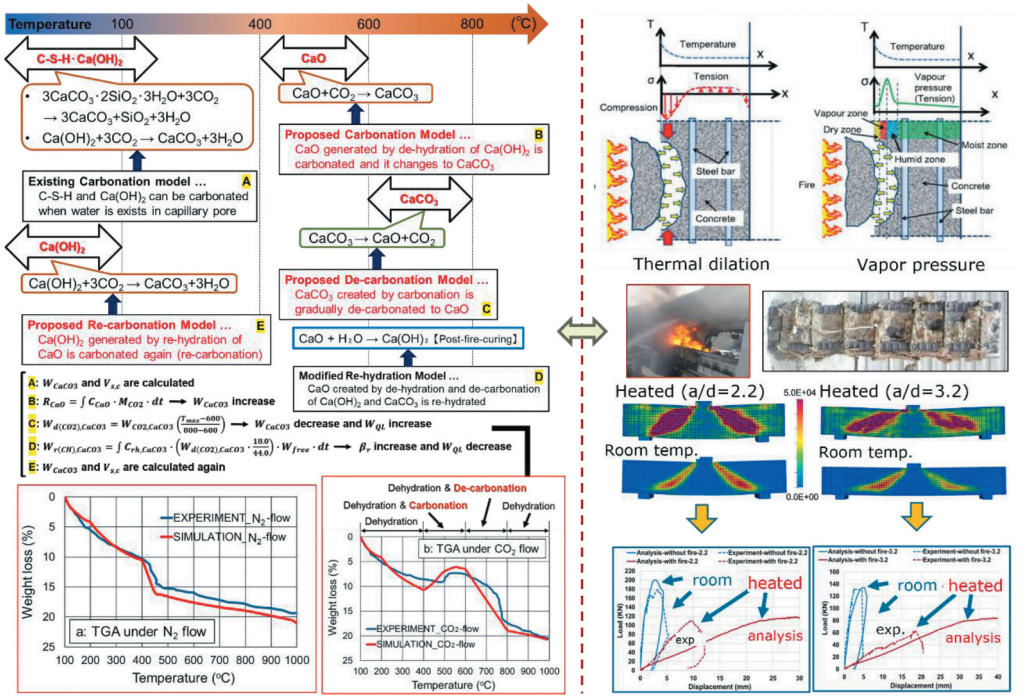

Figure 10. Micro and macroscopic modeling interlinked at high temperature of fire accident.

4.3 *Precast construction and joints*

The precast system facilitates both swift construction under normal circumstances and rapid restoration during emergencies, contributing to resilience. Figure 11 illustrates the reuse of existing structural members for newly constructed ones immediately following the 2011 earthquake in Tohoku, Japan. The intact members were severed from damaged bridges and transported to the new site to expedite transportation recovery. The overall bridges, comprising both old and new members, underwent examination in terms of the seismic performance and serviceability. Additionally, the precast system is currently underway for newly designed and constructed bridges as shown in Figure 11. The technical intricacies of precast systems stem from the evaluation of mechanical joint behaviors and their modeling within a computational framework. Figure 12 illustrates an example of RC joint through which reinforcing bars penetrate (Zewdie et al. 2022).

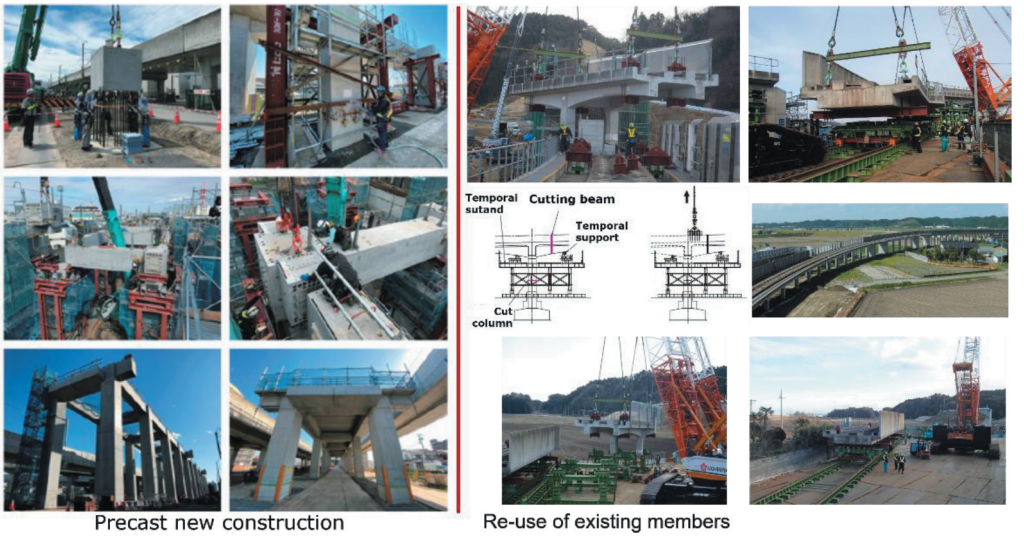

Figure 11. Precast construction: reuse of members after disaster.

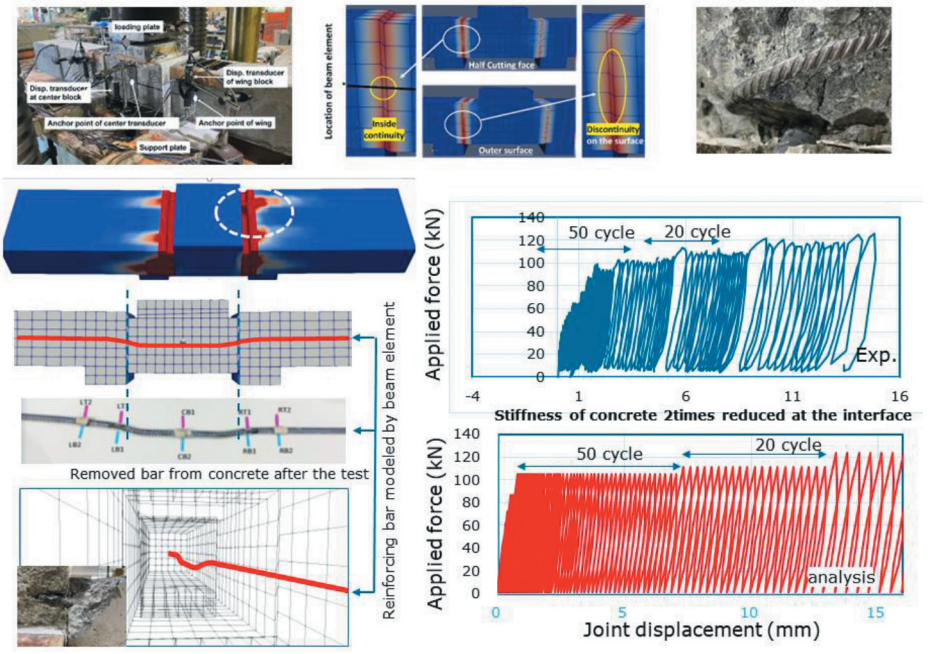

Figure 12. RC Joint kinetics along joint planes and the impact to surrounding structural members.

Joint dynamics have been represented by interface elements in FEM and placed at the junction planes of different members since 1980s. Generally, it fairly works if a pair of connected members are massive and/or well reinforced around the connection devices. In more general cases such as small concrete cover and lower confinement around the highly stressed areas, joint elements with finite volume becomes available with no reduced deformational field as shown in Figure 12. Especially, so called bond cracking along reinforcing bars can be reproduced in computation where the 3D stress field is reproduced by bearing force from the bent portion of reinforcing bars.

5 CORROSION RELATED MANAGEMENT

5.1 *Safety performance assessment of corroded members*

The upper part of Figure 13 displays the finite elements for RC with rebar corrosion. In this configuration, straight tensile rebars without end-hooks and with full anchorage of 90° hooks were positioned (Han et al. 2020 & 2022). Mass loss data from an accelerated corrosion test were utilized for validation (Maekawa et al. 2008). The load was applied at the midspan of the beam, considering uniform corrosion along reinforcing bars and incorporating a three-times volumetric expansion for corrosion products. A comparison between the tests and analyses is presented (Furukawa et al. 2019). As corrosion increases, stiffness and shear strength decrease due to splitting crack, accurately simulated. The FE model also captures the behavior of the corroded (NH) specimens, revealing an increased shear strength compared to no corrosion case. Beyond a corrosion degree of 3%, stiffness and shear strength gradually decrease, consistent with the prediction. The analysis highlights the formation of a diagonal compressive strut like arch similar to the past experiences.

The long-term shear behavior of RC members under sustained loads was examined. Since the impact of reinforcing bar corrosion is highly time-dependent, realistic timescales of the natural environment is applied. The bottom part of Figure 13 illustrates the model used for the long-term analysis, with a specific focus on the shear span-to-depth ratio. Three different current densities (15, 75, and 150 μA/cm^2) were considered for the corrosion simulations. The critical sustained load level causing delayed shear failure decreases as the shear span-to-depth ratio increases. Diagonal shear cracks are observed to initiate from flexural cracks. It is important to note that gradual corrosion does not lead to delayed shear failure. The critical time and corrosion degree at which shear failure takes place decreases with faster corrosion rates. Additionally, shear span-to-depth ratio amplifies the detrimental effects of corrosion on the long-term actions.

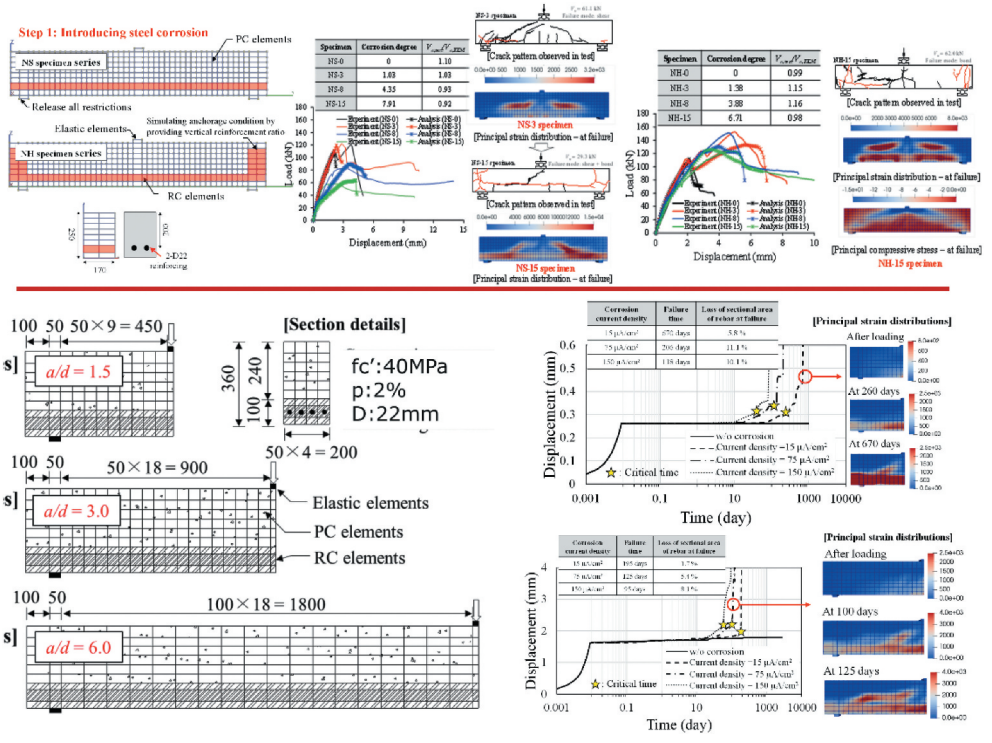

Figure 13. Corrosion impact to RC shear capacity under short and long-term loading.

5.2 *Electro-ionic kinetics for corrosion risk assessment*

Steel corrosion not only brings about varying macroscopic performances of structural concrete but also alters the ionic concentration in micro-pores and their equilibrium with solids of cement hydrates because steel corrosion is an electrochemical reaction. To assess long-term corrosion in conjunction with dynamic ionic equilibrium, the electric potential field must be integrated with the framework, as illustrated in Figure 2 and Figure 14 (Wang et al. 2022 & 2023). Here, the Nernst-Plank equations and polarization modeling for cathodic and anodic reactions are concurrently solved alongside the governing equation of solid mechanics. Consequently, reinforcing bars are conceptualized as smeared within the referential volume, enabling consistent utilization of smeared crack modeling.

With this scheme, ionic motions can be estimated and equilibrated minerals of cement hydrates are explicitly obtained. Figure 14 indicates dynamically varying ionic concentration of calcium accompanying the corrosion of reinforcing bars in tandem. At the anodic pole, much calcium ion is supplied by dissolution of portlandite which may cause erosion of concrete composites under CO_2 environment. This situation is produced when we apply the cathodic protection. Thus, the entire fields with mutual interaction will be the basis of long-term performance evaluation.

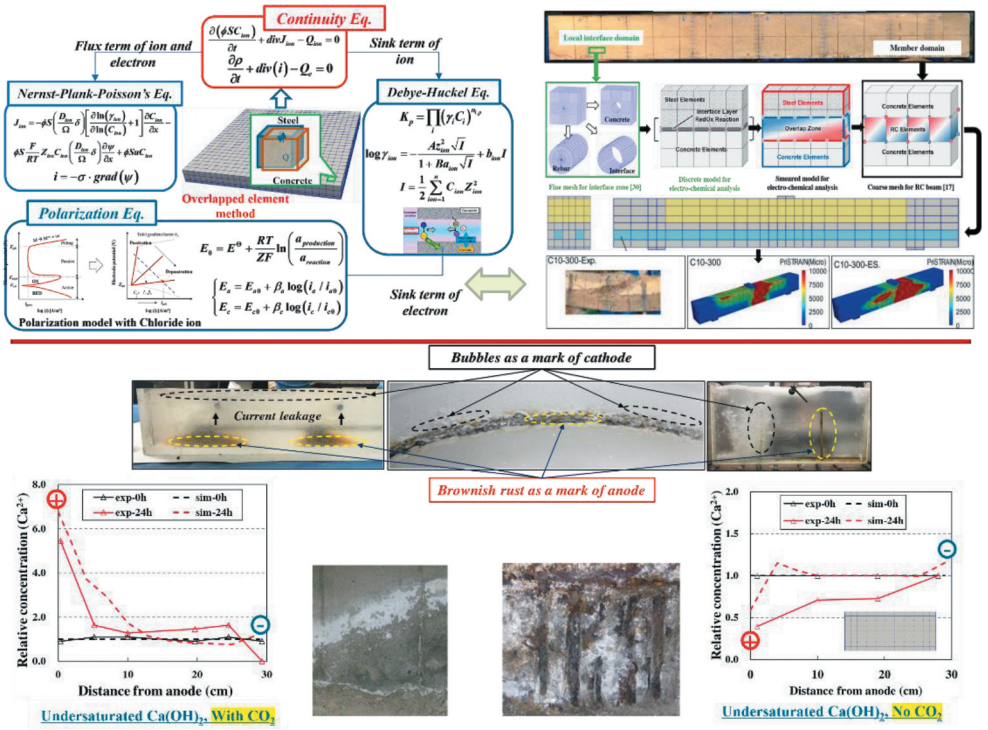

Figure 14. Electric potential field linked with chemo-physical and mechanical events in multi-scale referential volumes.

6 CONCLUSION

Chemo-physical and mechanical modeling on a multi-scale referential volume is presented for the evaluation of remaining lifespan of bridges within the framework of performance-based design and maintenance. Recent applications of the integrated system to the performance assessment of brides in service was presented for verification and validation. The risk of failure and modes of deformation of structural concrete are reasonably evaluated, but the integration of electric fields with thermodynamics of solids and multi-ions is just beginning. Upgrading

reliability is required and applicability ranges must be clarified. Thus, behavioral monitoring and inspection are indispensable. In other words, presented multi-scale modeling may serve engineers as a guide to seek for more appropriate parameters. Coupled deep experiences, practice and solid scientific knowledges are crucial for further progress.

From empirical and subjective O&M to statistical and objective asset management

S.C. Nørager
Danish Road Directorate, Copenhagen, Denmark

ABSTRACT: This paper delves into the Danish Road Directorate's (DRD) vision for a modernised asset management model. DRD manages the Danish national road network comprising 3800 km of road and 2400 structures and has over the past 40 years developed well-defined asset management process and solutions. Due to the technical debt in its IT-infrastructure, DRD is currently implementing new software solutions which have opened up for the development of a new asset management model. DRD's vision for the new asset management emphasises uniformity across assets and introduces functions like cross-asset optimisation and assessment of sub-optimum strategies. A governance framework ensures data quality and performance benchmarks, while automation plays a pivotal role in objective condition assessments and data collection. The implications of the new model on bridge assets are explored, with an evolving role for bridge engineers and the potential for enhanced understanding of asset behaviour through artificial intelligence (AI).

1 INTRODUCTION

Asset management plays a crucial role in maintaining infrastructure integrity and optimising resource allocation. For the Danish Road Directorate (DRD), this practice has evolved over the past 40 years, influenced by asset importance, characteristics, and the organisation's varying levels of expertise. DRD was established in 1949 to develop and manage the Danish national road network, which today consists of approximately 3800 km of road and approximately 2400 structures. The national road network represents only 5% of the entire road network in Denmark but caters for over half of the traffic. DRD manages directly the network and procures the contracting services required to carry out the different O&M activities.

In response to an aging IT-setup that requires an overhaul, DRD envisions a transformation in its practices. This paper delves into DRD's vision for a new asset management model, driven by the integration of digital solutions to enhance transparency, automation, and cost optimisation. The paper also explores the implications of this transition on bridge assets, emphasising the shift from subjective assessments to automated, data-driven condition evaluations and the promising role of artificial intelligence (AI) in revolutionising data collection and analysis.

2 DRD'S CURRENT PRACTICE OF ASSET MANAGEMENT

2.1 *General practice across assets*

DRD has 25 no. assets subdivided into approximately 105 no. elements managed in 21 different IT-system that cover activities like data collection, data registers, condition assessments, cost optimisation, job procurement, job management and financial control. The management of different assets has over time been developed into different models with different levels of

DOI: 10.1201/9781003483755-7

sophistication, partly reflecting the importance or value of the different asset classes (for example pavement and structures vs. street lighting), partly reflecting the idiosyncratic properties of different assets, and partly reflecting the different levels of knowledge within the company.

Using the terminology provided in Federal Highways handbook on management of ancillary (FHWA, 2019), adopted O&M strategies can be defined as 'condition-based', 'interval-based' and 'reactive'. Condition-based O&M is a proactive approach to asset management that includes predictive maintenance and continuous monitoring. Interval-based O&M follows a set schedule of activities, regardless of the asset's current condition. Reactive O&M is a strategy applied when asset failure doesn't severely impact its operation or when effective monitoring methods are lacking; it involves repairing assets after they fail and is commonly used when monitoring methods are ineffective or when there are no clear deterioration patterns.

DRD's pavements and structures are based on condition-based strategies (except winter road maintenance, which is a considerably different process and is not covered by this paper). The drainage system is a mix of different O&M strategies: Visible drainage infrastructure is condition-based, however interval-based cleaning and flushing of the entire drainage network is carried out to ensure function, and buried drainage infrastructure is reactive-based, as collecting routine condition data for these assets has proven to be prohibitive. ITS systems are interval-based, and most ancillary structures are reactive.

DRD's asset management process involves several key steps. Firstly, the responsible engineer gathers the necessary condition data for a specific asset. Subsequently, the engineer conducts a needs assessment, outlining the required O&M activity, associated costs, and scheduling considerations while striving to minimise the costs and to minimise the disruptions to road users.

The needs assessments for all assets are then consolidated by the O&M manager, who oversees the cross-asset coordination. This pivotal role involves two critical responsibilities: (1) Informing decision makers of the funding requirements and (2) prioritise O&M activities for the upcoming year based on the allocated budget approved by decision makers, thus finalising the production plan. As it takes one year to compile and agree the Danish national finance act (it is normally approved in parliament in November/December for the year starting in January), the funding requirements reported to decision makers is for two years ahead. The quality and precision of the forecasted funding requirements are therefore important for DRD. In addition, the prioritisation task by the O&M manager is to reconcile the needs and the allocated budget, as these may well have changed compared to the submitted funding requirements.

Finally, the responsible engineer executes the production plan, while the O&M manager oversees progress and financial aspects throughout the plan's implementation.

2.2 *Current practice for bridges*

DRD's current practice for bridges is documented in well-established project models and manuals published under the Danish Road Standards (Vejregler, 2018).

Bridge inspections are carried out at three levels of detail: Routine, principal and special inspections. Routine inspections are conducted regularly to ensure road safety and plan operation activities. The frequency of routine inspections depends on factors such as the nature, age, and condition of the structures, as well as traffic intensity and composition. They are also conducted in response to special events that might impact the infrastructure's integrity.

Principal inspections are carried out at regular intervals of up to 6 years to provide a comprehensive assessment of the structure's condition. These inspections involve a thorough examination of all structural elements and help determine the condition levels of individual components. They are crucial for identifying safety defects and prioritising major maintenance work.

Special inspections aim to provide more precise information than principal inspections, especially for prioritising significant repair work and ensuring safety compliance. These inspections are typically initiated based on findings from routine or principal inspections.

From the principal and special inspection a condition grade is assigned to structural elements and the overall structure based on damage, functionality, and impact assessments. The total condition grade ranges from 0 to 5, which can be summarised as:

Grade 0: No significant damage, similar to a newly constructed element.
Grade 1: Minor signs of degradation, repairs not needed, similar to a new element.
Grade 2: Minor damage or lower-level development, occasional improvement required.
Grade 3: Damage advanced, risk of lost function, remedial action needed within a few years.
Grade 4: Severe degradation, function close to termination, immediate remedial action required.
Grade 5: Complete degradation, immediate action essential.

If the condition is 0 to 3, there are automatic rules how to determine expected maintenance work and when they must be planned for based on standard life-time expectancies. If the condition is "3 with worsening development" to 5, the bridge engineer is responsible to determine the required maintenance works based on the condition assessment carried out and price it, plus activate a special inspection.

Based on the special inspection, the bridge engineer shall confirm the required maintenance work, the pricing and determine the optimum time to carry it out. This is done by estimating degradation curves and determining the point in time, where postponing the maintenance project by another year will increase the cost by over 4% above normal indexation. The 4% is set as a financial threshold which describes that an investment would be wiser somewhere else in society. The bridge engineer shall also consider possibilities to bundle maintenance works to reduce secondary costs such as contract mobilisation and traffic diversion. The maintenance works for the coming 12 years are then reported to the O&M manager in the needs assessment for the bridges. The process then follows the same general procedure.

2.3 *Strengths and weaknesses of current practices*

DRD's existing asset management practices have been thoroughly tested and have provided decision makers with clear guidance, ensuring a reliable road network for road users. These practices align with the current capabilities of the market.

However, many of DRD's in-house asset management software systems are reaching a point of technical debt, making it impossible to maintain them effectively. Consequently, DRD has procured a new asset management software that is currently in the implementation phase. The process of adopting this new software has presented DRD with opportunities to identify significant improvements to the current asset management model due to advancements in data collection, data storage capacity, and computational capabilities.

The current practices, in particular for bridges, rely heavily on subjective assessments, evaluations, and designs carried out by the engineers. While dependable, this reliance on subjective judgment results in higher deviations in outcomes. The evolving landscape of data computation opens the door to substantial enhancements in this regard, enabling more automated, data-driven, and objective decision-making, ultimately leading to improved maintenance strategies.

In the current practice for bridges, a substantial portion of condition data is stored in stagnant file formats, such as PDFs, with only key results transferred to the existing IT-systems. This approach, while adequate for planning necessary maintenance work, poses a significant barrier to analysing past performance and correlations to external factors. However, with the increased data capacity and text recognition technologies, it is now possible to extract, store, and analyse information, providing more objective insights into asset performance and more accurate estimations.

Another challenge is the reliance on different IT solutions across various assets, resulting in time-consuming data transfer, information compilation, and missed opportunities for cross-asset optimisation. This situation is particularly cumbersome for the O&M manager, who collects needs assessments from all assets. The current setup lacks flexibility, as it doesn't allow for a comprehensive evaluation of different scenarios when prioritising projects based on

condition assessments. Revising the system landscape will enable better support for this iterative process.

Furthermore, the use of different IT solutions for different assets limits opportunities for optimisation, such as reducing secondary costs, which are currently addressed on a per-asset basis. This prevents DRD from fully capitalising on the potential for optimisation across different asset categories.

Considering that assets have varying performance requirements and degradation curves, cross-asset optimisation has, until now, relied on manual intervention and subjective evaluations by the O&M manager. However, the evolution of data computation presents the opportunity for significant improvement, allowing for more automated, data-driven, and objective decision-making across asset classes.

In addition, given the technical debt associated with current IT solutions, accommodating technological advancements in data collection and computation is currently challenging.

3 DRD'S VISION FOR THE NEW ASSET MANAGEMENT MODEL

3.1 *The new asset management model*

DRD's ambition is to leverage the development of digital solutions into providing a more transparent and clearer decision-making process, which is more automated and better geared towards optimising costs. The ultimate goal is to be able to do cross-asset cost optimisation.

The functions of the cross-asset model can be defined as:

- Data collection
- Condition assessment
- Identification of O&M activities
- Cross-asset optimisation
- Assessment of sub-optimal strategies

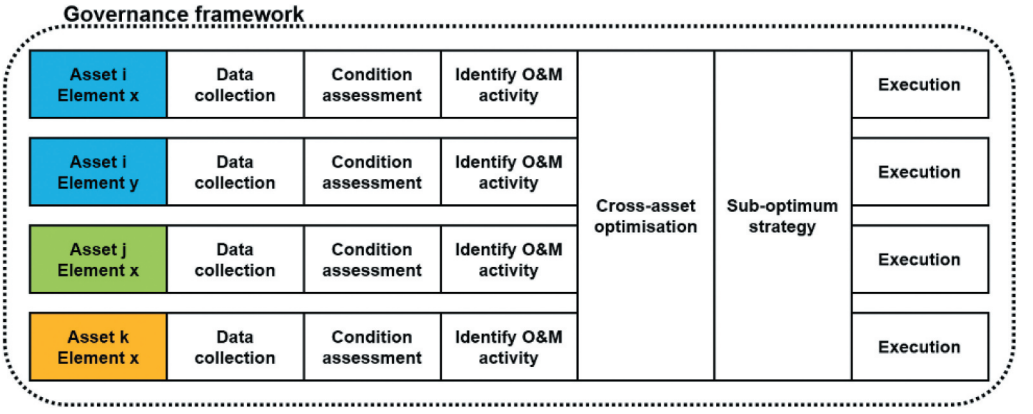

Figure 1. Overview of new asset management governance and functions.

To facilitate the cross-asset optimisation, it is imperative that uniform processes and assumptions underpin all assets. Consequently, a governance framework for the asset management model is being established, with the aim of providing precise guidance and coordination. This governance framework will define the model's structure, processes and essential constraints. For instance, the model will run at elemental level, which represents the primary asset subdivision. A standard bridge in DRD is defined in 15 elements, whereas streetlight could be divided into two elements: The post and the luminaire. Another example is the requirement that conditions on all elements must adhere to a uniform 1 to 5 scale, ensuring consistent and comparable reporting.

The governance framework delineates well-defined performance and service benchmarks for each element. It also establishes a clear and agreed hierarchy for these benchmarks in cases where budget constraints are encountered to ensure that elements that are required for uninterrupted traffic flow take precedence. The prioritisation process must take into account the traffic volumes to prevent a scenario where a bridge deck in a remote area is favoured over the pavement of a key motorway section. Different prioritisation models are under review.

Data is the core to the model and data quality is paramount when aiming at a high degree of automation. Data governance is therefore a key part of the governance framework. The data governance thoroughly defines the data type, data architecture, data ownership and what data sources shall be used. The utilisation of a single software solution to support the entire model is not envisaged. Instead, a modular approach within the IT landscape is advocated and in the process of being implemented. This approach allows for the flexibility to select the most suitable IT solution for each asset and provides the capacity to replace modules when more advanced solutions become available. For instance, the equipment and software employed for various data collection purposes may significantly differ among different assets.

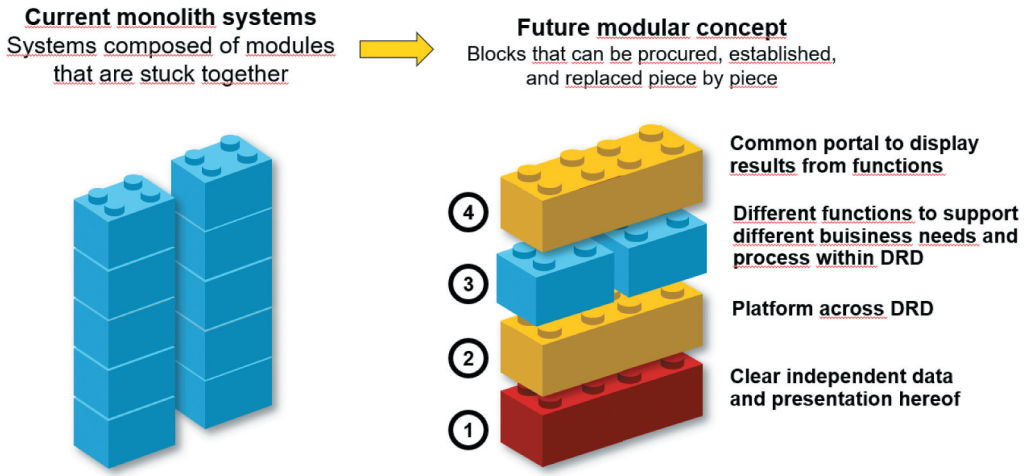

Figure 2. A modular IT-solution for the new asset management model.

The functions of data collection, condition assessment and identification of appropriate O&M activities based on defined maintenance strategies will in a broad sense stay same as current practice. The principal development introduced by the new model pertains to the automation of cross-asset optimisation and the ability to subsequently evaluate a sub-optimal strategy for a given financial constraint.

Cross-asset optimisation is designed to minimise costs by bundling O&M activities for various elements. For instance, it may involve anticipating the replacement of a waterproofing and wearing course on a bridge to coincide with the maintenance of an adjacent pavement section, thereby reducing the costs associated with mobilisation and traffic management. However, this economic advantage must be evaluated against the loss incurred by not fully utilising the lifespan of the bridge's waterproofing and wearing course. It's important to note that cross-asset optimisation operates without financial constraints and aims to establish the most favourable investment plan to achieve the agreed performance and service benchmarks. This fundamentally constitutes the needs assessment.

Sub-optimum strategy is carried out when allocated budgets differ from the needs. In this instance, the model will reverse the cross-asset optimisation and identify the preferred sub-optimal solution that ensures minimum monetary loss taking into account the prioritisation between asset elements (refer to description of performance/service levels). The loss is calculated as the loss from maintenance not being performed at the right time leading to increased

maintenance costs later; or the loss because maintenance is carried out too early resulting in the loss of the remaining lifespan of an asset. Basically, the loss will be the difference between the costs calculated under the sub-optimum strategy and the cross-asset optimisation. This will indicate the decision makers what the costs are for not meeting the needs, or in other words, what it costs to borrow in your assets when directing funds elsewhere.

It is obvious the model will only converge to results within certain boundaries. A scenario where a continuous major lack of funding takes place will not meet performance/service levels set. Asset owners that operate under these conditions, should consider a cross-asset optimisation model that maximises the benefits per euro spent. DRD's current pavement management system is an example for this latter type: The model runs an iterative process to find the best combination of maintenance strategies and pavement section that maximises the gains on 'road capital' given a certain budget (road capital is an effort to describe the financial value the pavement based on current costs and depreciation).

It is not expected that all assets will be able to enter the full model for different reasons. For instance, a maintenance building with no geographical relationship with the road network gains no benefit by having the O&M activities bundled with the rest of the network. Another example is that the cost of collecting data on individual signage may be too expensive to justify compared to a interval-based maintenance strategy that simply looks at replacing all signs along a 20km stretch. This however may well change with time, as data collection and condition assessment can be automated to an extent that costs are slashed and a condition-based approach, where only signs that do not meet performance requirements are replaced, is implemented. To ensure the flexibility that assets can change strategies and fall in and out of different functions of the model, it's imperative that all assets follow the overall governance framework.

The new asset management model shall also provide better overview of all the costs that go into the O&M, not only the execution of O&M activities. Risk allocation to cater for unexpected activities will be predicted based on past performance and the condition of the assets. In addition, a clear indication of the costs involved in data collection, engineering and overheads will allow a continuous evaluation of O&M strategies and opportunities.

3.2 *The resulting implications for bridge assets*

The new asset management model will necessitate adjustments to existing bridge-related practices. As an illustration, the role of the bridge engineer will evolve to encompass solely conducting investigations, condition assessments, and confirmation of maintenance strategies per element. However, the consolidation of activities will be automated, streamlining processes. The changes required for entering the new asset management model are modest.

Current technological development, however, will have a more profound change to the way we manage bridge assets: Data collection, data storage and data computation combined will allow a fundamental shift from subjective assessments by the bridge engineer to automated and objective condition assessment. It's imperative that the new model is futureproofed to accommodate these technological developments.

As mentioned previously, increased data storage and text recognition, allow the extraction of information from historic inspections and allow a better objective understanding of the behaviour of the assets. It will improve the investigation into the correlation between degradation of elements and external factors such as traffic, temperature, rainfall, salting and more. This in turn will result in an enhanced understanding of the performance of different solutions and allow for better future planning against increasing traffic volumes and changing weather patterns.

The significant advancements in data computation through AI are poised to revolutionise current practices. Currently, the assessment of conditions and the definition of O&M activities heavily depend on subjective evaluations of bridge engineers, given the inherent uniqueness of each structure. AI will transform these processes, automating them and yielding a substantial advantage in terms of objectivity and accuracy. Noteworthy research in this domain includes studies conducted by the university of Hartford (Fang et al., 2024) where deep neural networks are employed to predict bridge condition ratings.

AI will also play a crucial role for data collection. Recent years have witnessed significant advancements in various data collection methods, such as drones, photogrammetry, remote sensing, and structural health monitoring. However, incorporating this data into asset management models has posed challenges. DRD have over the past years run a series of different inspections with unmanned aerial vehicles (UAV) to follow the maturity of the technology and the related services. Although it represents substantial improvement on health and safety, and software capabilities to detect damages have improved drastically and have become more consistent, it still requires an engineer to review and interpret the inspection result to provide a condition rating and provide a needs assessment. As it is now, there is limited gains both on finances or time to roll out unmanned inspections on large scale. This difficulty is in part also attributed to the substantial investments required for model adjustments to accommodate new datasets. AI, on the other hand, has enormous potential to makes this type of inspection viable, but more importantly, will enhance the flexibility in the asset management model to introduce new datasets while phasing out old data acquisition methods. This will facilitate seamless transitions between different data acquisition approaches. Nevertheless, it is worth noting that a seamless transition will still necessitate a temporary coexistence of old and new data collection methods, which will lead to an increase in data collection costs over a period. An asset owner shall therefore carefully consider when new data collection methods are introduced.

Innovations in building and bridge engineering associated with circular economy

L.M. Ottosen
DTU Sustain, Section for Construction Materials and Durability, Technical University of Denmark, Lyngby, Denmark

ABSTRACT: Circular economy is the central strategy in the EU chosen to decrease today's overconsumption of raw materials extracted from nature. Due to the vast amounts of raw materials used in the building and construction sector, it is pointed out as a key sector. At the end of life of structures, reuse of whole components is rated over recovery of materials for production of new components. The cases found in literature that relate bridge engineering and reuse are limited to a case on reuse of cut out concrete blocks in a pedestrian bridge. Related to buildings, there is more literature on reuse (though less than 100), so reuse is still very far from being mainstream. Learnings from reuse of the structural elements in buildings could inspire reuse in relation to bridges, however, there are no cases of reuse to the full strength potential. The barriers towards implementation of circular principles are several and can are categorized as: economic, sociological, political, organizational, technological, and environmental. The potential risks associated with structural safety when reusing elements need to be overcome by the development of methodologies for strength estimations and durability assessments.

1 INTRODUCTION

Our industrialized society is built on a linear use of resources. Mining activities from nature have supplied us with raw materials enabling us to develop the society we know today. Many resources are non-renewable. Still, we have a mainly linear use: extract - use - discard. This is not durable for future generation's supply of raw materials. In addition, the linear use of raw materials comes with environmental impacts. Waste needs to be handled and mining areas can mean environmental issues or even disasters.

The overconsumption of the earth's resources causes increasing concern worldwide, and to combat it, a strategy for circular economy has been developed in Europe (European Commission 2015, 2020). In "A new circular Economy Action Plan - For a cleaner and more competitive Europe, 2020" (European Commission 2020). In contrast to the linear economy, "take, made, dispose", the circular approach aims to prolong the lifespan of goods and reduce waste through efficient design and material use (Charef & Lu, 2021). The building and construction sector was pointed out as a key sector (European Commission 2020) in the transformation from a linear to a circular material use because this sector requires vast amounts of resources - it accounts for about 50% of all extracted materials. At the same time, the sector is responsible for over 35% of the EU's total waste generation. Also, greenhouse gas (GHG) emissions from material extraction, manufacturing of construction products, construction, and renovation of buildings are estimated to 11% of the total national GHG emissions (European Commission 2020). These are strong incitements for transforming the sector towards CE value chains as greater material efficiency could save about 80% of those emissions.

Incontestably, the circular economy requires non-trivial changes in terms of professional knowledge, stakeholder engagement, and their involvement in the asset lifecycle, material

DOI: 10.1201/9781003483755-8

circularity, procurement, policies, incentive schemes, and technologies (Charef & Lu, 2021). In a review, Anastasiades et al. (2020) concluded from a review that circularity relating to buildings was intensively studied in the scientific literature, but literature on circular economy in relation to bridge construction was not found. Due to this and because there are overall similarities (when dealing with the load carrying parts), it is interesting to outline current trends for circularity in the building sector, and this is exactly the aim of this paper. First, though, the general strategies and principles for circular economy are presented.

2 CIRCULAR ECONOMY – GENERAL STRATEGIES AND PRINCIPLES

2.1 *Definitions of circular economy and circular construction*

When discussing barriers to adopt circular economy in the construction industry, the need for a comprehensive understanding of the concept and its benefits is often raised (Ossio et al., 2023). The European Parliament (2023) explains a circular economy as a model of consumption and production where the life cycle of products is extended, primarily thanks to a better environmentally friendly design that makes it easier to repair, reuse and reproduce old products, an improved durability, better waste management, and new business models based on leasing, sharing, repair and recycling. However, critics claim that circular economy means many different things to different people. The review by Kirchherr et al. (2017) underlined this. They gathered 114 circular economy definitions.

Recognizing that there is a need for a commonly accepted definition of circular economy, the international standardization organization ISO published the standard "ISO/DIS 59004 Circular Economy – Terminology, Principles and Guidance for Implementation". In this standard, it is emphasized that the organization includes environment, social and economic systems based on the consideration that economic systems are embedded in the social systems which are in turn embedded in the environment. The standard defines the term "circular economy" as an economic system that uses a systemic approach to maintain a circular flow of resources through recycling, maintaining or increasing their value, and which contributes to sustainable development. The mentioned standard is one in a series, the ISO 59000 series, which is designed to harmonize the understanding of the circular economy and support the implementation of quantification.

The ISO 59000 series is not specific for any industry or sector, but it is generic. There is a need for standards which are sector specific for the building and construction industry, because of the special characteristics of this sector, such as the complexity of buildings and structures in e.g. the different lifetimes of components and not at least the often very long lifetime of the structural parts. In recognition of this, a number of European CEN standards are planned (Under CEN TC350), which will be developed specifically for Circular Construction. Danish Standards is in charge of this work. The first of the standards "Principles, terms and framework for implementation" will come out as a draft in the spring of 2024. The scoping of the next standards in the series are expected to be initiated in the same period.

2.2 *Principles of circular economy*

The circular economy is developed as a solution to the issue of resource depletion. As there have been and are different definitions on circular economy, there are different frameworks for implementation as well. The 2008 European Union Waste Framework Directive (European Commission, 2008) underlines that the waste hierarchy shall apply as a priority order in waste prevention and management legislation and policy: Prevention > preparing for reuse > recycling > other recovery (e.g. energy recovery) > disposal.

Another common way to express this is named the 4R framework: Reduce, reuse, recycle, recover. Many frameworks have extended the R categories, and, in the literature, a review found a total of 38 different R's (Reike et al. 2018). However, overall, they can be considered as undercategories to the 4Rs. One of the most used frameworks is the 9R framework developed by

Potting et al. (2017): Smarter product use and manufacture (refuse, reduce, rethink) > Extend lifespan of products and its parts (reuse, repair, refurbish, remanufacture, repurpose) > Useful application of materials (recycle, recover). A common ranking is that reuse is preferred over recycling.

2.3 *The development of circular economy as a concept*

Circular economy as a concept cannot be traced back to a single date or author. It has rather been formed through development over the years. As early as in the 1970s, some of the basic ideas were introduced. In literature, some key publications are often mentioned as specifically important milestones in this development (Stahel, 1982; Stahel & Reday, 1982; Pearce and Turner, 1989, and McDonough & Braungart 2002). A loop economy to describe industrial strategies for waste prevention, regional job creation, resource efficiency and dematerialization of the industrial economy was sketched in 1976 in a research report to the European Commission, and report was later published in 1982 as a book (Stahel & Reday, 1982). In the paper "The product-life-factor" (Stahel, 1982) formulated "extending the life of products optimizes the overall life of goods and reduces the depletion of natural resources and thus waste; it builds on and increases prosperity". The book by Pearce and Turner (1989) "Economics of natural resources and the environment" deals with the shift from the traditional linear or open economic system to the circular economic system, describing an economic system where waste in the extraction, production and consumption stages is transformed into inputs. They emphasize that economic efficiency is getting the most welfare possible out of a given resource. The concept of cradle-to-cradle as opposing the mainstream cradle-to-gate was formulated (McDonough & Braungart 2002).

Simultaneously to the theoretical development of the concept and thoughts they materialized. For example, in Denmark, the Kalundborg Symbiosis was formally established in 1972, when companies came together in the world's first industrial symbiosis, sharing streams of energy, materials and water. From 1989 it was named Kalundborg Symbiosis (Kalundborg Symbiosis, 2023).

Several countries have now set up plans in relation to the transformation to a circular economy (Charif & Lu, 2021). In 2000, the Japanese Government enacted the pioneering Law for Promotion of Efficient Utilization of Resources and a "comprehensive legal framework for moving towards a recycling-based society" (Su et al., 2013). In 2008, the Chinese Government introduced "the Law for the Promotion of the Circular Economy", to enable a shift towards the CE, followed by the "Circular Economy Development Strategies Action Plan" and more recently, "the 13th Five-Year Plan (2015–2020)" (Zhang et al., 2009).

The fact that the circular economy did not start as a movement with a clear starting point, but rather as initiatives that arose simultaneously, has added to the missing of a commonly recognized definition of "circular economy". It was, for example, emphasized in the literature study by (Kirchherr et al., 2017). Here, 114 definitions of circular economy were identified. The study concluded that the main objective of the circular economy is generally considered to be economic prosperity, followed by environmental quality; its impact on social equity and future generations is not mentioned in most studies.

The terms circular economy and sustainability are often used in academia, industry and by policy makers, but the similarities and differences between the two terms are not always clear. Geissdoerfer et al. (2017) concludes from a literature survey that the circular economy is often seen as a condition for sustainability, a beneficial relationship, or a trade-off.

3 CIRCULAR CONSTRUCTION AND LOAD-CARRYING ELEMENTS

The number of papers on circular construction has been increasing exponentially in the last few years, and by far most of the papers are from Europe (Ossio et al., 2023). There are very few studies with focus on circular construction principles related to bridges. Anastasiades et al (2020) performed a review and concluded that circularity in the construction sector generally

was discussed extensively in the current scientific literature, though nothing relating to bridge construction was found. Due to this and because there are overall similarities, this section outlines current trends for circularity in the building sector focusing on the strategies related to the materials (concrete, steel, and wood) in the structural components of a building.

The building sector is paying increased attention to circular strategies, but new buildings or renovation projects based on circular principles are still a niche and are generally in the stage of unique demonstration buildings (Ottosen et al. 2021, Eberhardt et al. 2022). There are still challenges to overcome in the implementation towards circular construction being mainstream. For example, the process of deconstruction is still based on cutting or breaking the structural members due to the monolithic nature of the connections (Selvaraj & Chan, 2024). This makes the reconstruction or reuse process more difficult as the structural member requires repair work. Further, the cutting and breaking work creates more waste and delays the process, eventually leading to higher costs. This indicates that the existing design for deconstruction technologies do not create a closed-loop system for resources (enabling reuse within the system), therefore, there is a need for new technology and design concepts to reuse the structural members (Selvaraj & Chan, 2024). Also, designing structures from reused elements is unlike conventional structural design because stock element availability is a design input. In other words, structures must be designed subject to availability of given element characteristics such as length and cross-section type, which have a major influence on the optimal structure layout and form. In this new paradigm structural form follows availability (Brütting et al. 2019). Topology and geometry optimization subject to stock availability allows to account for environmental considerations at early stages of the design process. Design through reuse of stock elements therefore opens new directions in structural form finding and optimization (Brütting et al. 2019). The potential of the different building design and construction strategies will most likely differ between different buildings, components, and materials. Thus, design and construction strategies should differentiate between the flow of different buildings, components, and material groups (Eberhardt et al. 2022).

Reused building components (bricks, beams, columns, truss, etc.) have far lower environmental impacts when compared with recycled materials (Geyer et al., 2002). It is primarily due to the significantly lower treatment and reprocessing required for building components reuse in comparison with recycling (Gorgolewski et al., 2008). Widespread reuse of building components can thus promote the circularity of materials in the building sector. However, the reuse of building components is not yet a mainstream practice (Rakhshan et al 2020). Recycling of construction materials will downgrade performance (Augiseau and Barles, 2017). The challenge then is to find different ways to meet the future demands for construction products by reusing existing products to reduce pressure on supplies and externalities (Hopkinson et al. 2019).

3.1 *Concrete*

Construction minerals account for the highest extraction rate of raw materials worldwide, and buildings present the largest material stock. Creating a circular economy requires an ability to couple closely the recovery and reuse of products from end-of-life buildings to stock replacement and maintenance (Hopkinson et al., 2019). Extracting pieces of concrete from obsolete buildings and reusing them, as is, in new assemblies is today rarely considered a strategy for improving the sustainability of the construction sector. By delaying the crushing of concrete into aggregates and avoiding the need for fresh cement in new buildings, the circular strategy is however expected to reduce greenhouse gas emissions and threats to natural ecosystems (Küpfer et al., 2023).

Küpfer et al. (2023) critically reviewed the state of practice and knowledge on the reuse of structural concrete components in new structures. Through a robust literature and case-study collection, the study builds a database of 77 case studies in Europe and the USA, (54 are built projects). They conclude among others that the practice has a long history. It has evolved since a pioneering period starting in 1967 (with a single case on reuse of floor slabs from a 6-story reinforced-concrete skeleton building for floor stabilization) and few cases in the

1990s, mostly in Northern Europe. Since 2011, the interest of concrete reuse has widened both in terms of type of reused components but also in terms of territories. Lately, the reuse of components extracted from cast-in-place concrete structures has gained interest. A large diversity of built projects has been identified, but the full potential remains unproven. Notably, applications involving reuse for equivalent or upcycled purpose related to reuse of components extracted from cast-in-place concrete structures are lacking.

An example of reuse of concrete in a footbridge is a study by (Devènes et al., 2022). Here cut out blocks of obsolete cast-in-place concrete walls were used for a new structural application: a 10 m-long post-tensioned segmented arch footbridge. With such a strategy, new and reliable concrete structures can be built with little to no cement inputs (Devènes et al., 2020).

Reuse is rated over recovery in a circular economy. However, in cases where reuse is not possible, recovery of secondary raw materials should be considered. Using recycled concrete aggregates (RCA) in new concrete can preserve the natural aggregate resources, reduce the need for landfill space and contribute to cost efficiency. However, due to characteristics of the RCAs, the short and long-term mechanical properties of the concrete are usually poorer than those of the natural aggregate concrete. Intense research is conducted to mitigate the negative effect, and due to the uncertainty and inferior properties of RCAs, they are generally utilized for non-structural applications such as pavement, filling material or gabion. However, the exploitation of RCA in structural is ongoing and constructions have been partly or fully built. Wang et al. (2021) recommended to improve environmentally friendly RCA treatments and hereby improve the load-carrying capacity of the concrete.

The global community is moving towards reducing CO_2 emissions resulting from the production and use of ordinary Portland cement while promoting the use of waste materials as alternatives and environmentally friendly construction materials (Oke et al. 2024). Research into de-carbonizing in construction using supplementary cementitious materials (SCMs) that are eco-friendly and, the utilization of the accelerated carbonation technique as a curing regime for developing green construction components are keys (Oke et al., 2024). The most extensively used SCMs in concrete production are derived from industrial by-products. Silica fume, ground granulated blast-furnace slag, and coal fly ash are the most popular SCMs used worldwide, however, the contribution of conventional SCMs in achieving mid- and long-term net-zero carbon goals has become controversial in recent years due to several constraints such as the limited supply, the associated transportation, and supply chain issues (Nehdi et al., 2024). Intensive research is ongoing worldwide on by-products and wastes from industrial, agricultural, and municipal processes as alternative SCMs, and these includes mine tailings and ashes from incineration of e.g. sewage sludge and wood.

3.2 *Steel*

Most research examining the second lifecycle of structural steel pertains to recycling rather than reuse, due to structural steel's especially robust recycling supply chain (Hopkinson et al 2019). There is a necessity to fundamentally change the material usage pattern to enable the circular economy in construction, which means the material recycling process (reproduction or remanufacturing) shall be changed to direct structural member reuse for a potential increase in productivity, profitability, and reduced material consumption in new construction, and steel has a major reuse potential (Selvaraj & Chan, 2024). Valen et al. (2023) investigated the technical feasibility, advantages, and disadvantages, when using the reclaimed steel members from decommissioned offshore platforms in a new onshore building and they concluded that the degree of practicality/feasibility of reuse of the decommissioned steel members was about 50%

3.3 *Wood*

In case a wooden bridge is chosen, the use of cutoffs of reclaimed wood is an option. An example related to reclaimed wood is (Browne et al., 2022) were prototypes of a beam and

load carrying wall were made from cutoffs of waste wood demonstrating a potential for waste wood to replace virgin material in typical structural functions, as well as offering new aesthetics, that maintain the waste stream's identity.

3.4 *Barriers and way forward*

Charef et al. (2021) assessed the barriers to circular economy in the construction sector and classified them into six categories: economic, sociological, political, organizational, technological, and environmental. The interrelation between the barriers from different categories was very common due to the holistic nature of the construction lifecycle. The barriers were also related to the diversity of stakeholders and the phases of the building process (Charef et al., 2021). Achieving the CE in construction is not only about people and technologies, but also requires regulations and policy knowledge (Charef & Lu, 2021). Integrated project procurement/delivery will reduce discontinuity, encouraging commitment from all stakeholders over a relatively long period. Incentive schemes should be developed to encourage material circularity not only during the design stage but also during the operation and end of life stages (Charef & Lu, 2021). Results indicate that addressing the economic, social, and regulatory barriers should be prioritized (Rakhshan et al., 2020).

A key challenge in choosing to reuse components today is the barrier constituted by the lack of standards, certification, and documentation systems for these materials. Such lack entails a significant documentation burden and risk for the owner when e.g. choosing to reuse components from another building. Rakhshan et al. (2020) state that although the impact of barriers under perception, risk, compliance, and market subcategories are very pronounced, the highest inter-dependency among the sub-categories is found between perception and risk. It suggests that the perception of the stakeholders about building components reuse is affected by the potential risks associated with this intervention (Rakhshan et al., 2020). This is in consistency with Krüger et al (2023) who state that limiting forces to a broader implementation of reuse of concrete in new structures include technical fears, project-management risks, and synchronization issues. This barrier must be overcome by the development of systems and methods that ensure equality in the choice between reused and new components, and this is exactly the aim of the StructuralReuse project (Ottosen & Gustafsson, 2024). The potential risks associated with structural safety when reusing elements must be overcome in order to use elements to the full strength potential. This includes both strength estimation and durability issues.

The digitalization of the construction industry, gaining momentum around the world, has already proven its worth in many activities and seems to be promising for the transition from linear to the circular economy. An overall improvement is reported, in terms of visualization, coordination, estimation and scheduling, whether during design or construction activities. It is also an excellent tool for strengthening the handover phase (Charef & Lu, 2021).

4 CONCLUSIONS

Papers dealing with aspects of circular economy and bridges are very sparce. The transition is more advanced related to buildings, though far from being mainstream. In a circular economy, reuse of whole elements rates over recovery of materials from demolished materials (such as e.g. recycled aggregates or steel for remelting). To adapt circular economy strategies, it is beneficial to include design for deconstruction principles, which can improve the possibility for reuse in the future. There is a need for implementation of methodologies enabling documenting the properties of the elements for reuse in order to overcome the risk related to using them.

AI support for bridge SHM and life cycle assessment

G. Marasco & S.N. Pakzad
Lehigh University, Bethlehem, PA, USA

ABSTRACT: This paper focuses on opportunities that AI models bring to the monitoring and life cycle assessment of bridge structures. The paper examines different phases of data collection and generation and presents a holistic approach to curation of data. The paper then discusses various analytics that could be used to translate data to information that is useful in learning the fundamental characteristics of the structures and producing diagnostic measures for assessing the state of the structures. New classes of neural networks are developed to perform these analytical tasks accurately and in a scalable platform. These methods allow large volumes of data from various sources, including data from mobile sensors, to be utilized for assessment of critical structural systems.

1 INTRODUCTION

Structural systems are subjected to both gradual phenomena like aging, fatigue, and corrosion and shock phenomena such as earthquakes, flood, and tornadoes that can change their design properties. According to the latest annual report released by the American Road Transportation Builders Association (ARTBA), there is an urgent demand for maintenance across more than 222,000 spans, of which 76,600 bridges are identified for replacement. Among the bridges in need of attention, around 42,400 are rated as structurally deficient and in poor condition. These deficient bridges experience a daily traffic of 167 million motorists that make them highly prone to fatigue-related issues. Despite a decrease of 560 bridges in poor condition compared to 2022, the current rate of repairs suggests that it would take nearly 75 years to address all the identified issues. Hence, there is an urgent requirement for accurate, reliable, and scalable approaches to evaluate the structural conditions of the infrastructure asset. This is crucial not only for ensuring public safety but also for the correct allocation of financial resources toward repair and maintenance operations.

Over the past decades, significant strides have been taken to advance the Structural Health Monitoring (SHM) field (Farrar 2012). The continuous progress in three main thrusts — dynamic identification, damage diagnostics, and life cycle assessment — has proven crucial in translating research efforts into practical applications in the real world. SHM procedures significantly benefit from progress in two mutually connected domains: sensing technology and artificial intelligence (AI). Improvements in sensing technology are notably enhancing the temporal and spatial resolution of monitoring data. Meanwhile, AI is driving the evolution of more sophisticated data-driven approaches capable of managing big data volumes and physics-related information.

Different sources of data are used for this research. This includes conventional wired sensors, wireless sensors that are less expensive and more convenient to implement for short to medium term deployments, as well as mobile sensors that use data generated by phones inside cars that travel over bridges.

Among the significant advancements in sensing technology, smartphone sensors stand out as particularly noteworthy breakthroughs. Modern smartphones come equipped with dozens

DOI: 10.1201/9781003483755-9

of sensors including accelerometers, gyroscope, GPS, and high-resolution cameras (Sarmadi 2023). Thanks to the persistent focus on enhancing the accuracy and reliability of these sensors, they have become suitable for the SHM field. Their potentialities are exploited in mobile sensing approaches by overcoming limitations related to equipment cost and the restricted spatial and temporal resolution inherent in traditional sensor networks. Over time, we have been achieving significant advancements in methodologies for extracting bridge dynamic characteristics from mobile sensors. Ongoing progress is aimed at addressing challenges such as the complex interaction between vehicles and bridge dynamics. In the end, using mobile sensors is presenting the opportunity for a paradigm shift in scaling analysis of bridge structures to include all or a large part of the bridge assets across the nation.

The possibility to collect large volumes of data through cutting-edge sensing technologies brings SHM at big-data scale. This enables the effective training of advanced deep learning architectures. Convolutional Neural Networks (CNNs) (Rawat 2017), Vision Transformers (Rosso 2023), and Graph Neural Networks (GNNs) are examples of architectures used in SHM that require substantial datasets for successful implementation, showcasing valuable outcomes in tasks such as damage identification (Dang 2022) and life cycle assessment.

In both damage detection and life cycle assessment, the indispensable role of AI becomes evident in achieving precise, reliable, and real-time condition assessment procedures.

The creation of innovative neural network architectures has demonstrated significant potential in the realm of damage detection, particularly in image recognition (Maeda 2018). We proposed an optimized CNN to identify and localize damages in terms of cracks (Gulgec 2019).

The evolution of architectures capable of capturing nonlinear relationships among various signals across a structure proves effective in optimizing sensor networks, reducing equipment costs, and overcoming accessibility challenges in critical structural areas. Maes and Lombaert (Maes 2023) present a virtual sensing to monitor fatigue at structural elements not equipped with physical sensors. Virtual sensors relying on mathematical processing to generate the desired data are developed to circumvent the need for expensive and labor-intensive direct measurements. We proposed to use long short-term memory (LSTM) to build a data-driven model for life cycle assessment purposes (Gulgec 2020b), yielding excellent results in strain predictions. Furthermore, emerging architectures like Vision Transformers and GNNs show great promise in this field.

This paper provides a comprehensive review of the latest developments in sensing technologies and methodologies aimed at achieving efficient, accurate, robust, and real-time structural condition assessment solutions. A comprehensive strategy, based on sophisticated cloud-based storage solutions, is proposed to efficiently manage the large volumes of data collected or generated for the subsequent processing operations aim at extracting damage-sensitive features, detecting and localizing damage, quantifying its extent, and providing a prognosis about the structural remaining useful life. introduces novel approaches to transform data into information that is useful for structural condition assessment, advancing the dynamic identification, damage diagnostics, and fatigue life estimation. It provides methodologies for scalable infrastructure monitoring via mobile sensing in the civil engineering field, incorporating the interaction of vehicle suspension effects and vibrations caused by road roughness, enabling dynamic response extraction from vehicle data. Additionally, it presents techniques for bridge modal identification using asynchronous mobile data, a crucial step in integrating mobile sensing into system identification. In parallel, advanced deep learning architectures have been designed to efficiently detect and localize damage, such as cracks, utilizing long-term data availability. They excel in identifying abstract features and complex classifier boundaries for damage diagnosis, offering high accuracy and computational efficiency. Furthermore, cutting-edge AI algorithms, including Transformers, Convolutional Neural Networks, and Graph Neural Networks, are exploited to improve traditional bridge fatigue assessment. Deep neural network architectures are designed for indirectly sensing strain response from bridge acceleration data, overcoming equipment cost and accessibility limitations associated with critical structural areas. The outcomes demonstrate the feasibility and significant progress over existing methods.

The organization of this paper is as follow. Section 2 describes different sources of data into a cloud-based analytics perspective. Sections 3 illustrates the most recent analytics for dynamic identification, damage diagnostics, and fatigue life estimation. Section 4 provides the main conclusions and delineate potential future research directions.

2 SHM DATA SOURCES TOWARD ADVANCING IN SENSING TECHNOLOGIES

The methodologies employed in the initial phase of SHM processes, focused on data collection and generation, have undergone significant advancements in the last two decades. The progress of cyber-physical systems has sparked questions regarding the capture of data from physical infrastructure and its seamless integration into a connected information system. This Section delves into diverse data sources, highlighting their strengths and limitations in light of advancements in sensing technologies.

The structural condition of physical infrastructure can be measured directly or indirectly (Martin 2021). Despite direct measurements can be cost-intensive, prone to noise, and limited by technical challenges arising from spatial or environmental conditions, physical sensors are traditionally used to capture the structural response directly.

Wired networks using cables to send data to a central storage are the most common methods for collecting bridge data. Several studies show the implementation of wired sensing system to capture vibration data and estimate the dynamic characteristics of the structure (e.g., modal properties or parameterized function) (Maes 2021). However, the widespread use of wired networks is hindered by high maintenance and costs.

To overcome such limitations, wireless sensors networks (WSNs) are a valid alternative. Over the years, WSNs for SHM purposes have demonstrated their ability to offer precise and spatially dense ambient vibration data. We designed one of the largest WSN for SHM. It was developed, implemented, and validated on the 4200ft long span and the south tower of the Golden Gate Bridge (GGB). The network, composed by 64 nodes, recorded vibrations data at 1kHz, with a jitter below of 10 μs and an accuracy equal to 30 μG. Details are shown in (Kim 2007). Subsequently, we designed an integrated system, encompassing both hardware and

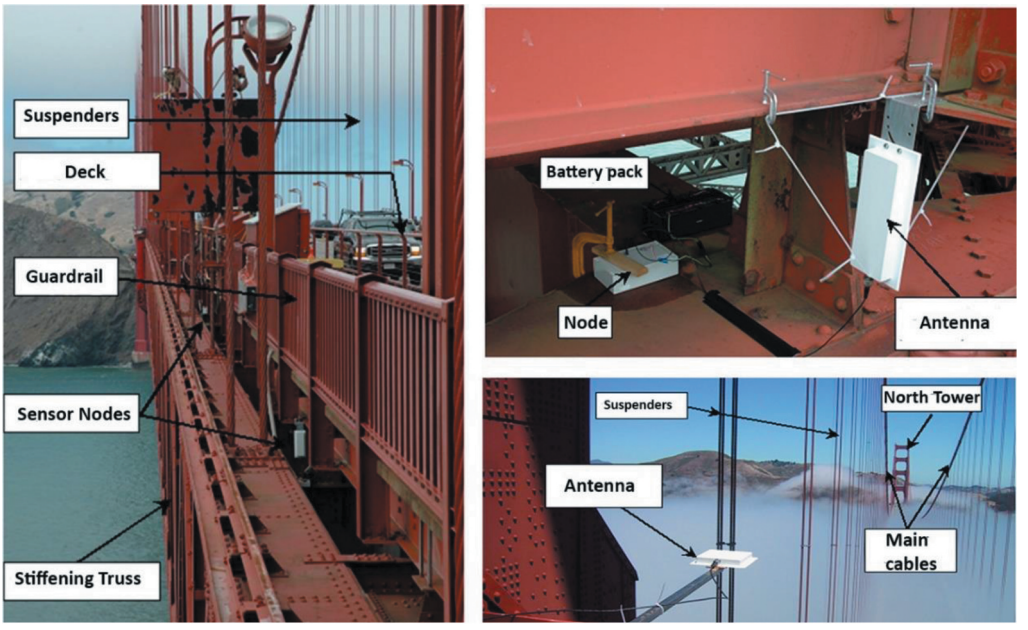

Figure 1. Views of the main-span and south tower of Golden Gate Bridge. Details about one WSN node with its battery pack and bi-directional antenna installed on the main-span.

software, for such scalable wireless sensor network, showing very accurate outcomes in identifying the bridge vibration modes.

Data obtained from the experimental setup were utilized to assess both the scalability of the network and the integrity of the data.

The performance remained robust and scalable, even in scenarios where a significant number of hops were necessary for communication. Deepening can be found in (Pakzad 2008).

Our later studies focusing on WSNs, the details of which are presented in (Pakzad 2009, Pakzad 2010), confirmed elevated resolution and confidence in detecting vibration modes. The errors in estimating vibration properties turned out to be minimal, with frequencies exhibiting the highest accuracy and damping ratios being the least accurate. Figure 1 shows a view of the WSN instrumentation deployed on the Golden Gate Bridge for the aforementioned investigations. It is worth nothing that a further benefit of WSNs lies in their efficiency in facilitating widespread sensor installations at a reduced cost. We demonstrated that this cost-effectiveness can be further enhanced through optimal sensor placement techniques, as illustrated in (Chang 2014). Yet, challenges persist concerning connectivity and power requirements.

Within the realm of direct measurements-based methodologies, the adoption of nondestructive techniques (NDT) that generate images/maps has become prominent. Examples include Digital Image Correlation (DIC) and Ground Penetrating Radar (GPR). The approaches associated with the automated analysis of these images are closely tied to classification challenges, and over the years, progressively sophisticated techniques rooted in AI have been devised. Recent breakthroughs have demonstrated remarkable outcomes, particularly with the utilization of Vision Transformer and CNNs. Deepening regarding the methodologies developed over time to analyze such data within the damage diagnostics area and the future research directions can be found in Section 3.2.

An additional direct methodology involves the utilization of mobile sensors, a strategy bolstered by the spread of smartphone devices and improvements in sensor accuracy. In a recent study (Matarazzo 2016), we highlighted the capacity of these sensors to capture structural vibration data during the transit of vehicles across the bridge. This ensures comprehensive spatial coverage with minimal sensor deployment. Details about the analytics methods developed over time to exploit this sensing approach in a dynamic identification perspective and the current challenges are provided in Section 3.1.

In addition to physical sensors, virtual sensors have emerged as a cost-effective alternative to make data acquisition more widespread and avoid labor-intensive direct measurements. The utilization of virtual sensors has been significantly enhanced by advancements in deep learning architectures. Virtual sensors, also referred to as soft sensors, act as substitutes for real ones, obtaining indirect measurements through mathematical processing (Wilson 1997). They have demonstrated remarkable effectiveness across diverse domains, including chemistry, computer science, and transportation systems, as illustrated in studies such as (Ankara 2004, Morgul 2014). The recent progress in deep learning has given rise to new classes of neural networks capable of understanding highly complex and nonlinear relationships within data. We have showcased the advantages of deploying such architectures in the SHM domain in a recent investigation (Gulgec 2020). The development of virtual sensors can generate data at numerous crucial structural points, starting from simpler and more cost-effective measurements. Section 3.3 provides insights into the advancements associated with this sensing approach for fatigue life estimation purposes.

3 METHODS

Processing operations within the SHM framework focus on three aims: to extract damage-sensitive features, to identify damage, and to provide with prognosis about the remaining useful life.

This section delves into recent advancements dynamic identification methods using smartphone-vehicle-trip (SVT) data, damage diagnostics methods based on image data, and fatigue

life estimation methods by means of virtual sensing. These advancements aim to effectively address the three aforementioned key aims.

3.1 *SVT data-based dynamic identification methods*

Vibration-based techniques for bridge monitoring have been developed over the past two decades for infrastructure dynamic characterization (Fritzen 2005). Conventionally, this involved setting up fixed spatially dense networks, wired or wireless, and employing system identification techniques to develop digital twins (Nicoletti 2023) and damage detection methods (Kostic 2017).

The main drawback associated with such networks is the high cost and the limited scalability of fixed sensors, hindering widespread adoption due to setup and maintenance expenses (Avci 2021). In this context, mobile sensing emerges as a promising solution.

This technique involves using sensors inside vehicles that travel across a bridge, measuring vibrations inside the cabin. Even though vibration signals include both bridge and vehicle dynamics, the aim is to predict the dynamic features of the bridge mitigating the impact of vehicle dynamic. Mobile sensors-based techniques have the capability to notably boost the speed and scale of infrastructure monitoring at unprecedented level, with low setup costs.

Compared to stationary sensing, the mobile one provides numerous advantages, offering better spatial resolution and requiring fewer sensors, as detailed in our recent studies (Matarazzo 2016a, Matarazzo 2016d). We demonstrated such advantages with laboratory tests and computer simulations in (Matarazzo 2018a).

Over the past decades, there has been a notable emphasis on addressing the challenge of estimating modal parameters such as frequency, damping, and mode shape using data collected from mobile sensor networks. Initially, the methods proposed focused on the estimation of individual modal parameters. For instance, Yang et al. (Yang 2004, Siringoringo 2012) presented methodologies for frequency estimation, while Gonzalez et al. (Gonzalez 2012) introduced techniques for damping estimation. In more recent times, we had substantial efforts in the development of Structural Identification (SID) techniques to produce a notable progression in the field, moving beyond the singular parameter focus of earlier methodologies. We firstly introduced structural identification formulas under the Expectation-Maximization framework, known as STRIDE. More details can be found in (Matarazzo 2016c, Matarazzo 2016b). Despite the high accuracy of the method in estimating modal parameters from datasets with incomplete observations, the STRIDE technique faced challenges related to scalability. To address this limitation, we presented an extension called STRIDEX, specifically designed for the truncated physical model (TPM); insights are included in (Matarazzo 2016b). This method offers comprehensiveness, convenience, adaptability, computational scalability, and is characterized by scalable information (Matarazzo 2018). In its initial implementation, STRIDEX demonstrated remarkable precision in generating a mode shape comprising 248 points using data from a pair of mobile sensors. Subsequent experimental tests highlighted its capability to successfully estimate higher modes and their associated mode shapes solely based on data collected from mobile sensors, as shown in (Matarazzo 2018b). Subsequently, in further studies we focused on the development of SID methods using matrix completion (MIMC) to obtain modal parameters from data recorded by a high number of mobile sensors (Eshkevari 2020).

To validated our proposed approaches, we presented studies where data from crowdsourced SVT are exploited to precisely identifying modal characteristics of real bridges. In (Matarazzo 2020) two case studies are showed. The first case study used smartphone data from "controlled" field experiments and "ridesourcing" datasets on a long-span suspension bridge in California, the Golden Gate Bridge. The second case study is applied to "partially-controlled" crowdsourced data recorded on a bridge in Ciampino, Italy. The methodology is developed to determine the most probable modal frequencies (MPMFs) via the synchrosqueezed wavelet transform and a data aggregation technique. In a further study, we showed the success of wavelet transforms in multiple real-world applications to identify modal frequencies and absolute mode shapes (AMS), namely mode shapes without the phase information, using highly

uncontrolled mobile sensing data. The study represents the most comprehensive real-world investigation into monitoring bridges using data from crowdsourced SVT, aiming to simulate the capabilities of detecting structural damage by means of AMS identification. The method examines more than 500 trip spanning four bridges (Golden Gate Bridge-USA, the Cadore Bridge-Italy, the Ciampino Bridge-Italy, and the Gene Hartzell Memorial Bridge-USA), with the main spans varying from 30 to 1300 meters in length. The presented approach offers three main advantages: (1) it relies solely on SVT data obtained from ordinary smartphones, eliminating the need for additional sensor data or GIS information, (2) given the continuous increase in smartphone usage, it facilitates regular and current estimations of AMS, and (3) it boasts a high spatial resolution in AMS. These functionalities can be integrated into a Software-as-a-Service (SaaS) system for automated collection, initial processing of data, and storage in the cloud. The system comes equipped with tools to facilitate the nearly real-time assessment of the structural conditions.

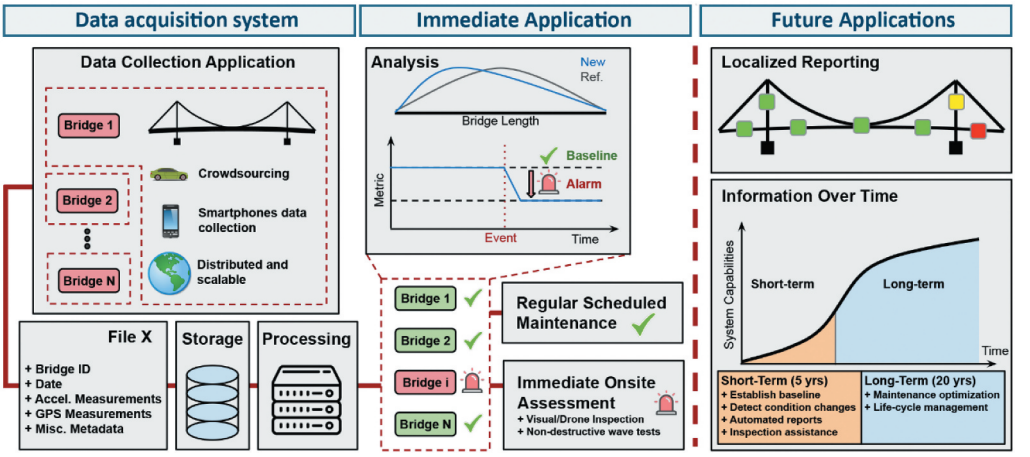

Figure 2. Scalable platform for system identification.

Figure 2 displays the flowchart outlining the envisioned scalable system identification platform. The smartphone app, equipped with bridge registries and user-defined geo-fences, automatically records vibration data upon entering these zones. The data is packaged and stored in the cloud. Periodically, a backend server processes the stored data, applies the algorithm to identify current AMS estimations for each bridge, and generates a time series of real-time dynamic features. This ongoing process enables continuous monitoring for anomalies indicative of structural changes, triggering automatic alerts for onsite inspections by bridge owners. More details can be found in (Eshkevari 2023).

Figure 3 illustrates the graphical representation of the procedure for identifying AMS.

After initial preprocessing, the synchrosqueezed wavelet transform is applied to shift each acceleration time series into the time-frequency domain, and then compute the instantaneous magnitudes. After that, the bridge is segmented with overlapping sections considering two parameters: the width (Δ) and the spatial stride (S). By calculating the average magnitudes within individual segment at the modal frequencies for each trip, a distribution of magnitudes is obtained for each location. The average of these distributions represents the AMS estimate. To enhance robustness on noisy datasets, a slight bandwidth (ε) encompassing the modal frequency is considered during the averaging step.

Our current research endeavors are centering around advancing SID techniques utilizing mobile sensors to obtain accurate frequencies, full-mode shapes (including phase information), and modal damping ratios of bridges. The uniqueness of this last our approach lies in estimating a dense spatial cross-spectrum. This is achieved by spatially averaging time-frequency cross-spectra obtained from pairs of mobile sensors at the same time on the bridge.

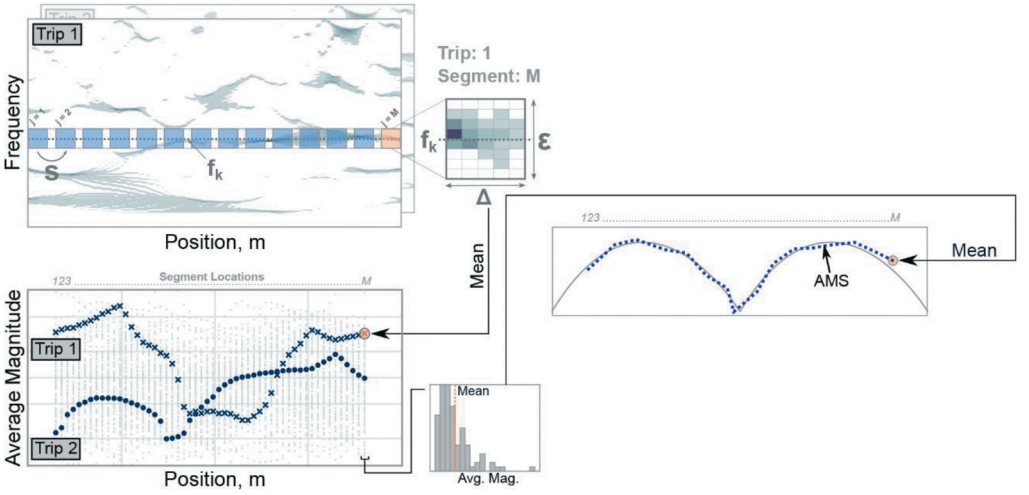

Figure 3. AMS identification methodology.

The averaging step involves computing mean values for both magnitude and phase within each spatially discretized cross-spectrum area. This effectively reduces the influence of vehicle dynamics on the results and numerical and laboratory experiments showed very promising outcomes.

The experimental mobile sensing platform depicted in Figure 4 illustrates the setup utilized at Lehigh University for validating the STRIDEX Structural Identification (SID) method and supporting the ongoing research endeavors.

3.2 *Image data-based damage diagnostics methods*

The assessment of structural integrity can be performed by means of a hierarchical approach to damage identification, as outlined by Farrar and Worden (Farrar 2012). This structured process encompasses five distinct levels: detection, localization, classification, assessment, and

prediction. Image recognition methodologies turn out to be critical for the acquisition of information for identifying, locating, and estimating the severity of structural damages.

The image recognition field has significantly benefited from the strides made in deep learning domain, which has become the backbone of support for structural assessment and damage identification techniques. Within this domain, one of the most pivotal contributions has stemmed from advancements in neural network architectures. Starting from the beginning of the 1990s, neural networks turned out to be an alternative to traditional techniques from statistical pattern recognition like the Bayesian discriminant and the Parzen windows. Foremost among these architectural advancements are CNNs. By exhibiting optimal performance when applied to the analysis of two-dimensional data formats, including images, videos, and similar visual data, the CNNs architectures are one of the most significant breakthroughs in image recognition. They eliminate the necessity for manually extracting features, possess the capability to recognize abstract and intricate classifier boundaries, and can discern diverse features of the problem. Moreover, thanks to the convolutional and pooling operations, they decrease the computational cost to address very complex tasks. Their demonstrated high precision, reliability, and computational performance across numerous studies establish them as a pillar in the realm of image recognition.

By leveraging image recognition techniques, the process aims to not only detect and pinpoint structural anomalies but also categorize them according to their nature and severity. This advanced approach aids both in identifying areas of concern and to facilitate a more comprehensive understanding of the structural condition.

We designed an optimized two-dimensional CNN specifically tailored for the accurate classification and localization of damage, present in the form of cracks within a gusset plate. The network is conceived to analyze strain fields in the form of tensors after an appropriate normalization process. Its design prioritizes efficiency in handling noisy data. To validate its performance, finite-element simulations of undamaged and damaged structural connections under different loading case, damage scenarios, and noise levels were initially conducted. Subsequently, the methodology has been validated using data obtained through DIC from laboratory testing. These tests involved inducing damaged conditions on the specimens, confirming the robustness of the proposed approach. In the proposed methodology, the initial layers of

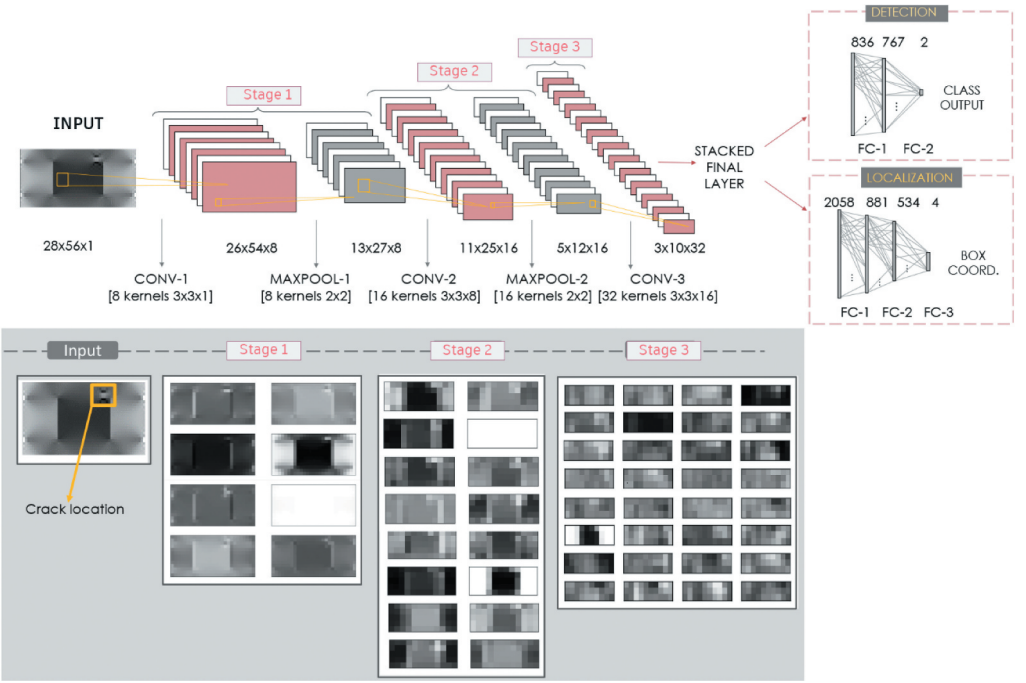

Figure 5. Proposed CNN architecture for crack identification.

a deep CNN are common for identification and localization. Subsequently, tailored back-end layers are formulated to address the specific requirements of each task. This design ensures a unified yet specialized architecture capable of effectively handling both identification and localization objectives. The features extracted in the initial layers of the network hold relevance for both tasks, thereby justifying the sharing of these network components. This deletes the necessity for maintaining two entirely distinct networks, resulting in a decrease in the overall training time and computational resource requirements. More details can be found in (Gulgec 2019, Gulgec 2020a).

Figure 5 illustrates the proposed CNN architecture. Despite the accurate outcomes obtained by the just presented approach, further research endeavors in this direction are essential for uncovering additional insights into the capabilities of CNNs, particularly in addressing more complex tasks related to damage detection.

3.3 *Virtual sensing-based fatigue life estimation methods*

Structural condition assessment can be performed not only by means of damage detection techniques but also estimating the structural remaining useful life. This is particularly important in steel bridges, where fatigue phenomena can cause important structural issues. Traditionally, it requires collecting strain (or stress) data at critical structural areas. While field measurements of strain signals contribute to reducing uncertainties compared to simulated ones, they are characterized by several shortcomings. These include elevated equipment costs, labor-intensive processes (Childers 2001), and challenges in accessing critical structural elements. By employing recorded stress or strain time histories, stress spectrums can be estimated to create rainflow diagrams. These diagrams are utilized to evaluate the remaining fatigue life of a structure through the counting of stress cycles, as outlined in (Fatemi 1998, Downing 1982).

The use of AI techniques to obtain strain signals with data-driven models has allowed to overcome such limitations. We showed the efficacy of LSTM to convert acceleration signals into strain signals. The methodology consists of training and testing steps. During training, the goal is to establish a connection between acceleration and strain for specific positions (R). A deep learning architecture is employed to minimize the error between predicted and actual strain signals. After the training, the model parameters are saved. In the testing step, the architecture uses acceleration data from specific locations to obtain strain data, accommodating cases where the number of requested locations exceeds R. The proposed approach undergoes a three-step training process to grasp extended time sequences. In each step, a randomly chosen sequence is divided into three parts: Part A, Part B, and Part C, which are subsequently employed in Step A, Step B, and Step C, respectively. During Step A, Part A, spanning from time i to $i+L$, is inputted into the first network (DNN 1). This sequence of length L is utilized for estimate abstract level features and serves as the initial state for Step B. This step functions as a nonlinear mapping of the input, capturing the sequence dynamics for enhanced learning performance and quicker convergence. In Step B, the second network (DNN 2), comprising LSTM memory cells, receives input from the sequence of length K and the initial state estimated in Step A. These memory cells act on the input sequence for further processing. The LSTM cell converts acceleration subsequences into strain ones, spanning from time $i+L+1$ to $i+L+K$, while simultaneously updating the internal and the hidden states. During Step C, the time series related to Part C is employed to enhance initial state estimations for DNN1 in subsequent iterations. The main objective of the proposed methodology is to simultaneously minimize the loss between the cell states from Steps B and C and the discrepancy between real and predicted strain signals. Figure 6 shows the flowchart of the general methodology. More details are shown in (Gulgec 2020). The method shows very good results but it is validated at a laboratory experiment scale with an unrealistic high loading. Moreover, advancements in machine learning field showed that LSTM is not the best architecture for such task.

Our recent research efforts have showcased the effectiveness of an advanced architecture that integrates Transformers and CNNs to convert acceleration signals to strain signals. This combination accurately estimate strain signals by using acceleration data collected from the Gene Hartzell Memorial Bridge in Easton, PA. As depicted in Figure 7, the deep neural

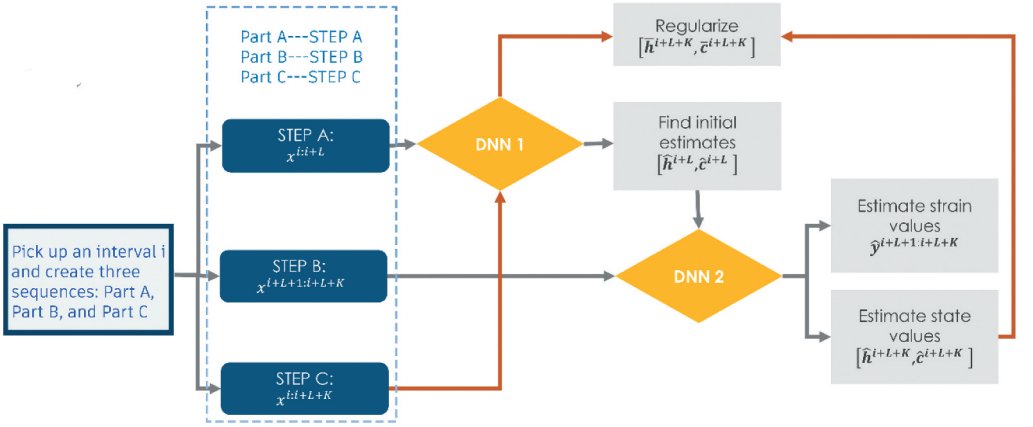

Figure 6. Proposed methodology based on a three-step training approach.

network makes predictions for two distinct versions of the strain signal: the pseudo-static and the dynamic version. The CNNs are adept at forecasting the pseudo-static component, while the Transformers excel in capturing the dynamic part.

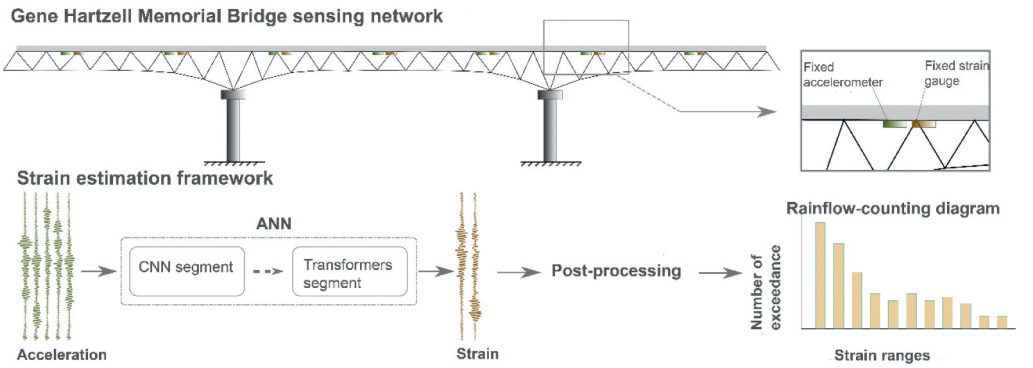

Figure 7. Strain estimation workflow.

In addition to CNNs and Transformers, GNNs emerge as potential architecture for the fatigue life estimation task. Most recent advancements in machine learning introduced the idea, already exploited in other fields like biology (Wang 2022), social networks (Ying 2018), and computer vision (Jiao 2022), that data can be organized on a graph structure. By considering the structural nodes, where sensors are positioned, as the graph's nodes, and the structural elements as its edges, information related to the mechanical connections among these nodes can be incorporated into the model. This integration is achieved through the utilization of the adjacency matrix characterizing the graph. Therefore, employing this architecture in the structural field enables the model to incorporate information concerning both spatial relationships and actual mechanical connections. This presents a promising avenue in civil engineering, and recent studies (Kim 2023) indicate the possibility to obtain further advantages by employing more advanced adjacency matrices. Despite up to this point the application of this architecture in civil engineering has primarily concentrated on areas such as damage classification (Dang 2022) and static structural response prediction problems (Whalen 2022), a recent study of ours has shown encouraging outcomes in the conversion of acceleration to strain signals for a numerical case study. For further details refer to (Marasco 2023). Ongoing efforts are dedicated to further developments in this domain.

4 CONCLUDING REMARKS

This paper introduces the most advanced sensing technologies as well as the most cutting-edge methods for converting raw data into meaningful information, specifically geared towards enhancing structural automatic condition assessment reliability and scalability. The focus is on advancing dynamic identification, improving damage diagnostics, and overcoming limitations of the current fatigue life estimation techniques. Firstly, it emphasizes the potential presented by mobile sensors in enhancing spatial resolution and reducing monitoring costs. The proposed techniques leverage asynchronous mobile data to successfully extract bridge dynamics in terms of modal parameters. Secondly, it underscores the contribution of advanced deep learning models to the improvement of damage diagnostics and fatigue life estimation techniques. A deep understanding of the state-of-the-art architectures, including CNNs, Transformers, and GNNs, enables the development of new architectures to address the current challenges in structural condition assessment. The proposed methodologies have undergone validation through both numerical simulations and real-world case studies, demonstrating significant promise in advancing the current state of the SHM field.

Innovations in bridge management in Australia to rise to the challenges of today and the future

Nigel G. Powers
National Transport Research Organisation, Melbourne, Australia

ABSTRACT: Australia has a relatively small and dispersed population across a significantly large continent. Its economy is heavily based on the movement of freight which is primarily done on its road network due to capacity and access limitations on other alternatives such as rail, air, and water. The freight task is growing rapidly due to unprecedented population growth, coupled with increased demand from trading partners in Asia and rapid changes in technology, e-commerce, and consumer behavior. To remain competitive in a global market, the movement of freight must be fast, efficient, and effective. This is a significant challenge with an ageing road bridge network designed and built to outdated standards, loads increasing in frequency and mass and more frequent extreme climatic events like floods and bushfires.

Australia's road infrastructure managers are investing in research to seek innovations and practical and implementable improvements. Partnerships between researchers and infrastructure managers are critical to ensure innovations are identified, best practice is furthered, and the ever-increasing risk is appropriately managed. To achieve this and rise to the challenges faced research programs have covered many areas including the refinement of structural assessments, assessing structural risk, identifying innovative materials and maintenance, rehabilitation and strengthening techniques, improved monitoring practices and enhanced testing and analysis. The outcomes of this research will be shared along with recommendations for future investment and research.

1 INTRODUCTION

Australia's freight task is growing at a rapid rate due to unprecedented population growth, coupled with increased demand from our trading partners in Asia and rapid changes in technology, e-commerce, and consumer behavior. Overall, transport logistics was valued at over A$135.5 billion in 2023 and has been steadily increasing since. A significant proportion of freight is transported using the road network and to remain competitive this network needs to facilitate fast, safe, efficient, and effective access.

This is a significant challenge with an ageing bridge network and many of the in-service bridges built to outdated standards and for loads that are less than the allowable loads on the road network. Australia is also a land of temperature and weather extremes with major climatic events quite frequent which constantly tests the resilience of our bridges. When you combine the above with a freight industry constantly pushing to increase access and allowable loads, infrastructure managers have a major challenge to rise to.

In rising to this challenge, Australia's infrastructure managers are being innovative, partnering with industry to conduct research and address the problems they are facing. In partnership with industry and with funding from the State and Federal Governments, there has been significant research and development with the monitoring, assessment, and management of bridges.

DOI: 10.1201/9781003483755-10

2 AUSTRALIA'S FREIGHT TASK

The effective and efficient movement of freight across Australia is critical for the Australian economy. A significant proportion of freight is transported on the Australian road network. This is due to constraints on the rail network and the characteristics of the land not being conducive to using other transport forms like air and sea freight.

It is estimated that the overall transport logistics industry contributed A$135.5 billion to Australia's GDP in 2023. This is expected to grow to 173.8 billion by 2029 (Mordor Intelligience, 2023) thus access across the road network is essential.

2.1 *Population growth*

Australia's population was 26.64 million as of 30 June 2023 (Australian Bureau of Statistics, 2023). Over the last ten years the average annual growth rate was 1.4% and is expected to continue to grow in the decades ahead. By 2071 Australia's population is predicted to reach between 34.3 and 45.9 million people (Australian Bureau of Statistics, 2023).

This increase poses a significant challenge for infrastructure managers. Not only will it result in more vehicles being on the road network but it will also generate freight to provide the infrastructure needed to support such growth.

2.2 *Australia's size*

Australia is the sixth largest country in the world at 7.688 million square kilometers and accounts for 5% of the world's land mass (Geoscience Australia, 2023). The Australian Road Network is estimated to have a total length of 873,573 kilometers. Australia has a low population density with 3 inhabitants per square kilometer (World Data.Info, 2023).

The above aspects combine to create a significant challenge for Australia's road infrastructure managers. The large country size and length of network and the relatively small and dispersed population create the challenge of providing the funding required to build and maintain the network to the required standards.

2.3 *Trade*

Australia's national freight is predominantly generated by our trading partners in Asia. 75% of Australia's goods exports are going to Asia, in particular the booming economies of China and southeast Asia (Infrastructure Australia, 2018). This is expected to continue, if not increase over coming years.

This also poses a challenge to infrastructure managers with Australia's reliance on the road network to transport freight, the increase in trade will increase the quantity of heavy vehicles across the network. With freight operators striving for more efficient movement of freight, often resulting in larger and heavier vehicles, this will create further challenges for infrastructure managers to meet.

2.4 *E-commerce*

As with many countries across the world, e-commerce is booming Australia wide. The predicted revenue for e-commerce in Australia in 2023 is A$71 billion and this is expected to increase to A$94.61 billion by 2023 (ECDB, 2023).

The vast majority of this results in the delivery of parcels across Australia via the road network. Due to the nature of these deliveries, they are generally small and light and thus does not create a structural burden on our bridges but more a capacity issue for our already congested urban road networks.

2.5 *Road freight*

In 2017–2018 Australian freight vehicles moved an estimated 214,789 million tonne-kilometres of freight across Australia's road network (Australian Bureau of Statistics, 2019). This represents a 5.0% increase since 2016.

The majority of road freight transported crude materials (30 per cent) such as stone, sand and gravel, followed by manufactured goods (12 per cent) and food and live animals (11 per cent).

Over 95% of Australia's road freight is carried by vehicles heavier than 4.5 tonnes with the B-Double (Figure 1) accounting for 40% of all frieght movement (ACIL Allen Consulting, 2014). B-Doubles typically carry a load of approximately 68 tonnes. With current frieght industry initiatives across Australia for more high productivity vehicles, such as B-Triples with a mass of up to 85 tonne, this will allow road freight to grow and be a cost effective form of transport. Such large and heavy vehicles create challenges for the road network in terms of safety and bridge capacity.

With such a heavy reliance on road freight for Australia's economic prosperity, it is critical to ensure that our road infrastructure can safely accommodate the movement of frieght across the network.

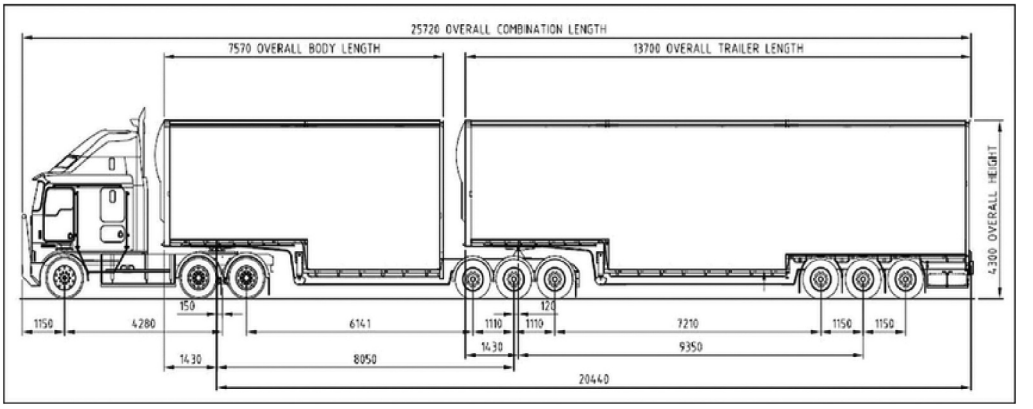

Figure 1. Typical B-Double. dimensions in mm. source: Spark, 2013.

3 AUSTRALIAN BRIDGE NETWORK

3.1 *Background*

Similar to the rest of the world, Australian bridges have developed over recent centuries from timber and masonry structures prior to the 18th century, progressing to steel structures towards the end of the 19th century and the network is now dominated by steel and concrete structures.

Timber bridges have largely been removed from the road network over the years to make way for more modern materials and structures and to carry the loads that are now on the road network. That said, timber structures are still very important on the road network as timber is often the only material readily accessible in the remote parts of Australia. For example, the Queensland Department of Transport and Main Roads still has over 300 timber bridges in service across its network (Austroads, 2018).

This is also the case for masonry structures. While some masonry structures remain in service, many have been removed from service across the network, like Winchelsea Bridge shown in Figure 2, due to condition and uncertainty of structural capacity.

3.2 *Current asset manager information*

In Australia there are approximately 53,000 road bridges (Caprani, 2018). Of these:

- Approximately 23,000 are managed by the State and Territory Road Authorities,
- Approximately 30,000 are managed by Local Government Authorities, and
- A small number are managed by private road operators.

Figure 2. Winchelsea Bridge, Victoria – opened in 1867.

3.3 *Design eras in Australia*

Before 1900, standards for bridge design and loading did not exist. Many were built to withstand the loads from horse and cart and may have been tested using a 16 ton road roller. Some of these bridges are still in service today.

In the early 1900's, bridge design developed, and the loading gradually progressed. In the 1920's and 1930's a loading was specified for the class of road with Class AA roads based on a 20 ton traction engine, Class A roads 15 tons and Class B roads 10 tons.

From 1947, bridge design loading was made uniform across Australia with the adoption of AASHTO and the design loading of H20 S16-44 truck (approximately equivalent to 33 tonne semi-trailer). There was a construction boom across Australia during this period with the current network made up of approximately 50% of bridges built to this standard (Caprani, 2018).

In 1976 – 2004 this progressed to T44 (approximately 47 tonne semi-trailer) with the current network consisting approximately 25% of bridges built to this standard.

With the development of the Australian Standard for Bridge Design, AS5100 – Bridge Design Code, the design load progressed to SM1600 which is equivalent to 2 x 75 tonne semi-trailers, nose to tail. These are estimated to make up 10% of the current bridge network.

4 PARTNERSHIPS WITH INDUSTRY TO MEET THE CHALLENGES OF TODAY AND THE FUTURE

4.1 *National asset centre of excellence*

In 2013 the Department of Transport and Main Roads Queensland (TMR) and the Australian Road Research Board, now National Transport Research Organisation (NTRO), established the National Asset Centre of Excellence (NACOE). NACOE delivers engineering excellence through leading road asset research that welcomes innovation and drives road management practice efficiency, creating fit-for-purpose engineering solutions (NACOE, 2023).

NACOE's research contributes to improving road safety initiatives to help save lives, reduce our carbon footprint, and deliver significant cost savings to the people of Queensland.

The program has a particular emphasis on pavements and materials technology, and covers the following key discipline areas:

- Pavements
- Asset management
- Structures
- Network Operations
- Road Safety
- Heavy Vehicle Management
- Sustainability

4.2 *Western Australian Road Research and Innovation Program*

The Western Australian Road Research and Innovation Program (WARRIP) is a collaborative research initiative between Main Roads Western Australia (MRWA) and NTRO. The WARRIP explores cutting edge research in:

- Pavements and surfacing,
- Asset management,
- Road safety,
- Sustainability, and
- Road structures.

The WARRIP aims to deliver innovative, sustainable, and cost-saving solutions for road infrastructure projects throughout Western Australia. The projects are delivered by subject matter experts in both MRWA and NTRO as well as engaging with industry and academia (WARRIP, 2023)

4.3 *Research projects*

The following outlines a small number of projects delivered under NACOE and WARRIP that have contributed to meeting the challenges of ageing infrastructure and the significant freight task.

4.3.1 *Deck unit bridge deck analysis under live load*

TMR's road network includes approximately 3000 bridges and 4000 culverts. Of these, more than 1900 Deck Unit (DU) bridges (Figure 3) have been built since the 1960's. A DU bridge is a bridge type commonly used in Queensland as it is simple to construct and cost effective for smaller span structures. It consists of individual, pre-cast, prestressed concrete hollow beams units that are connected via Transverse Stressing Bars (TSB). It relies on the TSB for the beams to act in composite as it does not have shear keys or a concrete overlay.

With DU bridges making up approximately 60% of the TMR bridge stock, the accurate analysis of their structural capacity is very important to make informed decision regarding allowable loads. Through the standard numerical analysis of DU bridges possible inadequate

Figure 3. Typical DU bridge. source: NACOE.

capacity was identified. Due to limited documentation and research on DU bridges a four-year project was commissioned to conduct load testing, assess the ultimate capacity of each beam, conduct performance and ultimate load testing of a partial DU bridge and investigation of the effects of TSB damage on the structural performance of a bridge.

The in-service monitoring and load testing in the first year of the project was conducted on a two-span bridge with spans of 8.3m long, each with 13 DUs. The results from the testing showed the bridge superstructure performed better than theoretically predicted with the load transfer like that of a flat slab bridge. This outcome was critical with the results being used to calibrate numerical models and refine capacity assessments.

Destructive testing was conducted on DUs taken from a decommissioned bridge. Tests were conducted on bending and shear on 9.1m long units from a bridge built in the 1970s. The tests concluded that the bending and shear performance was higher than estimated in the design specifications. Testing was also conducted on the concrete and steel which yielded higher values than also estimated in the design specifications.

A partial DU bridge was assembled including six 8.3m long DUs and one Kerb Unit (KU) from a decommissioned bridge, see Figure 4 below. The performance load testing delivered results consistent with the in-service testing and the failure mechanism was predominantly ductile.

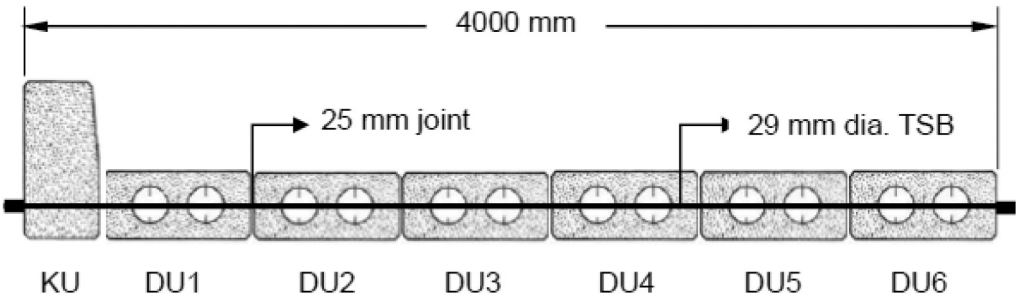

Figure 4. Cross section of the partial DU bridge used for testing. source: NACOE.

Finally, a DU bridge with 16m spans and TSB at 2m (Figure 5) was used to test the effect of TSB damage. Damage was gradually introduced by severing the TSBs and then conducting load tests. The testing showed that extensive TSB damage leads to an 18% increase of the load distribution factor, 32% increase in strain and 30% increase in vertical deflection.

The outcomes of this project have provided TMR with an improved understanding of DU bridges and how they behave under load and with TSB damage. This has helped them to make more informed decisions on the restrictions of heavy vehicle movements and on the maintenance, strengthening and replacement of DU bridges.

4.3.2 *Virtual WiM – enriching WiM and enhancing decisions*

This project was commissioned to explore an opportunity to enhance TMR's existing Weigh-in-Motion (WiM) network by supplementing it with data from other sources. TMR has 60 WiM installations and 126 networked classifier installations across its 33,000km road network. When determining access and planning outcomes, policy decision makers are regularly required to exercise judgment balancing productivity and risk. Decisions must be made with an often-incomplete subset of information and knowledge available. This incomplete knowledge can lead to sub-optimal decisions and utilization of the network.

To enhance the WiM data other sources of data were identified including:

- bridge monitoring,
- automatic number plate recognition,
- GPS tracking of heavy vehicles,
- authority to operate,

- onboard mass management, and
- classifier data.

These sources of data were combined with the WiM data which created a virtual WiM (Figure 6) tracking tool which dramatically increased the range of network covered. This was achieved through extrapolating data from a WiM site and applying it to a classifier site which was statistically similar. This extrapolation methodology was tested by comparing WiM sites where the extrapolated data was compared to the actual data collected which showed strong correlation.

The virtual WiM tracking tool developed was used to track load platforms as these pose the largest risk to TMR's bridges due to their overall mass. The trial was successful and was able to provide TMR with valuable information about specific loads crossing bridges which informed risk assessments and future heavy vehicle access decisions.

The virtual WiM approach enhances data quality, coverage, accessibility and the value of existing WiM datasets. It provides greater volumes of reliable data to make informed decisions on heavy vehicle movements without the need for significant investment in WiM assets across the network.

Figure 5. View of span 9 of test bridge. source: NACOE.

4.3.3 *Timber bridge management*

Across Australia, in particular in rural areas, timber bridges still make up a significant proportion of in-service bridges. The majority of these were built and designed before 1950 to outdated standards and for loads significantly less than current legal loads. Due to this NACOE and WARRIP recently conducted the two below research projects related to the management of timber bridges.

4.3.3.1 In-line timber replacement options

TMR manages over 300 timber bridges across its network. Some of these require replacement or significant rehabilitation in coming years. The replacement often occurs in-line with closure of the bridge and provision of sidetrack and crossing to facilitate safe and efficient construction. To reduce the timeframe for construction TMR was interested in investigating the available rapid construction methods in the industry and understand their compliance with TMR bridge design criteria and specifications.

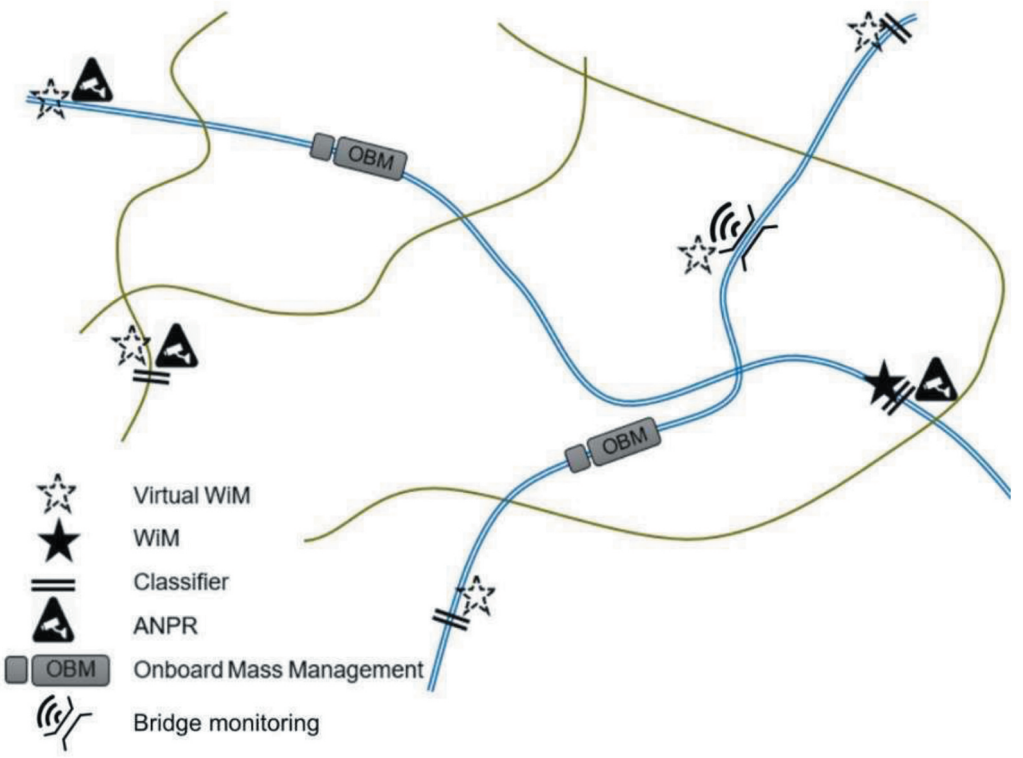

Figure 6. Virtual WiM concept combining various data sources across the network. source: NACOE.

As part of the project, NACOE determined the typical functional requirements for bridge replacement projects and investigated the available market solutions. Six pre-engineered solutions were reviewed to understand their applicability and limitations. A matrix was developed to inform decision makers of the feasible options based on a typical project and product characterization.

The matrix provides details for the following aspects for the available solutions:

- Lengths available
- Widths possible
- Number of lanes
- Number of spans
- Design life
- Design traffic load
- Design standard
- Substructure and superstructure material
- Construction duration
- In-line constructability
- Approximate cost (deck only per sq.m)
- Departures from TMR Standards
- Limitations

To assist TMR with the selection of the available options a decision supporting tool was developed. The selection process was broken into three main steps covering the following areas:

- Site condition screening
- Preliminary section
- Final selection.

The site condition screening step consists of assessing site accessibility, bridge componentry, geometry, design, construction, and resource availability. The output of this assessment is then compared to the solutions available in the market to see which best matches the specific site.

The preliminary selection stage utilizes a matrix that was developed for several advanced parameters against the bridge systems available to further refine the outcome from the site condition screen step. The matrix includes aspects like componentry, typical geometry, design loading and standard, duration of construction, cost and importantly departures from TMR standards.

The final selection step includes a detailed review of data provided for each bridge system which helps TMR to better understand the design criteria and performance of the product.

The decision supporting tool created as part of this project provides a consistent and unbiased approach to the selection of the most appropriate rapid construction system. The tool also provides a significant time saving.

4.3.3.2 Advanced epoxy timber pile repair

MRWA has many bridges across its network with timber piles originally constructed 60-80 years ago. It has been monitoring these structures over time and has identified a common defect pattern due to pile decay (Figure 7). They have been utilizing an epoxy fill solution for their timber piles for approximately 20 years to address this decay and mitigate further localized deterioration. This solution is relatively cost and time effective when compared to other solutions such as pile splicing or full replacement.

A WARRIP opportunity was identified to further develop this solution and investigate whether it could also increase structural capacity. The first stage in the development of this solution was to investigate currently available epoxy resins to see what is most suitable for this method. The resins identified were assessed against key criteria including viscosity,

Figure 7. Trial site showing typical pile decay. source: WARRIP.

permeability, bond characteristics, shrinkage, pot life, cure time and characteristic strength. Based on this criteria epoxy resins were selected for on-site field trials to test and further refine the construction methodology and test the epoxy resins suitability. After two weeks the sections repaired were cut and removed to observe the penetration across the cross-section, see Figure 8 below.

Figure 8. Pile cross-section showing epoxy resin penetration. source: WARRIP.

The trials conducted have led to further refinement of the construction methodology including pile preparation, improvement to formwork and reducing the volume of material required. This has also led to improved selection of the epoxy resin and refinement of the MRWA specification for this work. This research will continue in 2024 to evaluate the mechanical and structural performance of the epoxy resin repair solution.

5 CONCLUSION

Australia is a large country with a dispersed population and its economy is heavily reliant on the road network to transport freight efficiently and effectively to remain competitive in the global market. Those tasked with managing the road network face significant challenges with an ageing road bridge network designed and built to outdated standards, loads increasing in frequency and mass and more frequent extreme climatic events like floods and bushfires.

Australia's road infrastructure managers are investing in research programs such as NACOE and WARRIP to rise to the challenges posed. Through these programs they have been able to improve the assessment, maintenance, and management of their structures to provide the level of service required by the freight industry and the community and support Australia's economy. These programs have also provided a significant return on investment with

Benefit Cost Ratios (BCRs) as high as 14 on some projects and the overall program BCRs being in the range of 3.6 to 5.7. Continued investment in research and programs like NACOE and WARRIP will help Australia to meet the challenges or today and into the future an provide benefit to the Australian economy and community.

ACKNOWLEDGEMENTS

I would like to acknowledge the following:

- IABMAS 2024 Committee for requesting me to deliver a keynote paper and presentation at their conference.
- Department of Transport and Main Roads Queensland for partnering with NTRO under the NACOE Program and for review and input into his paper.
- Main Roads Western Australia for partnering with NTRO under the WARRIP and for the review and input into this paper.

Field tests for remaining life prediction of aged bridges

A. Miyamoto
Prof. Emeritus, Dr. Eng., Yamaguchi University, Ube, Japan

ABSTRACT: The remaining life prediction is a crucial part of the systematization of maintenance planning because it can be used to estimate the end of service duration of the bridges. This paper describes the details of how to predict the remaining life of an aged RC-T girder bridge based on the chloride ion and carbonation tests results of the concrete cores and the cross-section cutting-off girders as the field tests required to determine the performance of concrete from material(durability) point of view. The concrete cores were tested for both carbonation and chloride ions whereas the cross-section cutting-off girders were tested for carbonation only. The results of the concrete cores investigation show that the main factor in the deterioration of the bridge is carbonation and that chloride ion attack has also contributed to the deterioration of the bridge. In order to establish a method of the remaining life prediction based on the chloride ion and carbonation tests results of the concrete cores and the cross-section cutting-off girders, a flowchart is proposed for the remaining life prediction of an RC bridge based on the extent of deterioration due to carbonation and chloride attack. The end of the service life (duration) was defined as the point at which the cumulative amount of steel corrosion reached a critical value which is obtained by a practical bridge management system (J-BMS BREX) to predict the remaining life of the existing concrete bridges.

1 INTRODUCTION

Lifetime management for civil infrastructure is becoming more important issue in sustainable development of societies around the world. In advanced countries the benefits of long-term management of civil infrastructure have been recognized by the experts of the discipline. Integrated lifetime management and maintenance planning includes continuous condition assessment, predictive modeling of performance, maintenance planning and decision-making procedures regarding maintenance action (Sarja 2006). The remaining life prediction is a crucial part of the systematization for maintenance planning because it can be used to estimate the end of bridge's service life(duration). The reinforced concrete (RC) structures such as aged bridges are exposed to the environmental impact and strongly influenced by environmental conditions during their service life resulting in reducing of the remaining life. High level of carbon dioxide as a result of the high traffic volume leads to carbonation process. The chloride attack should be considered as another factor of deterioration if the location of the bridge is near the sea. Either carbonation or chloride attack or both can lead to corrosion of the reinforcing bar. The most serious deterioration mechanisms that occur in RC bridges are associated with corrosion (JSCE 2013).

In case of aged bridges, a bridge management system, J-BMS which integrated with a bridge rating expert sub-system, BREX has developed by the authors for making appropriate safety evaluation and remaining life prediction (Miyamoto & Motoshita 2015, Miyamoto & Asano 2018). Especially, the remaining life prediction by the system needs to be verified through the concrete core tests extracted from some parts on main girders, deck slabs and bridge piers(local), such as compressive strength, carbonation depth, chloride ion concentration, etc., and cross-section cutting-off girder examinations of a target bridge for entire carbonation depth, cover concrete thickness, inside cracking, etc. respectively.

This paper describes a new method for predicting the remaining life of an aged bridge using the limited number of concrete cores, and verify the remaining life prediction results using cross-

DOI: 10.1201/9781003483755-11

section cutting-off girders. Because the remaining life prediction is one of the methods to estimate the end of life of the bridge and moreover to determine how best to make these decisions be made concerning whether to maintain or to demolish/reconstruction the target bridges. The remaining life of both concrete cores and cross-section cutting-off girders was calculated using some equations according to the method to predict the remaining life, with the requirement that the cumulative amount of steel corrosion (Q) equal to 75 mg/cm^2. This value is similar with the remaining life as indicated by the J-BMS BREX system in the evaluation of deterioration of the bridge due to chloride ion attack (Takahashi, et al. 2012). Therefore, the possibilities will be open to identifying the relationships between local evaluation results (were obtained by examining concrete cores), overall structural evaluation results (were obtained from the J-BMS BREX system), and the entire evaluation results (were obtained by examining cross-section cutting-off girders). By expanding the scope of an evaluation from local to the entire structure of the bridge, it may also be possible to enhance testing efficiency by reducing the total number of the concrete cores which are necessary for testing. The main objectives of this study are: ①to develop a method for predicting the remaining life of an aged bridge through the chloride ion and carbonation tests on concrete cores and cross-section cutting-off girders, ②to predict the remaining life and service life from concrete cores and cross-section cutting-off girder. The service life prediction is restricted by a criterion value i.e., cumulative amount of steel corrosion, Q = 75 mg/cm^2 which is obtain by the J-BMS BREX system, ③to verify the remaining life prediction results of the concrete cores with cross-section cutting-off girders.

Although there are various definitions of terms related to service life (duration) for RC structures, in this study the end of the service life was defined as the point at which the cumulative amount of steel corrosion due to carbonation and/or chloride ion attack reached a critical value. Figure 1 shows a schematic illustration of terms related to service life. The service life was divided into four stages: initiation, propagation, acceleration, and deterioration stages. The initiation stage is identified on the basis of the measured carbonation depth and the thickness of remaining concrete cover. The initiation of corrosion occurs when the thickness of remaining concrete cover falls below 10 mm. The propagation stage can be defined as the stage in which cracking occurs due to corrosion. Cracking will occur if the cumulative amount of steel corrosion is approximately 10 mg/cm^2. The acceleration and the deterioration stages are defined with respect to the critical value of the cumulative amount of steel corrosion, which in this study was taken to be 75 mg/cm^2.

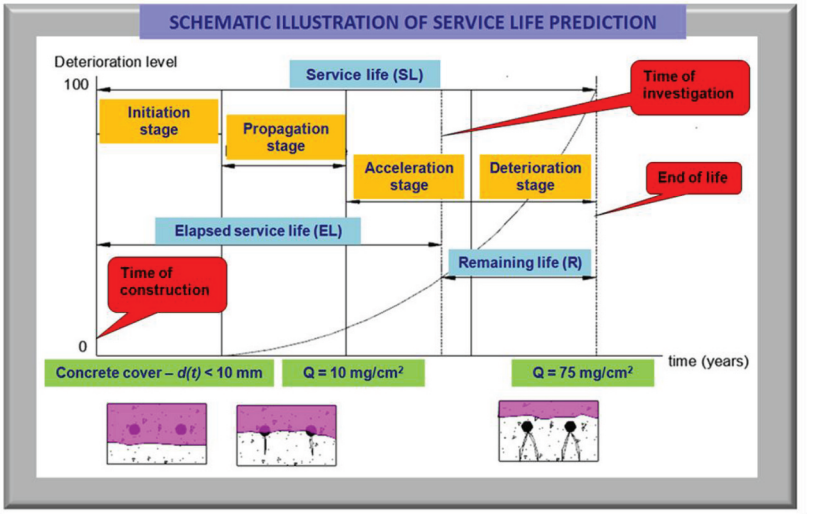

Figure 1. Schematic definition of service life (duration) and remaining life.

2 CONCEPT AND FLOW OF FIELD TESTS FOR REMAINING LIFE PREDICTION

2.1 *Target (Aged) bridge and flow of field tests (*Widyawati 2015)

The target bridge investigated for this study is an aged bridge to be removed ("SK-Bridge" over 72 years old) located on the main route of National Highway No. 2 at the border between Yamaguchi and Hiroshima prefectures, Japan. The SK-bridge has simple supported eight-span reinforced concrete cantilever T-girder (5 girders) structure, total length of 168.3 m and a width of 11.0 m, and was completed in 1942. The bridge was exposed to high level carbon dioxide environment during its service period because of the high traffic volume on the main route, and was located less than 1 km upstream from the Seto Inland Sea. Figure 2 shows the configuration and dimensions of the SK-bridge before removal.

Figure 3 shows the main concept and flow of investigations and inspections for the field tests mainly through close visual inspection and materials (concrete core and cross-section cutting-off girder) test results. According to the flow, at first, close visual inspections in-situ were carried out by professional engineers for predicting quantitatively of remaining life of the target bridge by applying the J-BMS BREX with field inspection data. Then, in order to verify the remaining life prediction result by the system, concrete core tests which extracted from some parts of SK-bridge and cross-section cutting-off girder examinations were carried out from the durability point of view. Finally, as a new bridge health monitoring method for short and medium span bridges, "bus-based monitoring system" using a public bus was conducted along with a safety index, "characteristic deflection" which is relatively free from the influence of dynamic disturbances due to such factors as the roughness of the road surface and a structural anomaly parameter (Miyamoto & Yabe 2012).

2.2 *Concrete core tests*

2.2.1 *Extract of concrete cores*

In this study, concrete cores were extracted from Girder 1 to Girder 5 of Spans 1 and 3 (Figure 2), which are the inspected girder spans. The coring locations are shown in Figure 4 for Spans 1 and 3 with cross dots (⊕), white dots (○) and black dots (●). The concrete cores were extracted from four regions roughly demarcated according to cross beam locations in each span. It was assumed, for purpose of this study that each core shows the average state of internal deterioration in each region (Widyawati 2015). The extracted concrete cores were examined for chloride ion content test called C-series that is identified as ⊕ and "C". The numbers of C-series are 11 specimens for Span 1 and 12 specimens for Span 3. M-series were examined for carbonation test that is identified as ○ and "M". The numbers of M-series are 15 specimens for Span 1 and 20 specimens for Span 3. Furthermore, S-series were examined for both carbonation and chloride ion content tests that is identified as ● and"S"with 6 specimens for both Span 1 and 2.

2.2.2 *Chloride ion test*

The concrete cores of C-series were analysed for chloride ion content. The concrete cores at depth between 0 and 105 mm in depth direction were divided into seven pieces (at interval of 15 mm) and, thus, prepared for analysing the chloride ion content. The measurement was conducted in accordance with JIS A 1154: 2003; "Methods of test for chloride ion content in hardened concrete" and the specimens were examined down to the depth at which the initial chloride ion content could be determined. In the test method, the total amount of chloride ion contained in the powder sample which is extracted with nitric acid, and its mass rate to the sample was measured.

2.2.3 *Carbonation test*

The concrete cores of the M-series were analysed for carbonation test. The measurement of carbonation depth was conducted in accordance with JIS A 1152: 2011; "Method for measuring carbonation depth of concrete". The carbonation test is most commonly carried out by spraying 1% phenolphthalein solution on the surface of the concrete cores. The carbonation depth was assessed using 1% phenolphthalein solution, the indicator that appears pink (or purple) in contact

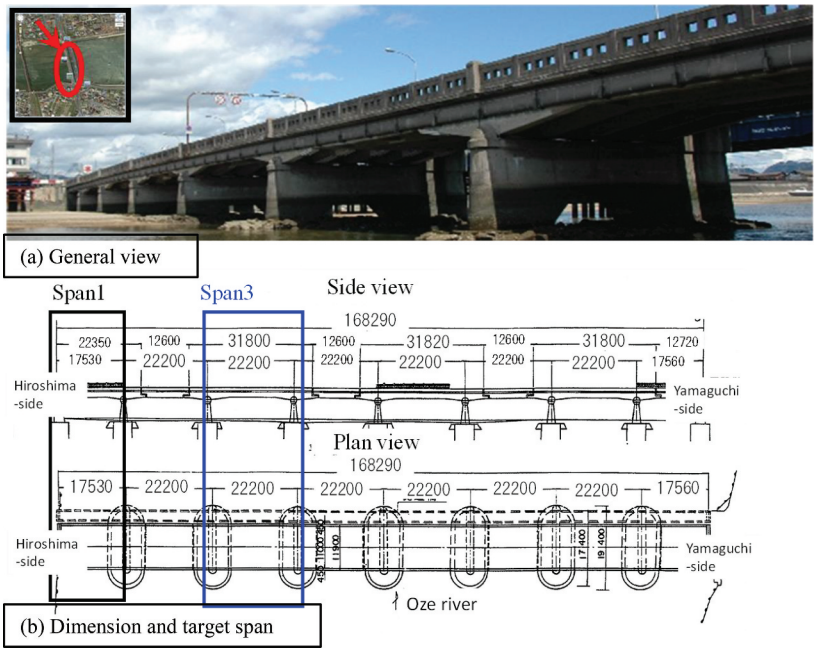

Figure 2. Details of SK-Bridge (before removal) and inspection area (span) (unit: mm).

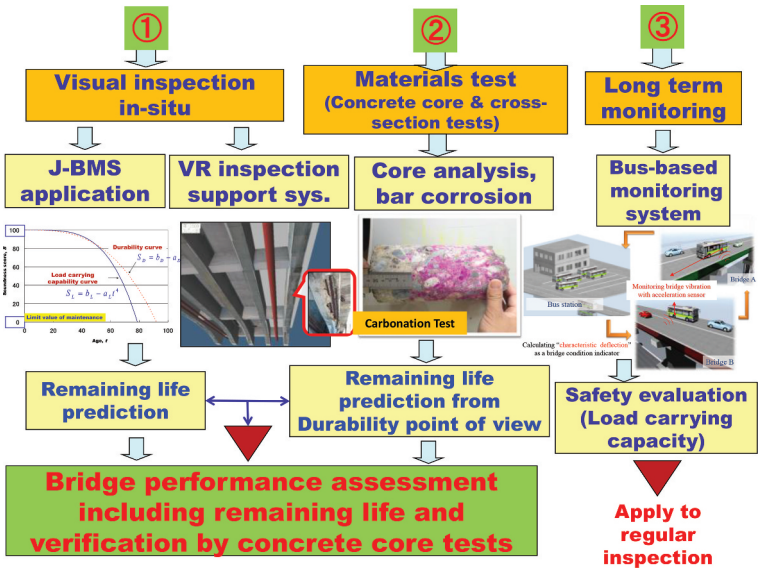

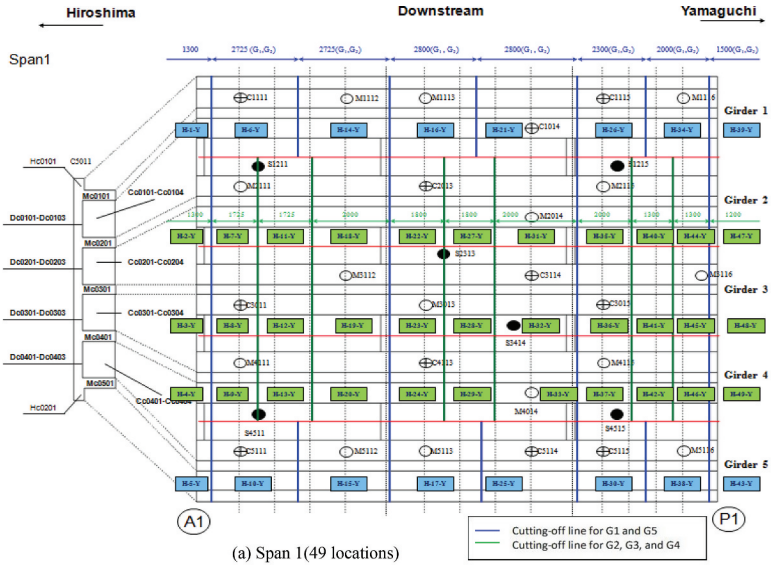

Figure 3. Concept and flow of field tests for remaining life prediction.

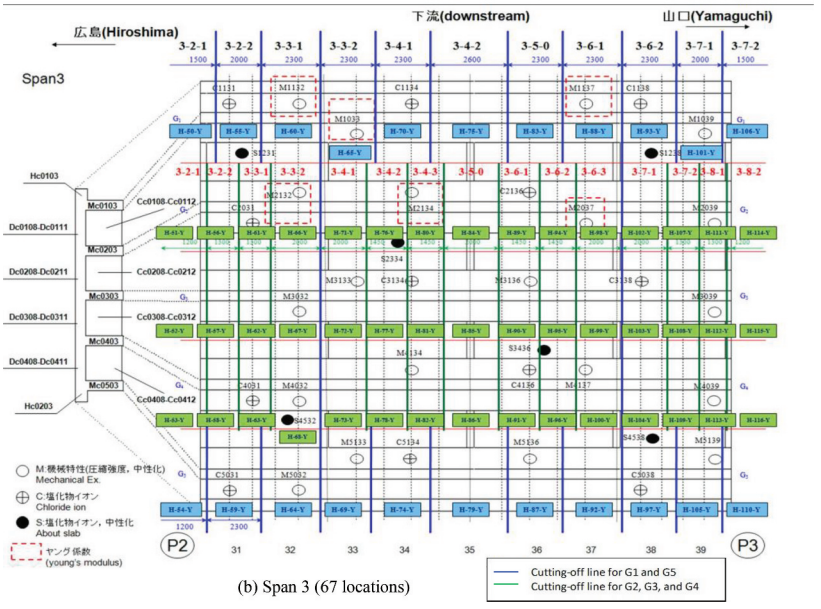
with alkaline concrete. Collared area is detected alkaline area, defined as the healthy concrete area (un-carbonated). Collarless area is defined as the carbonation area. To avoid further carbonation on the cutting-off surface, the carbonation test was carried out immediately within 30 minutes after cleaning. Carbonation depth is the distance between the concrete cover surface and the boundary between collared and uncollared areas.



2.3 *Cross-section cutting-off girder examinations*

2.3.1 *Cross-section cutting-off girders*

The demolition of the bridge provided a good opportunity to obtain many types of useful information. Two spans, Span 1 and Span 3, shown in Figure 2, were inspected. Each span consisted of five girders, Girder 1 (G1) through Girder 5 (G5) (see Figure 4). The girders had been cut into pieces with the maximum weight approximately 10 tons, in order to move from the bridge location to the demolishing place. The cross-section cutting-off girders locations with the identification symbol for each cross-section cutting-off girders are shown in Figure 4(a) for Span 1 and Figure 4(b) for Span 3. Figure 5 shows an example of cross-section cutting-off girder after

(a) Span 1(49 locations)

(b) Span 3 (67 locations)

Figure 4. Location of concrete cores extracted and cross-section cutting-off girders.

Figure 5. Example of cross-section cutting-off girder of SK-bridge.

spraying phenolphthalein. The total number of cross-section cutting-off girders of Span 1 and Span 3 were 49 and 67, respectively. Each cross-section cutting-off girders has an identification symbol. It was given the identity as: H-number-Y, where "H" is Hiroshima side and "Y" is Yamaguchi side. "Number" is the number of cross-section cutting-off girders, 1 to 116 pieces.

2.3.2 *Examination of cross-section cutting-off girders*

The demolition of SK-Bridge began with the removal of each span of the main girders of the bridge. The first girder removed was the outer girder on the mountain side, G5. The outer girder on the sea side, G1, was removed next, and then the inner girders, G4, G2, and G3 were removed.

After the girders were removed from the bridge, they were placed on a temporary bridge. The cutting process used the special equipment for cutting concrete called a wire saw machine with the diamond wire. The cross-section cutting-off girder was cut with a maximum weight approximately 10 tons, it is the maximum weight that could be moved by a truck to a particular place to be demolished.

2.3.3 *The thickness of concrete cover measurement*

The cross-sections cutting-off girders were examined to measure the thickness of the concrete cover on the reinforcement. The thickness of the concrete cover is very important because the concrete cover serves to protect the reinforcing bars from damage due to environmental exposure. Among the environmental effects that may cause corrosion in reinforcing bars are attacked by carbon dioxide, acid, and salt (Papadakis, et al. 1991). As well known, corrosion in the reinforcing bar affected the deterioration of the reinforced concrete structures. Therefore, the thickness of concrete cover should be controlled to meet the minimum requirements needed. The thickness of concrete cover is the thickness of concrete between the concrete cover surface and the outer reinforcing bar. In this investigation, the location of embedded reinforcing bars is quite varied. Then, the value of thickness of concrete cover was assumed by average values of the measurement. This was measured for the sea sides, bottom sides, and mountain sides of the girders.

2.3.4 *Carbonation depth measurement*

Carbonation tests are most commonly carried out by spraying a phenolphthalein solution on freshly exposed surfaces of concrete or on concrete cores. In this study, this carbonation test method was applied to the cross-section surfaces of the cross-section cutting-off girders. To avoid further carbonation of the cut surfaces, the carbonation tests were conducted within 30 minutes of the cross-section surfaces being cleaned and prepared for testing. In accordance with Japanese Industrial Standard JIS A 1152, the carbonation depth was assessed by examining the area of the surface that appeared pink or purple after application of the phenolphthalein solution. The concrete in areas where this coloring appears is alkaline and is considered to be healthy and to have experienced no carbonation. The concrete in areas that remain collarless is not alkaline and is considered to be concrete that has experienced carbonation. The carbonation depth of the cross-section cutting-off girders was also measured. The carbonation depth is the distance between the concrete cover surfaces and the boundary between the collared and uncollared areas.

3 TEST RESULTS AND REMAINING LIFE PREDICTION

3.1 *Results of the thickness of concrete cover measurement*

Table 1 shows the thickness of concrete cover measurement results for the cross-section cutting-off girders from Spans 1 and 3. The results shown are the averages of the values obtained by measuring the distances between the concrete cover surface and the outer reinforcing bars. In an RC bridge, the most serious deterioration mechanisms are those that lead to corrosion of the reinforcing bars, resulting in a reduction in the effective cross-sectional area of the reinforcing bars and in spalling of the concrete cover. The nature of the deterioration in an RC bridge may be chemical, such as reinforcing bar corrosion due to carbon dioxide and chloride attack on the concrete. Concrete cover serves to protect the reinforcing bars from environmental exposure that leads to corrosion. In the deterioration process caused by carbonation, the thickness of concrete cover affects the time required for carbon dioxide to reach the reinforcing bars. A thicker concrete cover increases the diffusion time of carbon dioxide in the concrete.

Table 1. Thickness of concrete cover and carbonation depth (average) of Spans 1 and 3.

		Thickness of concrete cover			Carbonation depth

Average		59.42	50.46	55.03	61.68	36.93	57.06

3.2 *Carbonation depth measurement results and carbonation rate coefficient*

The carbonation depth measurement results for the cross-section cutting-off girders from Spans 1 and 3 are also shown in Table 1. The results shown are the averages of the values obtained from five to ten measurement points. The carbonation rate, which can be obtained from the carbonation depth measurements, can be used to predict the carbonation depth in future years. The thickness of concrete cover and the carbonation depth can be used to predict the initiation of corrosion due to carbonation. The initiation of corrosion is frequently identified from the remaining concrete cover, i.e., the difference between the thickness of concrete cover and the carbonation depth. In previous studies (JSCE 2013), researchers have concluded that the initiation of corrosion occurs when the remaining concrete cover falls below 10 mm. Thus, the remaining cover affects the initiation of corrosion.

The carbonation rate coefficient, A can be determined from measurements of the carbonation depth, $d(t)$ in mm at time (t) in years. The change in the carbonation depth over time is calculated according to the $\sqrt{t}$ rule, as shown in Eq. (1):

$$d(t) = A\sqrt{t} \tag{1}$$

The carbonation depth results are the averages of the values obtained from eight to sixteen measurements from the cross-section cutting-off girders from each span.

3.3 *Chloride ion content and main deterioration factor*

Table 2 shows the chloride ion data obtained from the concrete core tests on the SK-Bridge. The apparent chloride ion diffusion coefficient was calculated from the following equation:

$$C(x,t) = C_0 \cdot \left(1 - erf\left[\frac{x}{2\sqrt{(D_{ap} \cdot t)}}\right]\right) + C_i(x,0) \quad (2)$$

where $C(x,t)$ is the chloride ion content at depth x at time t, C_0 is the chloride ion content at the concrete surface, D_{ap} is the apparent chloride ion diffusion coefficient, and $C_i(x,0)$ is the initial chloride ion content in the concrete. Table 2 also summarizes the results of the

chloride ion content tests (i.e., $C(x,t)$, C_0, and $C_i(x,0)$) of the concrete cores. The apparent chloride ion diffusion coefficient, D_{ap} is an unknown parameter in Eq. (2) and is determined from the results of the chloride ion content tests. The results obtained for depths of 30–45 mm in the concrete cores were used as the chloride ion contents at the reinforcement depth, $C(x,t)$.

According to the Standard Specifications for Concrete Structure Maintenance of the Japan Society of Civil Engineers (JSCE) (JSCE 2013), corrosion due to carbonation typically begins when the thickness of remaining concrete cover falls below 10 mm. This means that remaining concrete cover is an indicator of the degree of influence of carbonation. Table 1 shows the results of the concrete cover thickness and carbonation depth measurements. The average carbonation depths in the main girders of both Span 1 and Span 3 are greater than the average of the thickness of concrete cover, except for the bottom side of Span 3, which has received some repair work. The maximum carbonation depth was 60 mm or greater in more than half of the cross-section cutting-off girders, which is considerably greater than the thickness of the concrete cover.

The average chloride ion content determined from the tests on the concrete cores taken from the SK-Bridge was 1.07 kg/m^3, as shown in Table 2. This value is lower than the critical chloride ion content for steel corrosion of 2.0 kg/m^3. Table 2 also shows that only four of the 23 points on the bridge had chloride ion contents higher than the critical content for steel corrosion, and these contents were only slightly higher than the critical chloride ion content. Based on these results, it was concluded that the main cause of the deterioration of the SK-Bridge was carbonation because the carbonation depth was considerably greater than the thickness of concrete cover. The average chloride ion content did not exceed the critical chloride ion content for steel corrosion. However, given that the bridge is located less than 1 km upstream from the mouth of the Sagawa River that it spans, which empties into the Seto Island Sea, chloride ion attack is believed to have also contributed to the deterioration of the bridge.

3.4 *Service life prediction*

In this study, the end of the service life was defined as the point at which the cumulative amount of steel corrosion due to carbonation and chloride ion attack reached a critical value of Q = 75 mg/cm^2. This value was obtained from the J-BMS BREX system, which is used in cases in which the main deterioration factor is chloride attack.

The service life, SL in years can therefore be expressed as the sum of the elapsed service life, EL (in this case, 72 years) and the remaining service life, R in years, as shown in Eq. (3):

$$SL = EL + R \tag{3}$$

Although carbonation was concluded to have been the main factor in the deterioration of the SK-Bridge, based on its location, approximately 1 km upstream from the mouth of the river it spans, chloride ion attack was concluded to also have affected the deterioration of the bridge.

Figure 6 shows a flowchart of the service life prediction method for the case in which the deterioration is mainly caused by carbonation but is also affected by chloride ion attack. Initial corrosion due to carbonation is assumed to begin when the remaining concrete cover, i.e., the thickness of the concrete cover minus the carbonation depth, is 10 mm or less.

The carbonation depth at 72 years was obtained from the measurements of the cross-section cutting-off girders. The carbonation rate coefficient, A was calculated from the carbonation depth, $d(t)$ at time t using Eq. (1).

Eq. (4) is used to calculate the steel corrosion rate, V if the remaining concrete cover is 10 mm or less. If the remaining concrete cover at time t is greater than 10 mm, Eq. (5) should be used.

$$V = 1.32(Cl - 1.2)k \tag{4}$$

$$V = (0.840W - 0.145C + 1.32Cl + 0.0293W \cdot C - 0.0917C \cdot Cl + 0.658Cl \cdot W - 2.52)k \tag{5}$$

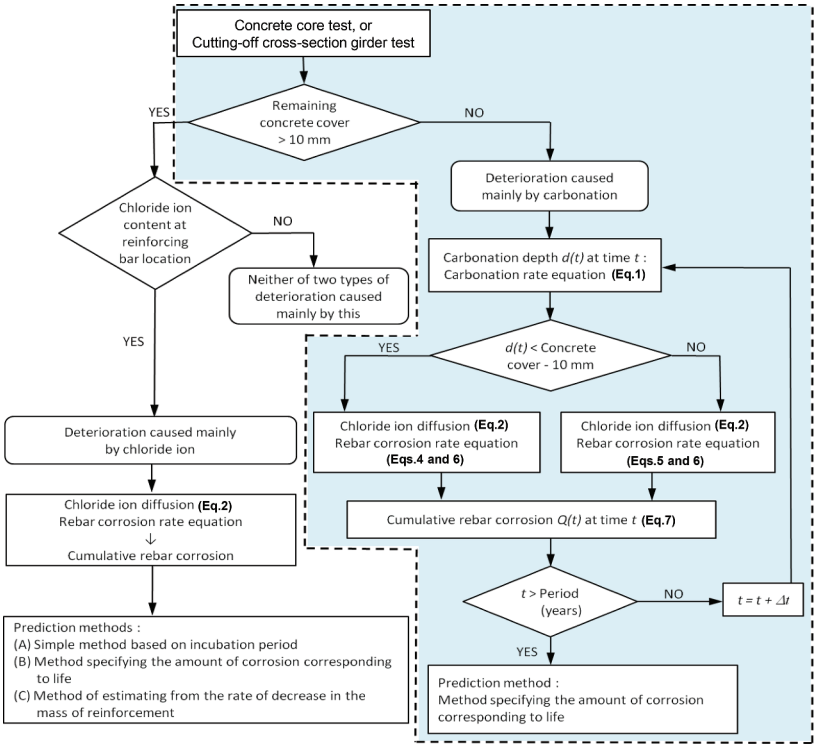

Figure 6. Flowchart of remaining life prediction.

where, V (mg/cm^2/year) is the steel corrosion rate, Cl (kg/m^3) is the chloride ion content at the reinforcement location, C (mm) is the remaining concrete cover, W (%) is the moisture content of the concrete surface, and k is a correction for the temperature parameter, tmp (°C), which can be calculated from Eq. (6):

$$k = 1 + 0.0381(tmp - 20) \tag{6}$$

The cumulative amount of steel corrosion, $Q(t)$ at time t, in kg/mm^2, can be calculated from the steel corrosion rate, $V(t)$ at time t and the integration time step, dt using Eq. (7):

$$Q(t) = Q(0) + \sum_{t=dt}^{t=X} \left(\frac{dt}{2} \left(V\left(t - \frac{dt}{2}\right) + V\left(t + \frac{dt}{2}\right) \right) \right) \tag{7}$$

where, $Q(0)$ can be calculated using Eq. (8):

$$Q(0) = \frac{dt}{4} \left(V(0) + V\left(\frac{dt}{2}\right) \right) \tag{8}$$

As in a previous study (Widyawati 2015), the remaining life, R of the SK-Bridge, as indicated by the results of the tests on the concrete cores, was calculated as the life expectancy, X in years minus the period of service, N in years. In this study, the service life, SL was calculated based on the time $t = t_1$ elapsed before the total amount of steel corrosion, calculated using Eq. (7), reaches the critical value, $Q(t)$ = 75 mg/cm^2, which was taken to be the indicator of the end of the service life. This is the critical value for the total amount of steel corrosion used in the prediction method of the J-BMS BREX system.

Based on the schematic illustration of the service life prediction (Figure 1), the propagation stage can be defined as when cracking occurs due to corrosion. Cracking will occur if the cumulative amount of steel corrosion exceeds approximately 10 mg/cm^2, which is considered to be the critical amount of corrosion corresponding to initial cracking. The deterioration stages are defined by the critical value of the total amount of steel corrosion, i.e., 75 mg/cm^2. Service life prediction was conducted for the cross-section cutting-off girders listed in Figure 4. The values used for *tmp* in Eq. (6) and *W* in Eq. (5) were 16 °C (mean temperature) and 4%, respectively.

Table 3 shows the results of the service life prediction. These results show that the time before reaching the critical amount of corrosion for initial cracking for the sea sides, bottom sides, and mountain sides of the girders were, on average, 55.6 years, 104.6 years, and 56.3 years, respectively. The service life prediction, based on the cumulative amount of steel corrosion reaching 75 mg/cm^2, were, on average, 81.5 years, 142.6 years, and 81.2 years for the sea sides, bottom sides, and mountain sides of the girders, respectively. As these results show that the predicted service life varies from -33.6 years to 217.7 years.

Table 3. Results of service life prediction for both span 1 and span 3 (on average).

3.5 *Discussions*

3.5.1 *Result of service life prediction*

The service life prediction shown in Table 3 are based on the cumulative amount of steel corrosion reaching 75 mg/cm^2, which is the same as the criterion used in the J-BMS BREX system, which is used in cases in which the main cause of deterioration is chloride attack. The service life prediction were almost the same for the sea sides and mountain sides of the girders, i.e., 81.5 years and 81.2 years, respectively. This means that for the sea side and the mountain side of the SK-Bridge, the service life prediction is approximately 81 years. The service life prediction for the bottom side is much longer, approximately 142 years, because of repair work done on the bottom side. This repair work was proven to work well. It effectively extended the service life by approximately 60 years, compared with that for the sea side and the mountain side.

3.5.2 *Comparison between service life prediction by concrete cores test and cross-section cutting-off girders examination*

Concrete cores were extracted from all of the girders in Spans 1 and 3, but only on the sea and mountain sides. On the bottom side, it was quite difficult to extract concrete cores because of the reinforcing bars embedded in the bottoms of the girders. In a previous study (Takahashi, et al. 2014), the service life prediction of the SK-Bridge, based on tests on concrete cores, was found to be approximately 77 years (remaining life of approximately 7 years). This service life prediction is similar to the values predicted in this study for the sea and mountain sides of the bridge, based on tests on the cross-section cutting-off girders, i.e., approximately 81 years (remaining life of

approximately 9 years). Service life prediction based on concrete cores represents the locations from which the cores were extracted. In contrast, service life predictions based on cross-section cutting-off girders represent the entire girders. The two sets of service life prediction were compared. The results are shown in Figures 7 and 8. The relationships between the service life predictions from the concrete cores and those from the cross-section cutting-off girders had correlation coefficients of 0.73 and 0.71 for Spans 1 and 3, respectively, on the sea side and 0.57 and 0.59 for Spans 1 and 3, respectively, on the mountain side. These correlation coefficients indicate good correlation. The service life predictions obtained on the basis of the core testing were similar to those obtained based on the testing of the cross-section cutting-off girders, which represent the entire span of the bridge.

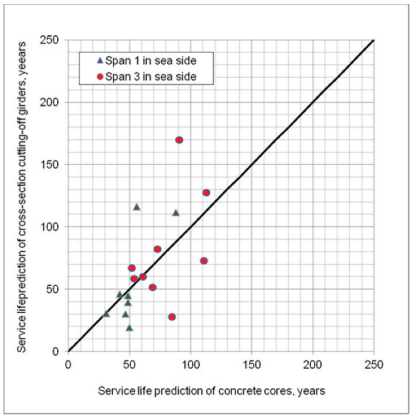

Figure 7. Relationship between service life prediction of concrete cores and cross-section cutting-off girders at 72 years on the sea side (on averages).

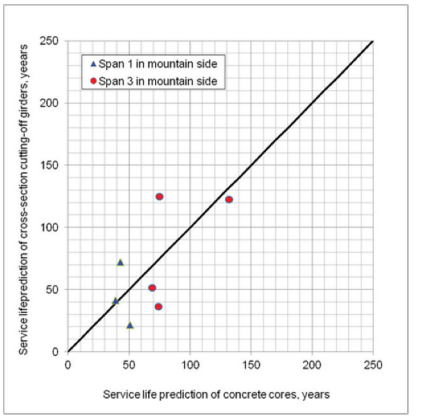

Figure 8. Relationship between service life prediction of concrete cores and cross-section cutting-off girders at 72 years on the mountain side (on averages).

4 CONCLUSIONS

This paper presents the details of carbonation tests and proposes a method to predict the remaining life of an RC bridge (72 years in service) based on the extent of deterioration related to corrosion of the reinforcing bars due to carbonation and chloride attack. Main conclusions of the paper are summarized as follows:

1) The results of the carbonation tests showed that the main factor in the deterioration of the bridge has been carbonation associated with corrosion of the reinforcing bars. However, because the bridge is located less than 1 km upstream from the mouth of the river it spans, which flows into the sea, chloride ion attack should be considered as another factor in the bridge's deterioration.
2) The end of the service life of the bridge was defined as the point at which the total amount of steel corrosion reached a critical value of Q = 75 mg/cm^2. The predicted service life of the SK-Bridge was predicted to be approximately 81 years (remaining life = 81 years – 72 years = 9 years) for the sea side and mountain side, and approximately 142 years (remaining life = 142 years – 72 years = 70 years) for the bottom side. The predicted service life for the bottom side was longer than for the other side because of repair work done on the bottom side.
3) The extent of carbonation is typically assessed by conducting visual inspections or examining concrete cores. However, in this study it was possible to conduct carbonation tests on cross-section cutting-off from girders from an existing bridge. The carbonation tests yielded a considerable amount of information, but the results exhibited some variability. Therefore, the results of the carbonation tests of the cross-sections cutting-off girders were verified by conducting carbonation tests on concrete cores. The service life estimates

obtained on the basis of the core testing were similar to those obtained on the basis of the testing of the cross-section cutting-off girders, which represent the entire span of the bridge.

4) The results of comparison between service life prediction for the case in which the deterioration is mainly caused by carbonation and also affected by chloride ion attack and for the case in which the deterioration is caused only by carbonation in the sea sides and mountain sides of the girders on both cases were almost similar, approximately 80 years. This caused by the differences in the requirements and thresholds used in determining the end of life on these cases and the different equations were used.

ABSTRACT: Monitoring measurements have been conducted on an integrated columns by multiple steel pipe applied to actual bridges to verify that the pier behave according to the concept assumed in the design. In this measurement, the response is measured for both ordinary conditions and small earthquake conditions. This study proposes a method for verifying the performance of an integrated column by multiple steel pipe using the measured data, and evaluated the performance of the piers using the measured data obtained so far. For ordinary conditions, the measured data were used to verify that the behavior of the piers was as assumed in the design, and for small earthquake conditions, the validity of the analysis model was verified by reproduction analysis using observed waveforms.

1 INTRODUCTION

In the Hanshin-Awaji Earthquake of 1995, piers collapsed or were severely damaged, and it took a long time to restore them. Therefore, Hanshin Expressway developed an integrated column by multiple steel pipes that have higher earthquake resistance than reinforced concrete piers or steel piers, and can be restored easily and quickly.

An integrated column by multiple steel pipes is a single column composed of four steel pipes connected by shear links that incorporate shear panels with historical damping functions. In this structure, vertical loads such as dead and live loads are supported by steel pipes, and horizontal loads such as seismic forces are resisted by shear links. In the event of Level2 earthquake, which is specified in the Specifications for Highway Bridges, Part V Seismic Design [1], the damage is concentrated in the shear panels so that the steel pipes remain sound, allowing vehicles to pass through quickly after the earthquake. In addition, during emergency inspections after an earthquake, the shear panels are damaged before other members, thus limiting the number of members to be inspected. Furthermore, in the event of damage that requires restoration, performance can be restored simply by replacing the shear panels, thereby contributing to the reduction of seismic life-cycle costs.

These concepts have been verified through analysis and experimentation and applied to actual structures such as the Ebie Junction and Nishi-Senba Junction on the Hanshin Expressway. However, it has not been verified whether the columns behave according to the concepts in the actual structure. In response, a monitoring plan based on the structural characteristics of integrated column by multiple steel pipes was developed, and the behavior of the actual bridge has been measured since April 2021.

In this study, we proposed a method for evaluating the performance of integrated columns by multiple steel pipes using the measured data. Furthermore, an example of the performance evaluation of integrated column by multiple steel pipes is shown using the data measured so far.

DOI: 10.1201/9781003483755-12

2 TARGET STRUCTURE AND MEASUREMENT

2.1 *Target structure*

The integrated column by multiple steel pipes targeted for evaluation was applied to the PD4 of the D-ramp (1), which is the crossing line from the Kobe Route to the Yodogawa-sagan Route at the Ebie JCT. A plan view of the D-ramp (1) is shown in Figure 1 (processed from an aerial photograph). The D-ramp (1) bridge including PD4 is a 5-span continuous steel box girder bridge with orthotropic steel deck between PD1 and PD5 (92.7 + 60.5 + 50.5 + 49.0 + 78.9 = 331.6 m). The end bearings are movable at PD1 and fixed at PD5, and the piers between them are rigidly connected. The height from the ground surface to the superstructure of PD4 is about 30 m, the highest of all the piers on the D-ramp (1), and is a location where the characteristics of the integrated column by multiple steel pipes can be fully utilized. The piers other than PD4 are conventional rectangular section steel piers.

A structural drawing of the PD4 is shown in Figure 2. PD4 consist of four steel pipes, connected by shear links in four cross-sections. A caisson foundation with a diameter of 7000 mm was adopted due to site constraints, and diameter of steel pipe and shear link dimension were determined from the caisson diameter. From the top of the caisson to a height of 13 m, including the second shear link from the bottom, the steel pipes are filled with concrete filling as in the case of conventional steel piers.

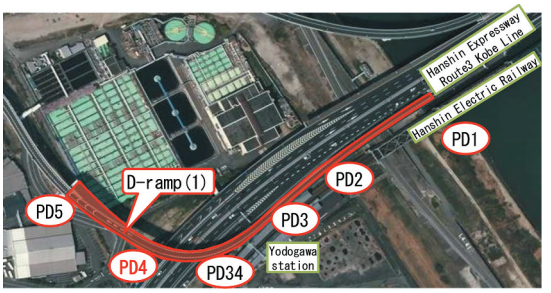

Figure 1. Bridge plan view of D-ramp (1).

2.2 *Measurement items*

The measurements based on the monitoring plan have been taken since April 2021. Figure 3 shows the locations of the measurement equipment and the names of the measuring points, and Figure 4 shows the installation status of the equipment.

The measurement cross section of the strain gauges was set at the base of the piers at 100 mm from the protective concrete, and at the top of the piers at a minimum distance of 100 mm from the fillet between the superstructure and the piers to avoid the effect of the stress concentration. Strain gauges were attached to each steel pipe at four points in the longitudinal and transverse direction and at 16 points per cross-section, and the direction of measurement was vertical direction. Accelerometers were set 100 mm below the ground surface and above each shear link of Pipe B, for a total of five locations. The measurement directions were the longitudinal direction, the transverse direction, and the vertical direction regarding the integrated column by multiple steel pipes.

Table 1 shows the frequency and duration of measurements. The effect of live load is measured once a year for about three days in spring, when traffic is average, and the effect of wind load is measured once a year for about one days when strong winds, such as typhoons. The effect of temperature load is affected by atmospheric temperature, so it is measured four times a year for about one week in spring, summer, fall, and winter. In the case of an earthquake, a trigger is determined by an accelerometer installed at the base of the steel pipe, and measurement is started when a certain level of acceleration occurs. In this measurement, the threshold value is set to 1 gal so that data can be obtained even for small seismic motions.

Table 1. Interval and duration of measurements.

Situation		Number of times and timing of measurements	Measurement Period
Ordinary Condition	Live Load	Once a year(Spring)	About 3 days
	Wind Load	Once a year(typhoon)	About 1 days
	Temperature Change	Four times a year (Spring・Summer・fall・winter)	About 1 week
Earthquake Condition	Level 1 Earthquake	At the time of earthquake	300 seconds after earthquake
	Level 2 Earthquake		
	Over Level 2 Earthquake		

3 PROPOSAL FOR PERFORMANCE EVALUATION USING MONITORING RESULTS

Figure 5 shows the performance evaluation flow using the measurement results. In this flow, when the performance can be evaluated directly from the measurements, the performance is evaluated by organizing and analyzing the measurement data. On the other hand, when the performance cannot be evaluated directly from the measurements, the performance is evaluated indirectly by reproducing the behavior of the structure through analysis. When using analysis, the reproducibility of the model is first verified by comparing the responses at the measured positions in the analytical model with the measured actions. If there is a discrepancy between the measurements and the analysis results, the analytical model is reviewed after analyzing the factors that may cause the discrepancy, and the performance of the integrated column by multiple steel pipes is evaluated using the analytical model whose reproducibility is verified. Here, we show an example of analysis based on these two evaluation methods.

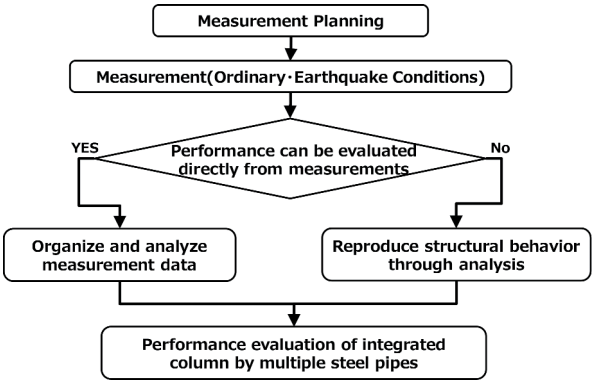

Figure 5. The flow of the proposed performance evaluation.

3.1 *Performance evaluation using measured data*

The following is an example of performance evaluation based on measured data for behavior under temperature change. The Integrated column by multiple steel pipes is assumed to "Four steel pipes resist horizontal loads as a single column". In contrast, since it is suspected that each steel pipe resists discretely, the behavior was analyzed using measured data during temperature change.

Among the measured data, the lowest outside temperature was 3.6°C at 5:38 on January 23, 2022, and the highest outside temperature was 39.1°C at 16:04 on July 23, 2022. Figure 6 shows the amount of change in pipe strain resulting from this temperature change (+35.5°C). Focusing on the strain at the base of steel pipes, the strain at the outer transverse direction of pipes B and D (B-b-2 and D-b-2) changed by +617 με and +649 με, respectively, and the strain at the outer transverse direction of pipes A and C (A-b-4 and C-b-4) changed by -350 με and -524 με, respectively. This is considered to capture the behavior of PD4 being pushed outward out of the curve due to the extension of the superstructure caused by the +35.5°C temperature change. And the strain at the outermost edge in the direction of extrusion is the maximum and minimum, respectively. In this manner the strain distribution behaves like a single column, so it was confirmed that the four steel pipes resist as a single column. On the other hand, the strain at the top of the steel pipes did not show the same tendency as that at the base of the pipes. This is because the strain at the top of the steel pipes includes not only the strain caused by the horizontal behavior due to temperature change but also the vertical strain caused by the live load.

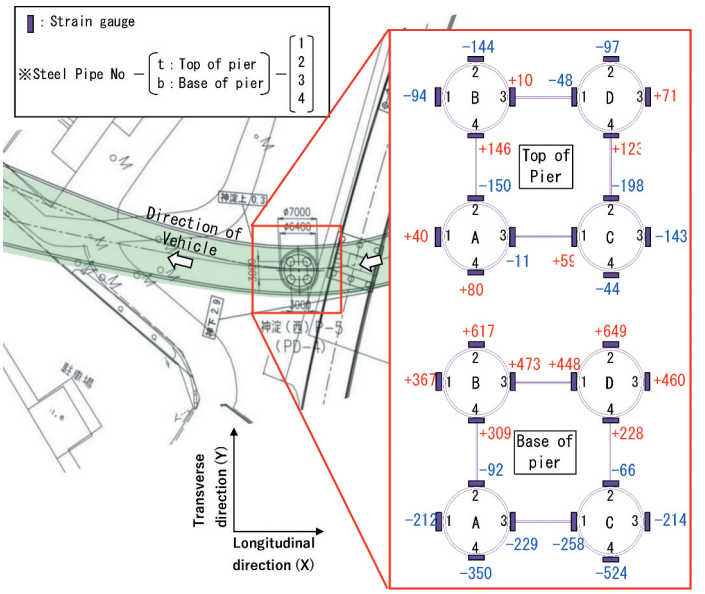

Figure 6. Change in steel pipe strain with temperature change (+35.5°C).

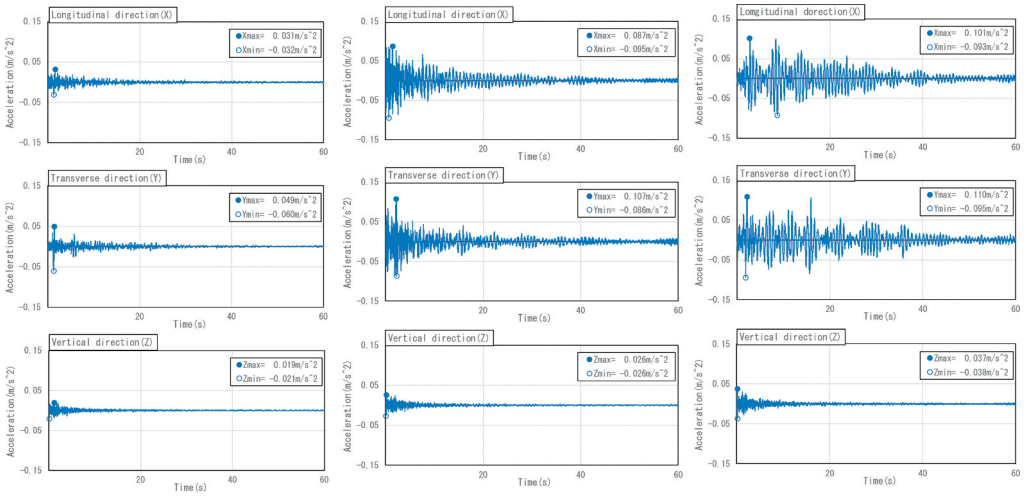
3.2 *Performance evaluation using analysis*

At 23:34 on March 31, 2022, a magnitude M4.3 earthquake occurred with its epicenter in the southern part of Kyoto Prefecture, recording a maximum intensity of 4 near Kameoka City, Fushimi-ku, Kyoto Prefecture. The seismic intensity of 2 was observed in Fukushima-ku, Osaka City, where Ebie JCT is located, and seismic observation data was obtained with the installed measurement equipment.

The integrated column by multiple steel pipes is designed to behave elastically in the event of small to medium-sized earthquakes. However, this behavior is difficult to evaluate from the limited number of measurement points shown in Figure 4 and from visual observation, so it is



necessary to reproduce the behavior of the integrated column by multiple steel pipes during an earthquake by time history response analysis and to evaluate the behavior using the analytical model. On the other hand, it has been reported that the nonlinear dynamic analysis models generally used in seismic design do not match the behavior of small- and medium-scale earthquakes. Therefore, since the acceleration during the earthquake could be measured, although it was a small earthquake, we first used this observation data to confirm the reproducibility of the behavior using a general nonlinear dynamic analysis model.

3.2.1 *Observation waveform*

The time history waveforms of the acceleration at the measured points and the acceleration response spectra with 5% damping are shown in Figures 7 and 8. The points at the base of the pier (Pt. 1), the second shear link from the base (Pt. 3), and the fourth shear link from the base (Pt. 5) are shown here as representative points among the accelerometers shown in Figure 6.

3.2.2 *Modeling of target bridges*

The analytical model was a fiber model that can account for biaxial bending moments, axial force variation, and geometric nonlinearity for the entire system of D-ramp (1). Figure 9 shows the 3-D frame model of the entire bridge system and the modeling method for the integrated column by multiple steel pipes. The fiber elements of the steel pipe cross section of the PD4 piers were divided into 64 sections in the circumferential direction and 2 sections in the thickness direction.

(a) Pt.1 (b) Pt.3 (c) Pt.5

Figure 7. Observed acceleration response time history waveform.

The function separating type bridge supporting of the PD1 are modeled with linear spring elements in the longitudinal and transverse directions.

Since the purpose of this study is to analyze the behavior of the actual bridge, the yield strength of each member is based on the actual strength. For the PD4 piers, the yield strength was set based on the material tests, σ_y = 377 N/mm^2 for steel pipes (standard value: σ_y = 315 N/mm^2) and σ_y = 229 N/mm^2 for shear panels (standard value: σ_y = 225 N/mm^2). The yield strength of the pier members, except for the PD4 piers, was the average value of the statistical data, based on the results of the statistical data survey.

3.2.3 *Reproducibility of small earthquakes*

A dynamic analysis was conducted using the acceleration measured at Pt.1 as the input earthquake motion to confirm the reproducibility of the acceleration measured at Pt.3, Pt.4, and

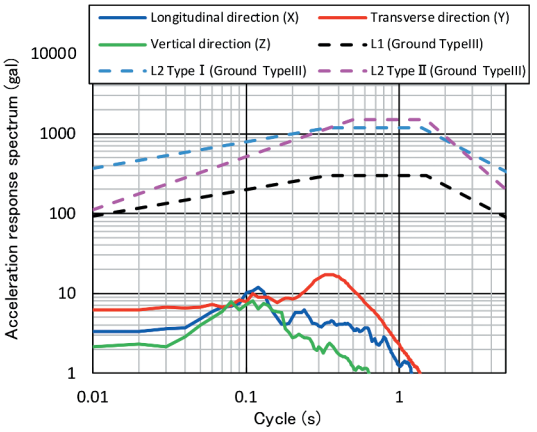


Figure 8. Acceleration response spectra of observed waveform (Pt.1).

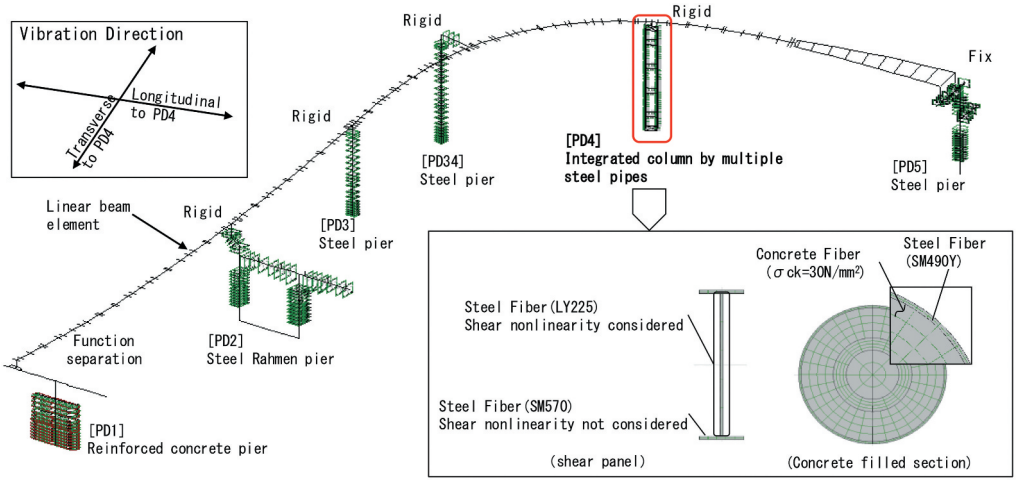

Figure 9. Analytical model of D-ramp (1) and the integrated column by multiple steel pipes.

Pt.5. Pt.1 is an accelerometer installed at the base of the PD4 pier, and this acceleration is the response acceleration waveform affected by the seismic response of the foundation structure and the interaction between the foundation structure and the ground. To use this response acceleration waveform as the input seismic motion, the boundary condition of the analytical model was fixed at the base of the piers, and the seismic motion was applied to the base of the pier. The earthquake motion was applied to the PD4 in three directions simultaneously: longitudinal, transverse, and vertical, in accordance with the direction of measurement. The general-purpose structural analysis program SeanFEM was used for the analysis.

Figure 10 shows a comparison of the observed and analyzed acceleration response time history waveforms in the longitudinal and transverse direction for Pt. 3, Pt. 4, and Pt. 5. In terms of the maximum acceleration, the observed waveform tends to be larger than the analytical result at Pt. 3, while the results at Pt. 4 and Pt. 5 are almost identical. However the acceleration response time history waveforms did not match, and there were some points where they were in opposite phase.

Figure 11 shows the Fourier spectrum of Pt. 5. Focusing on the lowest dominant frequency in the longitudinal direction, the observed waveform is 1.28 Hz, while the analytical result is 1.11 Hz. Similarly, in the transverse direction, the analytical results show a shift to the low frequency side (long period side) compared to the observed waveform. This is because the stiffness

of the superstructure of the analytical model does not take into account the stiffness of the concrete balustrade and pavement, and the stiffness of the concrete balustrade, especially when the width is narrow and the girder height is low, as in the case of a ramp bridge, is considered to have a large impact. In addition, because this is a curved bridge, the out-of-plane stiffness of the concrete balustrade is expected to affect both the longitudinal and transverse directions.

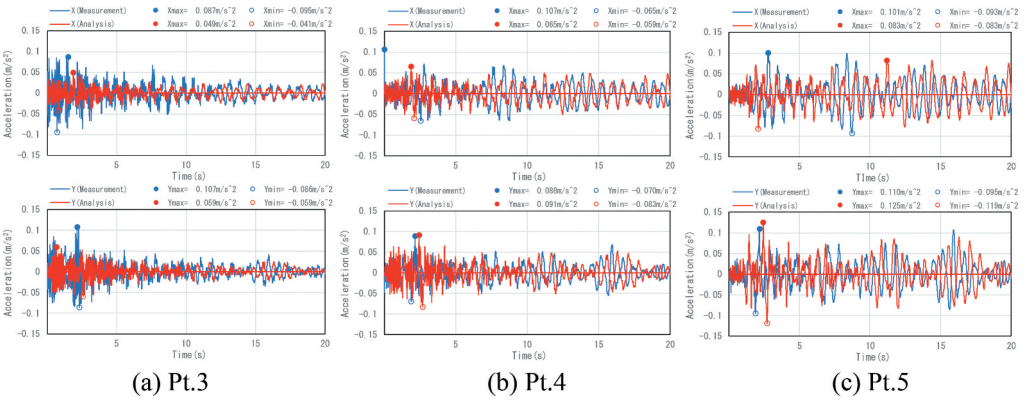

Figure 10. Comparison of observed and analyzed acceleration response time history waveforms (Upper row: bridge longitudinal direction, lower row: transverse direction).

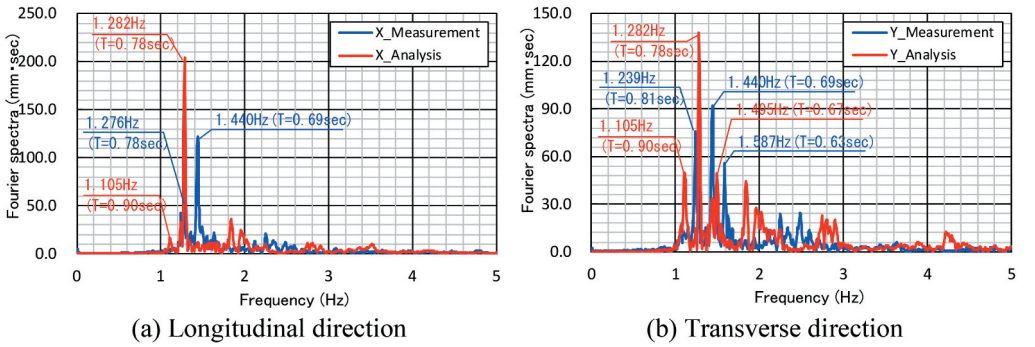

Figure 11. Comparison of Fourier spectra of observed and analyzed waveforms (Pt. 5).

Thus, it is necessary to check the reproducibility of the behavior of the measured positions using the analytical model, and if the measured values differ from the analytical values, the analytical model should be updated after analyzing the factors causing the discrepancy. It is effective to evaluate items that are difficult to evaluate from measurement data and visual observation, such as whether the entire steel pipe and all shear panels behave elastically, using an analytical model whose reproducibility has been confirmed.

4 CONCLUSION

This study proposes a method for evaluating the performance of integrated columns by multiple steel pipes using measurement data and an example of performance evaluation using the measurements obtained so far. The findings are as follows.

(1) An evaluation flow was proposed for cases in which the performance can be directly evaluated from the measurements, and for cases in which it cannot.

(2) As an example of the case where direct evaluation is possible from the measurements, the strain at the base of the steel pipe measured when the temperature changes was analyzed, and it was confirmed that the four steel pipes resisted as a single column as assumed in the design.
(3) As an example of a case that cannot be directly evaluated from the measurements, the measured acceleration during a small earthquake was used to verify the reproducibility of a general nonlinear dynamic analysis model. As an example of a case that cannot be directly evaluated from the measurements, the measured acceleration during a small earthquake was used to verify the reproducibility of a general nonlinear dynamic analysis model. The results showed that the analysis tended to be long-period in both the longitudinal and the transverse direction. This is thought to be due to the stiffness of the concrete balustrade, which is not considered in the analytical model.

In the future, it is necessary to analyze the causes of the discrepancy between the actual behavior and the behavior of the analytical model, and to evaluate the performance with a matched model. It is also necessary to evaluate the performance of the integrated column by multiple steel pipes piers when subjected to larger actions, using the measurement data obtained.

ACKNOWLEDGEMENTS

The authors would like to thank Hanshin Expressway Engineering Co., Ltd. and Naigai Kozo Co., Ltd. for their cooperation in measuring the behavior of an integrated column by multiple steel pipes.

Prediction of bridge service duration for CBM by the indirect monitoring using vehicles

Akito Yabe
Kozo Keikaku Engineering Inc., Tokyo, Japan

ABSTRACT: Recently, the structural maintenance way is transforming from the time-based maintenance (TBM) to the condition-based maintenance (CBM). On the other hand, to be realized the CBM, the end of service duration must be predicted and be decided taking measures by applying the state-of-the-art digitalized technologies. But it is impossible to carry the technologies for all huge number of bridges, cause to need huge budget. For solving the issues many kinds of solution were proposed. The most effective method is to narrow down the target by screening. By using vehicles such as city bus, the road roughness condition, bridge condition, and underground condition and so on will be measured frequently. And these are given us for analyzing as big data to evaluate the road condition. This result can indicate the end of service, even if the deterioration mechanism is unknown.

1 INTRODUCTION

A huge number of bridges exist all over the world. And now, a lot of bridge is constructed. From long ago, life cycle bridge maintenance has been widely discussed for establishing the rational maintenance strategies of existing bridges based on the end of bridge service duration. The service duration of a bridge the period during which people and vehicles can safely pass through it. And the safety indicators like as bending, shear or deflection capacity are relation with the end of bridge service duration. Also, it is a key technology for holistic bridge maintenance decisions. For evaluating durability, load carrying capacity and remaining service duration state-of-the-art digitalized technologies like as smart monitoring systems, non-destructive testing and digital twins are needed.

However, the safety indicator is composed highly complex and multi-oriented issue (JSCE2022). Because the safety indicator is influenced each other by material deterioration, maintenance condition, traffic condition, environment change, disaster damage, and so on. Therefore, an important point is surely notice that the bridge is coming on reaching the end of service duration.

And recently, the structural maintenance way is transforming from the time-based maintenance (TBM) to the condition-based maintenance (CBM). To be realized the CBM, the end of service duration must be predicted and be decided taking measures by applying the state-of-the-art digitalized technologies. And in the case of based on the operation by CBM for near the end of service bridge, it will be needed that more frequently inspection and investigating bridge condition. Because near the end of service bridge condition may change unexpectedly and rapidly bad. If inspection and investigating bridge condition are emptied many years, it become sever accident like collapse. But it is impossible to carry and to operate frequently the technologies for all huge number of bridges, cause to need huge budget.

For solving the issues many kinds of solution were proposed. The most effective method is to narrow down the target by screening. For monitoring methods that aim to screen a large number of bridges over a wide area, it is desirable to use general indicators, such as deflection, that are not dependent on bridge and deterioration type. Additionally, a mobile indirect monitoring system is more reasonable than a monitoring system installed on each bridge (Konstantinos Gkoumas et al. 2021).

DOI: 10.1201/9781003483755-13

In this paper, as one of the utilities of the indirect monitoring using vehicles is introduced. By using vehicles such as city bus, the road roughness condition, bridge condition, and underground condition will be measured frequently. And these are given us for analyzing as big data to evaluate the road condition. This result can indicate the end of service, even if the deterioration mechanism is unknown.

Figure 1 shows the relationship between current inspection operation and proposed system. In this study the monitoring system is designed specifically to detect fatal damage signs of relatively large changing at the acceleration and deterioration stages to be used in conjunction with a continuous monitoring system using periodic inspections and structural health monitoring (SHM) . This system assumes the use of especially buses of a kind of large vehicles. This is because,

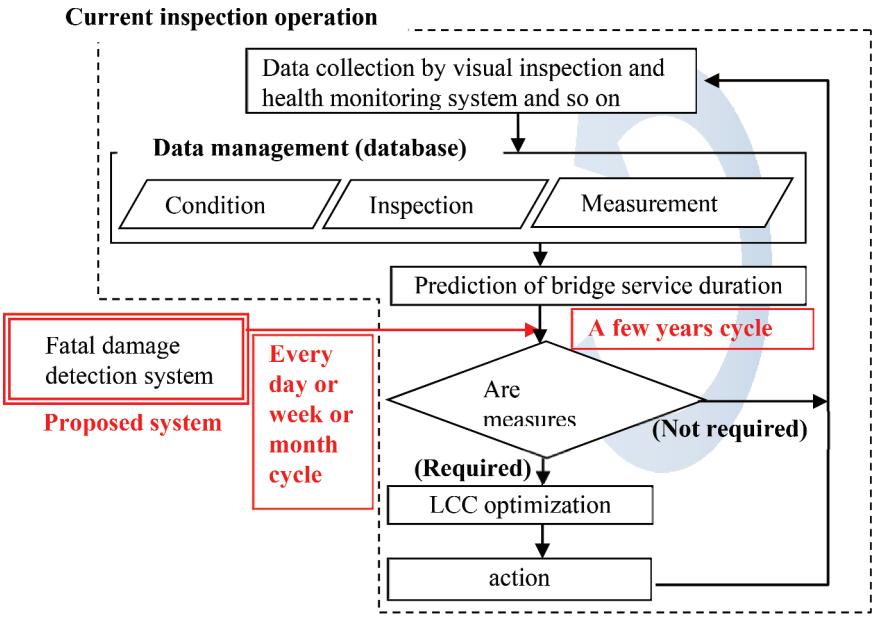

Figure 1. The relationship between current inspection operation and proposed system.

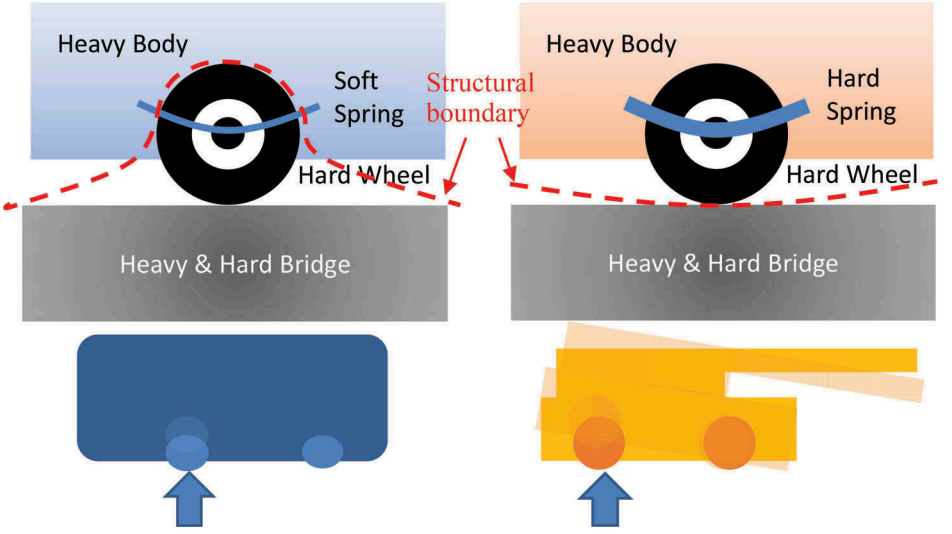

Figure 2. The structural feature of bus and others.

as shown in Figure 2, the structural boundary is unlike other large vehicles, the body of a bus for transporting people is structurally insulated from the wheels using soft springs (Akito Yabe 2020).

Figure3 shows the monitoring system using city bus. An acceleration sensor is installed on the center of the rear axle and connected to a data logger at the rear of the bus. Power is supplied from the bus. Acceleration data is saved together with location information obtained by the GPS sensor. After measuring, GPS data is used for extracting running on the bridge data, and the indicator of the end of bridge service be calculated.

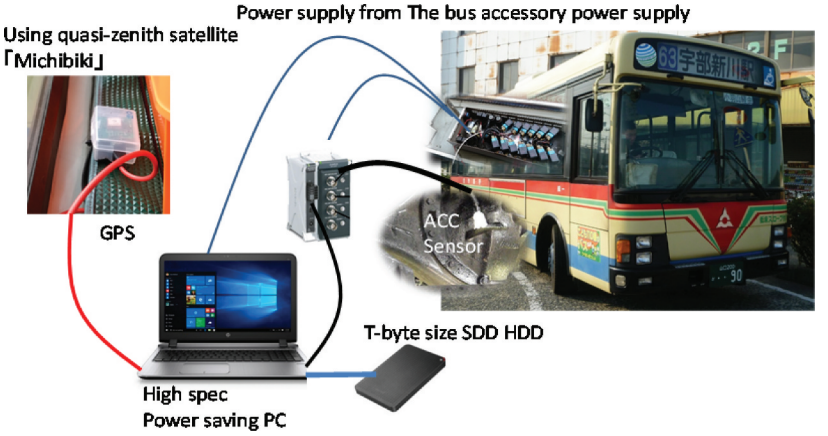

Figure 3. The monitoring system using city bus.

2 PRINCIPLE OF THE INDIRECT MONITORING USING VEHICLES

When a vehicle passes over a bridge, its mechanics model can be expressed as a dynamic interaction between the equation of motion of the bridge, expressed by Equations (1), and the equation of motion of the vehicle, expressed by Equations (2) (Kawatani, M. and Shimada, R 1988). The method of formulating a bridge structure model and a vehicle structure model as separate equations of motion and expressing their interaction at joints with input and output vectors is called the "substructure method".

$$M_m\ddot{u}_m + C_m\dot{u}_m + K_m u_m = \begin{Bmatrix} R_s \\ R_m \end{Bmatrix} \tag{1}$$

$$M_s\ddot{u}_s + C_s\dot{u}_s + K_s \begin{Bmatrix} u_{s_f} \\ u_{s_g} \end{Bmatrix} = \begin{Bmatrix} 0 \\ R_s \end{Bmatrix} \tag{2}$$

where the parameters are as follows
$M_mC_mK_m$, $M_sC_sK_s$: mass/damping/stiffness matrix for bridge and for vehicle,

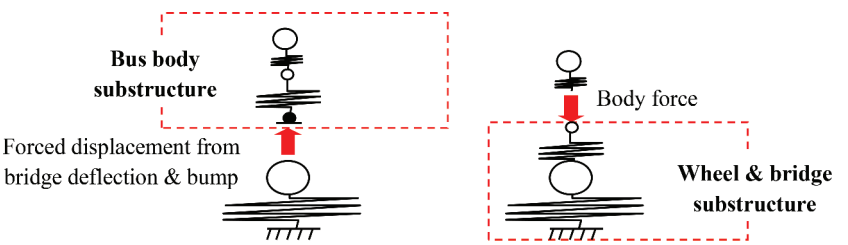

Figure 4. Substructures for modeling bridge and bus body.

$\ddot{u}_m \dot{u}_m u_m, \ddot{u}_s \dot{u}_s u_{s_f}$: response acceleration/velocity/displacement vector for bridge and for vehicle,
u_{s_g}: input forced displacement vector for vehicle, and
$R_m R_s$: support reaction vectors for bridge and vehicle.

For bridge–vehicle interactions, the vehicle wheel reaction to the bridge is input as the load vector R_s, and the bridge deflection ($\delta(t) \in u_m$) and road surface unevenness ($\lambda(t)$) are input to the vehicle as the force displacement vector u_{s_g}. Changes in bridge stiffness Km are reflected in the measurement results for both the bridge system and the vehicle system. Then, it can be concluded that, because structural anomalies of the bridge due to deterioration, etc. are reflected in changes in the nodal response $\ddot{u}_s \dot{u}_s u_{s_f}$ of the vehicle system, anomalies of the bridge, in theory, can be detected from the vehicle.

Here, let us consider substructure segmentation based on the bus body–wheel–bridge concept, as shown in Figure 4. First, let us take a look at the bus body–wheel system. In a mechanics problem in which the difference method approximation holds true, when forced displacement including the bridge deformation $\delta(t)$ is input to the wheel of the bus, the equation of motion can be approximated, as shown in Equations (3), by using the proportionality constant *P*, which is dependent on physical quantities that remain unchanged in the system, such as time, stiffness, damping and mass, and the state constant Co (known) before time t obtained by a Taylor expansion, etc.[22] This means that the system's response to the input vector is allocated proportionately depending on the system-dependent constants.

$$u_{s_f} \cdot P(M_s, C_s, K_s, t) + Co(M_s, C_s, K_s, t) = F(t) \tag{3}$$

where the parameters are
$M_s C_s K_s$: mass/damping/stiffness matrix for the vehicle,
u_{s_f}: displacement vector,
Co: known value before time t obtained by Taylor expansion, etc.,
$F(t)$: input vector to vehicle system, and
P: proportionality constant dependent on system.

Next, let us consider wheel–bridge vibration transmitted from the bus body. The response of the wheel and the bridge to the input from the bus body is allocated proportionately depending on the physical constants of the system. Let A_b represent the response vector of the bridge, and A_s, the wheel response vector of the bus. Then, we have matrix *P* expressed as shown below:

$$A_b = \mathbb{P}^{-1} A_s \mathbb{P} \tag{4}$$

This means that if Equations (4) holds true in a mechanics problem in which the difference method approximation holds true, then the vibration behavior of the bridge is proportional to the wheel vibration of the bus, and changes in A_b due to bridge anomalies are reflected proportionately in changes in wheel vibration, A_s, of the bus.

3 THE INDICATOR FOR THE END OF SERVICE

Next, let us explain the rationale behind the method for extracting damage/deterioration-related information from measured rear wheel vibrations of a bus without being affected by the dynamic characteristics of the bridge and the vehicle or the road surface profile. The rear wheel vertical vibration $\delta_a(t)$ of a bus running at a constant speed can be expressed as the sum of static displacement $\delta_{sa}(t)$, which is dependent on the measured rear wheel vertical vibration of the bus, and dynamic displacement $\delta_{da}(t)$, which is dependent on the road surface profile and the vibration characteristics of the bridge and the vehicle:

$$\delta_a(t) = \delta_{sa}(t) + \delta_{da}(t) \tag{5}$$

If it is assumed that the unevenness of the road surface can be expressed as a steady-state random Gaussian process with an average value of 0 and that dynamic displacement including

bridge–vehicle interaction is ergodic and Fourier-series-expandable, the dynamic displacement $\delta_{da}(t)$ can be expressed as their sum:

$$\delta_{da}(t) = S_r(\Omega, t) + \int_{-\infty}^{+\infty} X(f) \cdot e^{2\pi f t i} df \tag{6}$$

where the parameters are
$S_r(\Omega, t)$: density function for unevenness of road surface,
Ω: spatial frequency of road surface profile, and
$X(f)$: Fourier coefficient.

In Equations (6), the sample mean in the second term is 0. The mean of a sufficient number (N) of samples obtained from $\delta_{da}(t)$ can be expressed as

$$\frac{\sum_{t=1}^{N} \delta_{da}(t)}{N} 0 \tag{7}$$

Because the sample mean follows a normal distribution in accordance with the central limit theorem, $\overline{\delta a(t)}$ converges to a certain value (μ_a). For the sample mean $\delta_a(j)$ of a sufficient number (n) of samples, sampling is performed so that there is no overlap in the samples. If N is sufficiently large for $nk = N$ and $t = 1 \sim N$, the following equation holds true:

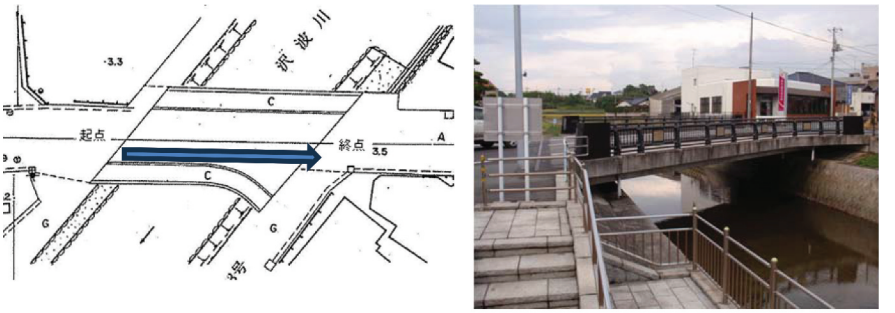
$$\mu_a = \frac{\sum_{i=1}^{n} \overline{\delta a(t)}_i}{n} = \frac{\sum_{i=1}^{nk} (\delta_a(j))_i}{nk} \frac{\sum_{t=1}^{N} \delta_a(j)_t}{N} = \frac{\sum_{t=1}^{N} \delta_{sa}(t)}{N} \tag{8}$$

This means that the mean displacement of the rear axle of the bus passing over the bridge obtained from a sufficient number (N) of samples can be extracted as a value, μ_a (referred to as characteristic deflection for short "CD"), that is relatively free from the influence of the vibration characteristics of the bridge and the vehicle and the dynamic displacement due to the unevenness of the road surface. On the basis of a similar assumption, the mean of the deflection $\delta_b(t)$ at a given point on the bridge during the passage of the vehicle converges to a certain value (μ_b) that is relatively free from the influence of dynamic deflection. By using static deflection $\delta_{sb}(t)$, μ_b can expressed. If similarity holds true between $\delta_{sa}(t)$ and $\delta_{sb}(t)$ as discussed earlier, and values extracted from measurements taken after the occurrence of deterioration or damage are represented by $\mu_a'$and μ_b', then the following equation can be defined:

$$\alpha = \frac{\mu_b'}{\mu_b} = \frac{\mu_a'}{\mu_a} \tag{9}$$

The rate of change α expressed by Equations (9) is defined as the structural anomaly parameter. After a given value of α is set, the characteristic deflection is monitored continuously. When CD has exceeded a certain limit, it can be judged that the bridge of interest has moved from the acceleration stage on to the deterioration stage.

4 LONG-TERM MONITORING EXPERIMENT TEST



The CD component is removed from the acceleration data acquired by the system in Figure 3 and converted to displacement data. From these data, the data when running on the center of the bridge is extracted and the characteristic deflection value is calculated.

Figure 5 shows the long-term monitoring experiment test field at Ube in Yamaguchi Pref. Japan. It was constructed 1998. From 2010 to 2014 the long-term monitoring experiment test was done for short and medium bridge. This bridge is "Prestressed Concrete Bridge". If it loses 50% of prestress force, a stiffness reduction rate is 0.5. and if it loses 90% of prestress force, a stiffness

reduction rate is 0.35 (Akito YABE, Ayaho Miyamoto, et al. 2013). Therefore, a structural anomaly parameter was calculated using dynamic interaction analysis between the bridge, road surface condition and moving vehicle by FEM shown Figure 6. The results are shown Table 1.

The acceleration stage was decided 1.93 as the prediction sign for coming on reaching the end of service duration soon and a structural anomaly parameter of the end of bridge service was decided 2.86.

Figure 7 shows the result of long-term monitoring experiment test. Blue dots are shown each characteristic deflection value. Yellow line is shown the acceleration stage criterion. Red line is shown the end of bridge service criterion. It was confirmed that there were no major structural changes during the experimental period. In the future, if the characteristic deflection value is over the yellow line, that is a sign of coming on reaching the end of service duration soon. And when will reach the end of bridge service can be predicted by the changes of characteristic deflection value like a blue dots line.

Table 1. Results of the structural anomaly parameter by FEM.

speed	Sound condition	Loses 50%%	Loses 90%
30km/h	-1.61 mm	-3.10 mm	-4.59 mm
40km/h	-1.60 mm	-3.10 mm	-4.60 mm
50km/h	-1.61 mm	-3.11 mm	-4.61 mm
average	-1.61 mm	-3.10 mm	-4.60 mm
a structural anomaly parameter		1.93	2.86

5 CONCLUSIONS

Main conclusions are summarized as follows:

1) It was shown that the bus is especially an effective large vehicle to be predicting when the bridge is coming on reaching the end of service duration for CBM.

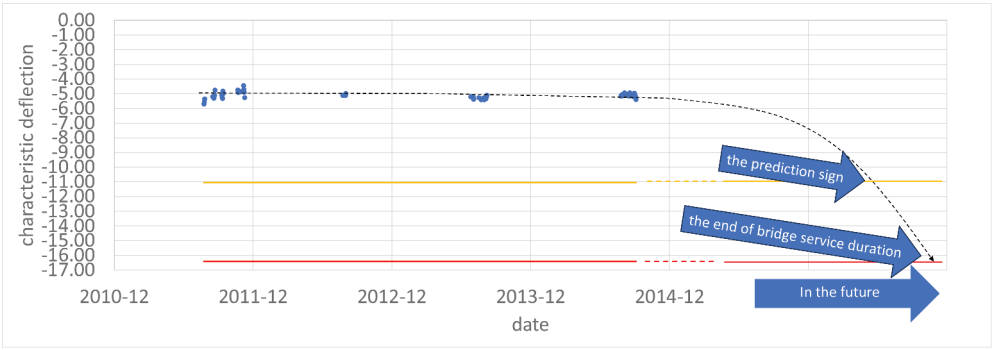

Figure 7. Result of the long-term monitoring experiment test.

2) The vibration behavior of the bridge is proportional to the wheel vibration of the bus. Based on this principle, a calculated "characteristic deflection" is one of indicator to notice the bridge condition.
3) On the long-term monitoring experiment test to a prestressed concrete bridge, it was assumed that the end of bridge service duration when prestress force will lose 90%. And it was assumed that the time when prestress force will lose 50% is the prediction sign for coming on reaching the end of the bridge service duration soon. Based on this assumption, a structural anomaly parameter of the acceleration stage could be decided 1.93 as the prediction sign for coming on reaching the end of bridge service duration soon by FEM.
4) The long-term monitoring experiment is shown that it is able to predict when coming on reaching the end of the bridge service duration soon by using bus.

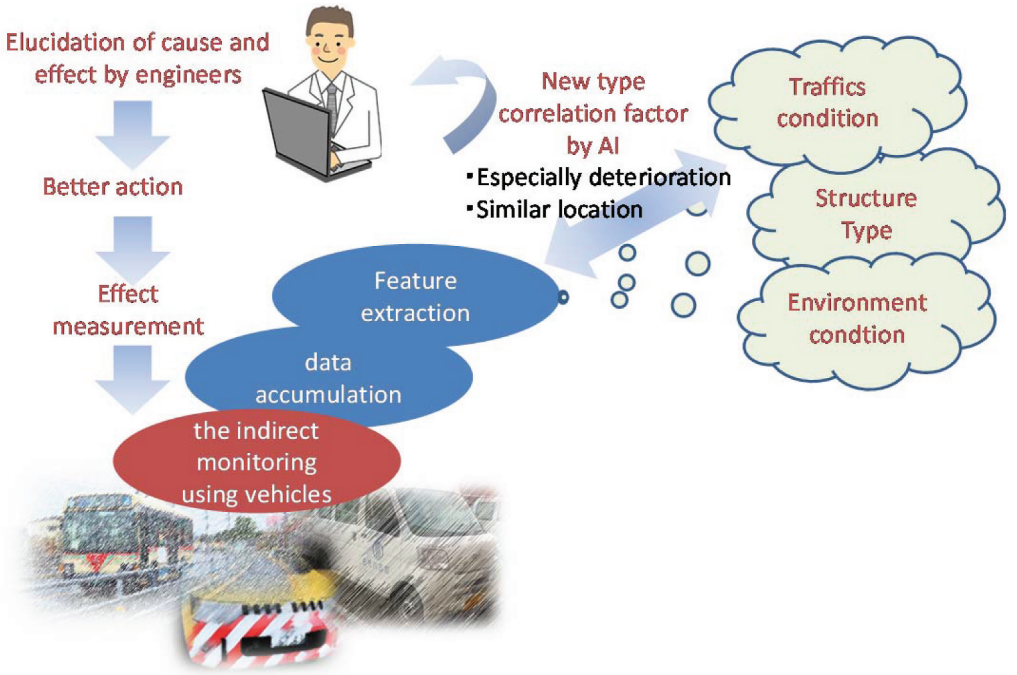

Figure 8. Future of the indirect monitoring using vehicles for CBM.

6 FUTURE OUTLOOK ON RESEARCH

This system has problems concerning data management. In this monitoring experiment measurement data have been picked up offline. Because measurement data is huge, so this system is not connected to online systems like internet. Currently, the development of inexpensive, high-speed, large-capacity wireless communication networks and cloud services is progressing. In the future, these services effectively applying is necessary for this system.

Figure 8 shows one of the indirect monitoring operation using vehicles for CBM. Not only this system but also other monitoring data will be connecter to internet and cloud services at real-time. And AI will help us to predict the end of the bridge service duration by detecting new type correlation factors from the complex cause-and-effect . Engineers have to play an important role in determining the rationality of such causal relationships.

Combining monitoring information and UHPFRC strengthening to extend bridge service duration

Numa Bertola* & Eugen Brühwiler
Laboratory for Maintenance and Safety of Structures, Swiss Federal Institute of Technology (EPFL), Lausanne, Switzerland

ABSTRACT: As many bridges are approaching the end of their supposedly theoretical service duration, finding novel technical solutions to extend their service duration is crucial, also for reasons of sustainability. In this article, two strategies (structural performance monitoring, and strengthening with ultra-high-performance fiber-reinforced cementitious composite (UHPFRC)) are introduced to avoid prematurely replacing structures. The case study of the Ferpècle road bridge (Valais, Switzerland) is presented since the two strategies were combined in 2023 to extend its service duration. This bridge is one of the first prestressed concrete bridges in Switzerland. Built in 1958, the structure consists of a single girder with a 34.5-meter span resting on abutments in the form of reinforced concrete piers. As the deck has a width of only 5.3 meters, bridge owners have decided to widen it to 7.9 meters in order to include two road lanes and a pedestrian way. Despite its good condition, the bridge must be strengthened as its load-bearing capacity (bending moment at mid-span) would be largely insufficient with the new deck width. To increase its load-bearing capacity while widening the bridge deck by 50%, an intervention with UHPFRC has been made. The innovative intervention enables clamping the abutments with the bridge deck to modify the static system to obtain a semi-rigid frame to reduce the bending moment at mid-span. Two load tests using the latest sensing technologies, before and after the intervention, have enabled the quantification of the design capacity and the validation of this pioneering intervention. This case study demonstrates the potential of novel technologies to extend bridge service duration, thereby improving the sustainability of the construction sector.

1 INTRODUCTION

High-performance fiber-reinforced cementitious composite (UHPFRC) has been used in structural designs for over twenty years in many countries (Graybeal et al., 2020). The UHPFRC mix consists of a matrix composed of fine-coarse particles (cement, sand, and silica fumes up to 1 mm in size), water, additives, and a large number of short and slender steel fibers (Brühwiler and Denarié, 2013). Steel fibers (accounting for at least 3 vol-%) give this material its specific mechanical properties and high durability due to its impermeability in service (Brühwiler, 2016).

The mechanical properties of UHPFRC are summarized by (Brühwiler, 2020). UHPFRC has significant characteristic tensile strength (up to 16 MPa) and compressive strength (up to 150 MPa). The elastic modulus is 45-50 GPa, and the material exhibits strain-hardening behavior in tension until 2 ‰. Tensile strength is usually increased by the addition of reinforcing bars (called R-UHPFRC), as for traditional reinforced-concrete structures (Oesterlee, 2010). Technical specification SIA 2052 ("Technical Leaflet on UHPFRC: Materials, Design and Application," 2016) is used to design UHPFRC elements, as well as reinforced concrete (RC) - R-UHPFRC composite elements.

With over 350 applications, Switzerland is a forerunner in using R-UHPFRC both for the construction of strengthening existing structures and new structural designs (Bertola et al., 2021b).

*Corresponding author: numa.bertola@epfl.ch

DOI: 10.1201/9781003483755-14

Regarding the strengthening of existing structures, R-UHPFRC has been used on numerous occasions to improve the load-bearing capacity of bridges, such as the Chillon Viaduct (Brühwiler and Bastien Masse, 2015), the Guillermaux Bridge (Hajiesmaeili et al., 2019) and, more recently, the Riddes Viaduct (El Jisr et al., 2023).

This article presents a recent application of R-UHPFRC for the rehabilitation, strengthening, and widening of a prestressed concrete bridge in Switzerland. The project involves widening the simply-supported bridge deck from 5.3 m to 7.9 m (+50%) by only intervening on the deck. The idea behind the reinforcement is to modify the static system by clamping the abutments to form a monolithic structure. This elegant intervention significantly strengthens the bridge through the parsimonious use of R-UHPFRC while preserving the existing structure. Monitoring campaigns before and after the intervention have enabled the validation of the intervention design.

2 BRIDGE EXAMINATION

2.1 *Presentation*

The Ferpècle Borgne Bridge is a prestressed reinforced concrete double-girder structure (TT cross-section) located in the Swiss Alps in the small village of Les Haudères (Valais) at an altitude of 1450 meters. The bridge was built in 1958 according to the plans drawn up by the engineering firm B.Deléglise - P.Tremblet in Sion, who took over Robert Maillart's engineering office in Geneva, which became Bureau Tremblet, now T Groupe.

The static system is a simply-supported beam with a 34.5-meter span, resting on abutments with side walls approximately 7 meters long (Figure 1). With a beam height of 1.75 meters, the slenderness of 1/20 is audacious for a simple beam. Visual inspection of the structure using the risk approach (Bertola and Brühwiler, 2021) showed that the bridge was in "defective" condition (rating of 3 out of 5), while structural elements are in "acceptable" condition.

2.2 *Structural examination*

With regard to the strength of materials, a C45/55 concrete grade (updated from the C30/37 at the construction) has been selected, leading to a compressive strength of $f_{cd} = 26\ MPa$. The tensile strength of the "Box-Tor-Caron" reinforcing steel was accepted at $f_{sd} = 300\ MPa$. For prestressed bars, an ultimate strength of $f_{pd} = 730\ MPa$ was assumed. Load levels are defined in the Swiss standards for existing structures SIA 269 (Swiss Society of Engineers and Architects, 2011). Structural safety is evaluated based on the concept of the degree of compliance n (Brühwiler et al., 2012) using design values of both structural resistance R_d and action effects E_d.

$$n = Capacity/Demand = \frac{R_d}{E_d} \tag{1}$$

A three-dimensional finite-element model was made in DIANA software to examine the structural safety. This modeling was carried out as realistically as possible, taking into account non-structural elements such as curbs and the asphalt pavement. In addition, each rebar and prestressing tendon have been included in the model. Prestressing is taken from the resistance side.

This model allows the calculation of stresses directly in reinforcing bars and prestressing tendons (Figure 3). For the ultimate limit state (ULS), traffic loads are placed at the most unfavorable locations (at mid-span for bending verifications and close to supports for shear verifications). The stresses in critical prestressing tendons are almost equal to their yield point. Using the numerical model, it is possible to determine the overall degree of compliance by progressively increasing the live-load until failure. A degree of compliance for the mid-span bending verification n_M equal to 1.05 was obtained, showing that the structural safety of the structure in its current state is guaranteed. Analogously, the degree of compliance for the shear verification n_V is equal to 1.10.

Nonetheless, it can be anticipated that after widening (from 5.3 m to 7.9 m), this structural safety will no longer be satisfied. A strengthening scheme will be necessary.

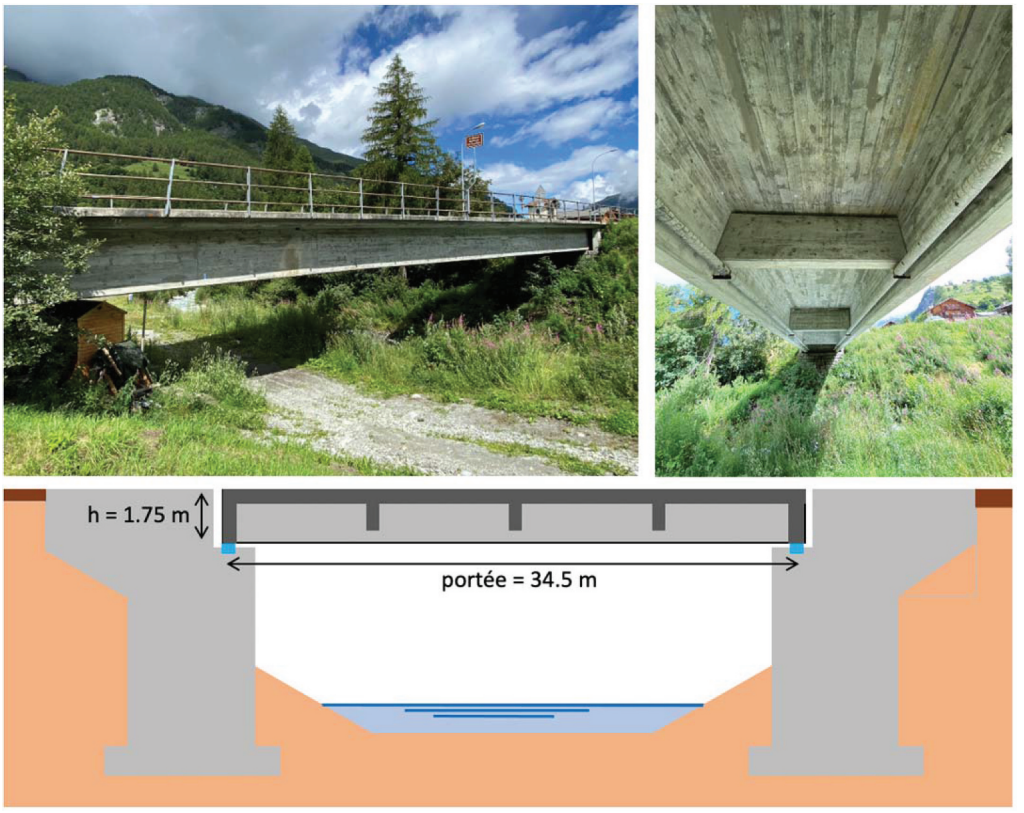

Figure 1. Presentation of the Ferpècle Bridge.

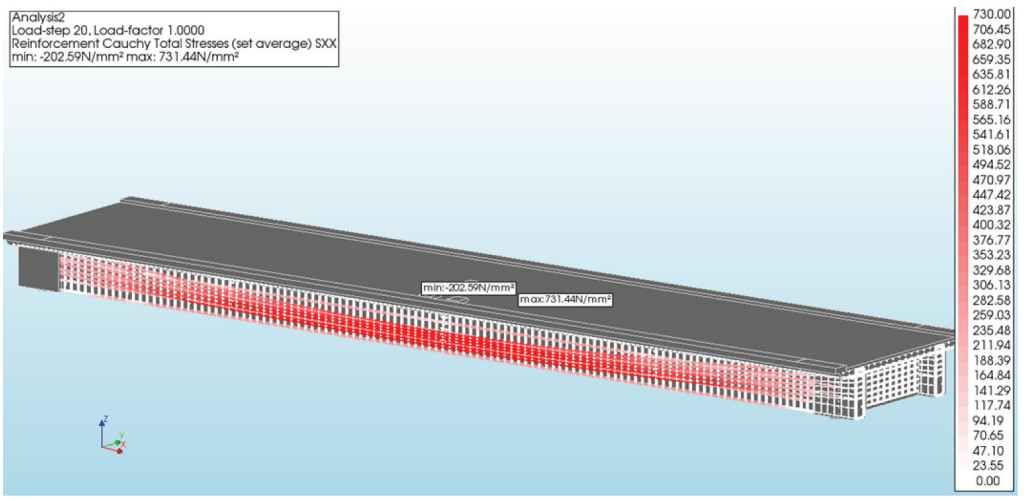

Figure 2. Finite element model and stress in prestressing tendons at ELU 2 (maximal bending at midspan).

3 INTERVENTION SCHEME

The widening of the deck from 5.3 m to 7.9 m, is made through a cantilevered full slab with a variable thickness, in R-UHPFRC (type UB; $f_{Utud} = 6.9MPa,\ E = 45\ GPa$), that is anchored

in the existing structure. At midspan, the deck thickness is increased from 25 to 27.5 cm (Figure 3). 20 mm of concrete from the existing slab is hydro-jetted, and the UHPFRC layer of 45 mm is poured on site. Transverse and longitudinal reinforcing bars (ϕ14 @ 150 mm) have been included in the UHPFRC layer. The RC – R-UHPFRC structure works as a composite element.

At the bridge supports, a thicker layer of R-UHPFRC (70 mm) is cast. Moreover, significant reinforcement steel bars (ϕ22 @100 mm) are included to increase the positive bending capacity. To achieve a monolithic structure, the abutments are clamped with traditional reinforced concrete to the superstructure, connecting the two prestressed beams with the deck, the abutment bottom wall the side walls (Figure 4). This intervention thus eliminates the need for expansion joints. The concept behind this clamping in the longitudinal intervention is (1) to create a semi-integral structure and (2) (partially) connect the beam in the abutments. These abutments also act as "counterweights" to take up the positive bending moment at supports.

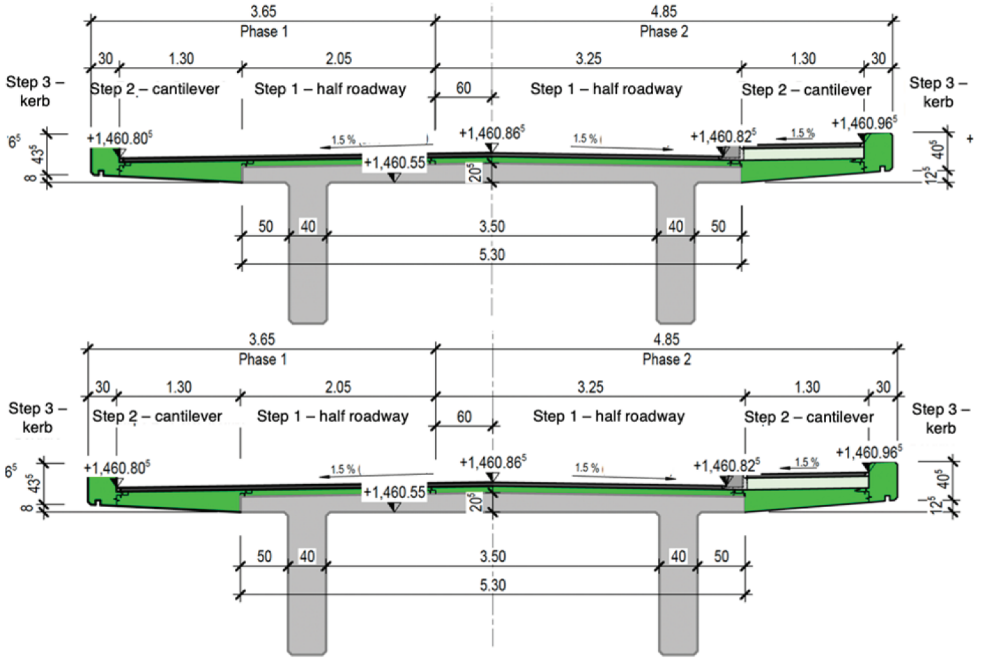

Figure 3. Cross-sections (in span and on supports) with new UHPFRC shown in green.

The concept of the intervention is to redistribute the bending-moment deficit at midspan to the supports. In this way, the static system is modified to form a semi-integral bridge with flexural rigidity at the supports, enabling it to take up this action. The new layer of reinforced UHPFRC (70 mm with (ϕ22 @100 mm) is used to create the necessary bending resistance at supports.

The numerical model is modified to predict the structural behavior after the intervention (Figure 5). For reliable predictions, the abutments are modeled and linked to the superstructure with UHPFRC. This model is used to verify the stresses in the UHPFRC tensile chord, beam compressive action, and abutment tensile reinforcements. Non-linear analyses are needed to effectively predict the strain-hardening behavior of UHPFRC in tension.

This new numerical model is used to evaluate structural safety. The overall degree of compliance obtained is 1.15. Model predictions show that the maximum stress in the new rebars at support is around 280 MPa, well below the yield point. However, some of the rebars in the abutment have stresses up to their yield stress at ULS, showing that this is a decisive factor in the design. In addition, the stresses in the UHPFRC (tension) and in the girder reinforced concrete

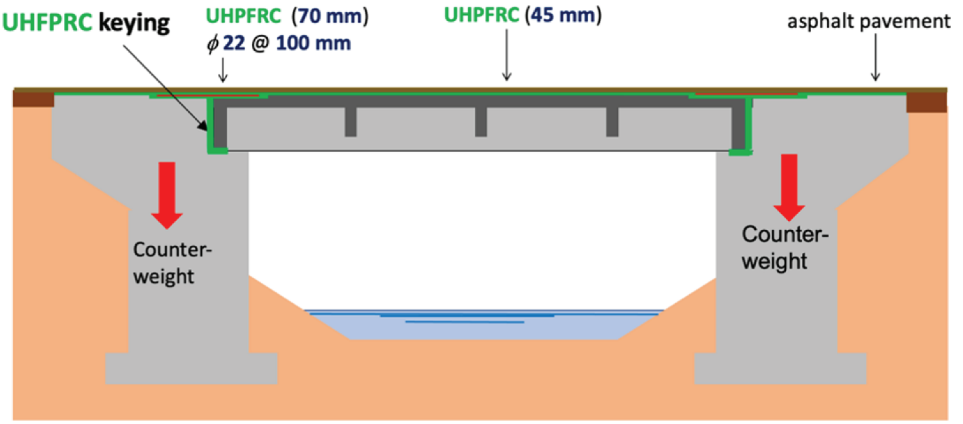

Figure 4. Scheme of the intervention (strengthening in the longitudinal direction).

(compression) are lower than their respective strengths. This difference is due to a greater participating width according to the numerical model than according to an analytical model.

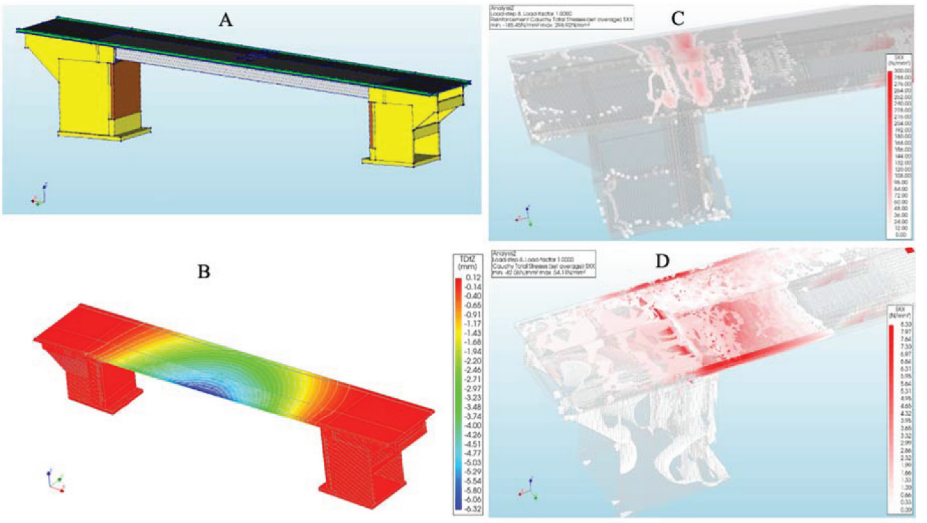

Figure 5. A) Finite element model of the bridge structure after intervention, B) Deformation under SLS load level; C) Tensile stresses in slab reinforcing bars at ULS; D) Tensile stresses in UHPFRC at ULS.

4 INTERVENTION WORK

The intervention was completed between April and November 2023. The work was carried out in two phases (upstream and downstream), enabling alternating traffic flow throughout the work.

In the first stage, scaffolding was erected, the asphalt pavement was removed from the entire deck, and the upstream curb was cut. Then, the formwork for the UHPFRC cantilever and the new curb was installed, and a new RC transition slab was poured. The UHPFRC is prepared directly on site. The deck and the new cantilever were cast in 3 stages (Figure 6), then the curb was cast in a single stage. Finally, the abutments were clamped. The work was then repeated on the downstream part of the structure.

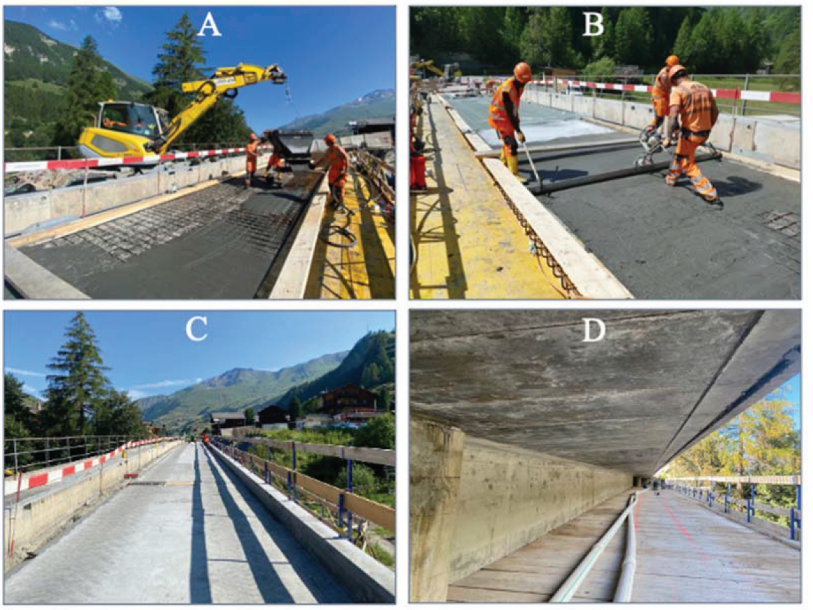

Figure 6. Photographs of the construction work. A, B) UHPFRC casting, C,D) results of the UHPFRC interventions.

5 VALIDATION THROUGH MONITORING

Two monitoring campaigns were performed prior to and after the structural intervention. The aim is to validate the change of the static system (from a simply supported beam to a fixed beam) and to update the material properties, such as the material elastic moduli. Each monitoring involves both static and dynamic excitations that are combined to model updating.

The first monitoring campaign (Phase 1) involved 3 static load tests with a 3-axle truck of 26,5 tons placed at quarter-spans and midspan. The second monitoring campaign (Phase 2) involved 5 static load tests with either one truck (to reiterate previous load tests of Phase 1) or two trucks to maximize the deflections. Additionally, dynamic load tests, which consist of a truck passing over the bridge at a given speed, were performed on both phases of the monitoring campaign.

In Phase 1, the monitoring system involved 10 deflection measurements made from the deck with a total station and targets on the bridge (supports, quartier spans, and midspan), and 10 accelerometers at the same locations. In Phase 2, the monitoring system involved 6 LVDT sensors on one side of the bridge on both girders.

Table 1. Measurements collected during monitoring campaigns.

Measurement	Before intervention	After intervention
1st modal frequency [Hz]	3.42	5.58 (+63 %)
Maximum deflection (extrapolation) [mm]	7.82	2.01 (-38.7 %)

Main data collected during these monitoring campaigns are shown in Table 1, where measurements prior to and after intervention are compared. As the first modal frequency is increased and deflections are reduced, it can be concluded that the rigidity of the structure has been increased significantly. After performing model updating (developed in later studies), it is shown that the global bridge behavior is significantly modified (Figure 7). Deformations predicted by the numerical models prior to and after monitoring match the measurements collected during load tests.

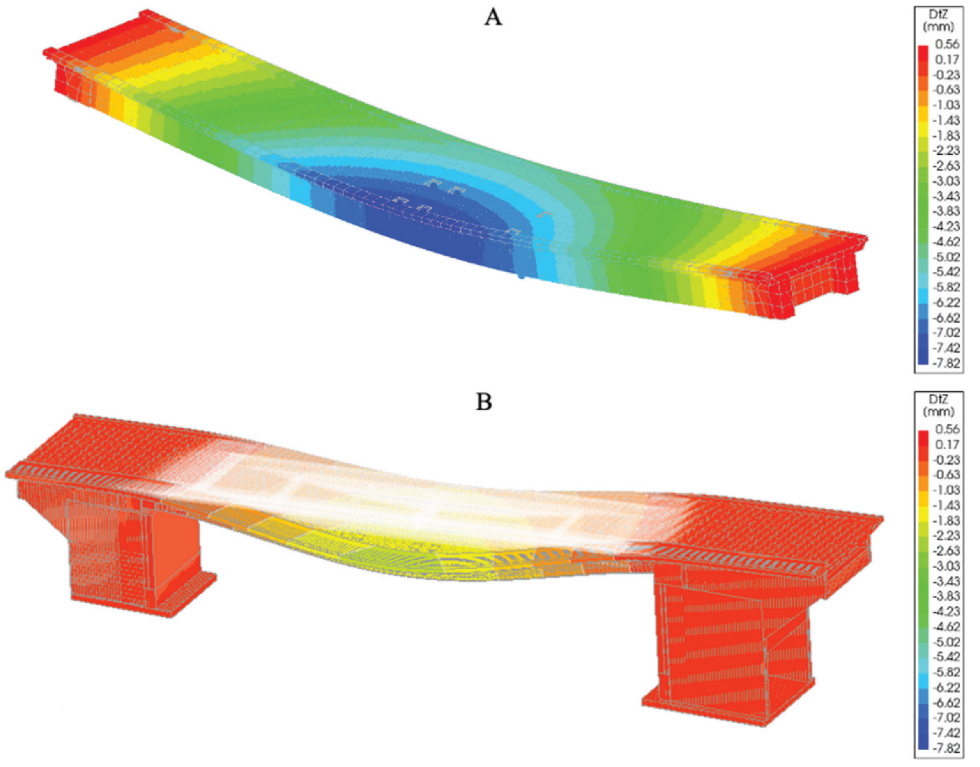

Figure 7. Bridge deflection behavior. A) Prior to monitoring; B) After monitoring.

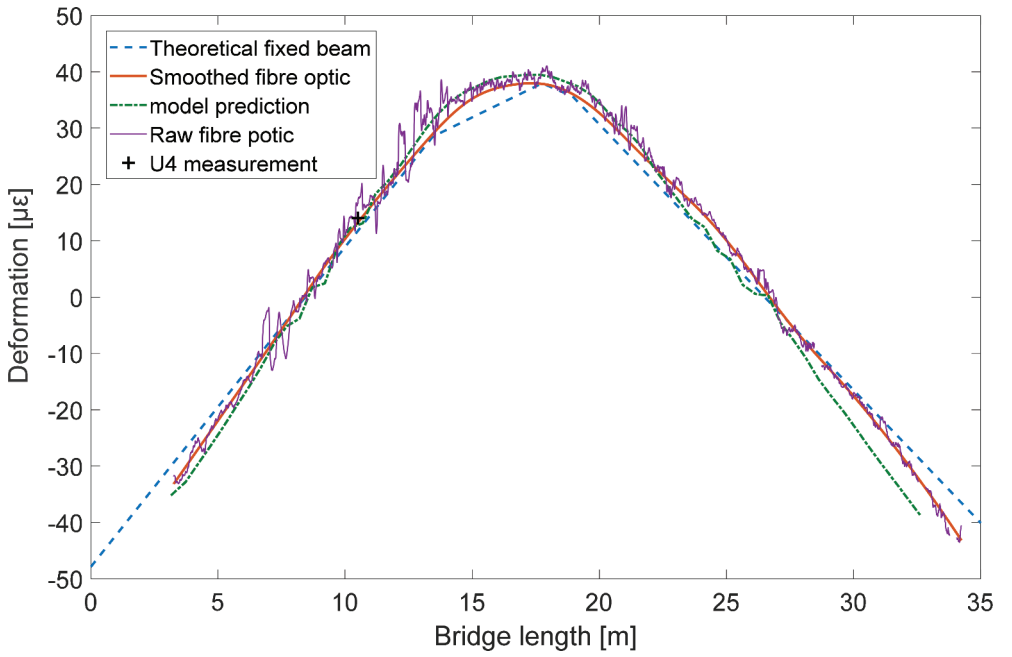

Figure 8. Comparison of model predictions, optical fiber strain measurements, and deformation of a theoretical fixed beam.

Two 32m-long optical fibers (SMARTprofile II from Smartec and a LUNA data acquisition system) were glued along both girders to validate the change of the static system. These optical fibers measure strain every approx. 3 mm along virtually the entire length of the structure. This corresponds to the equivalent of around 11,000 strain gages installed in series on each girder, enabling a much more detailed analysis than is usually the case where only a few strain gages are placed along the length of the bridge. Measurements are taken at a frequency of 5 Hz.

Strain predictions are compared with fiber optic measurements in Figure 8. The values in the cracks are removed from the fiber measurements ("raw fiber optic"). These values are then smoothened ("smoothed fibre optic") to remove local variations in the measurements and enable easier comparison. The theoretical deformation of a fixed beam with three concentrated loads (corresponding to the truck's three axles) is also presented. It can be seen that the predictions are very close to both the fiber optic measurements and the theoretical deformation. The average error is around 2 με. It can thus be concluded that the intervention resulted in the modification of the static system, where the bridge superstructure is being clamped to the abutments, creating a monolithic behavior of the structure. More in-depth analyses of the fiber-optic data will be made in future work.

6 CONCLUSIONS

This article presents the design, execution, and monitoring of the UHPFRC intervention on the Ferpècle bridge, one of the first prestressed concrete bridges in Switzerland. The project involved widening the bridge deck from 5.3 to 7.9 m (increase of about 50 %). The resulting need for reinforcement was met by redistributing actions (from midspan to the supports) based on the theory of plasticity at ULS. Strengthening only the top of the deck increases the structure's flexural load-bearing capacity by 44 %, while widening and rehabilitating the bridge. This case study demonstrates that UHPFRC can effectively strengthen existing structures by changing the static system. Compared with the demolition-reconstruction initially envisaged, the project is considerably less costly (-75 %) and has smaller associated carbon-dioxide emissions (- 55 %). The intervention was validated through an innovative monitoring scheme involving strain, acceleration, and deflection data. Measurements collected during load tests match the predictions of the finite-element models and correspond to the behavior of a fixed beam.

ACKNOWLEDGEMENTS

The authors are thankful to the Küpfer Geometres SA (M. Vaïk Küpfer) and IRMOS companies (Dr. Panagiotis Martakis and Dr. Yves Reuland) for the data acquisition during the load tests.

UHPFRC technology for the extension of the service duration of bridges

Eugen Brühwiler*
Laboratory for Maintenance and Safety of Structures, Swiss Federal Institute of Technology (EPFL), Lausanne, Switzerland

ABSTRACT: UHPFRC (Ultra High Performance Fiber Reinforced Cementitious Composite), complemented by reinforcement steel bars, is used for the rehabilitation and strengthening of existing bridges by adding a layer of UHPFRC, often on top of the bridge deck slab in reinforced concrete. Basic principles of the method and recent project realizations in Switzerland are presented. The underlying design concepts and issues of dimensioning and detailing are introduced, and main experiences in casting UHPFRC onsite are mentioned by means of three recent application examples.

UHPFRC interventions are cost effective and contribute in lowering the environmental impact because existing concrete structures are preserved and remain in service, rather than demolished and replaced. The service duration of bridges is thus extended significantly while responding to the demand of future use of bridges. The UHPFRC Technology allows to improve sustainability of bridges.

1 INTRODUCTION

The problems of insufficient durability of reinforced concrete bridges are known for several decades already, in particular in regions using deicing salts in winter and near the sea. So-called "retrofit" implies traditional repair methods, often leading to high intervention and user costs as well as limited durability. Novel intervention methods are urgently needed to improve existing reinforced concrete bridges.

UHPFRC stands for Ultra-High-Performance Fiber Reinforced Cementitious Composite materials. UHPFRC is composed of cement and other reactive powders, additions, hard fine particles, low amount of water, admixtures and very high amount of relatively short and slender steel fibers. The composition of UHPFRC is optimized with respect to compaction of particles leading to a waterproof material up to a tensile strain of about 0,1 %. The tensile strength of UHPFRC typically is about 12 MPa and the material shows significant strain-hardening behavior in tension. UHPFRC has compressive strength typically of 150 MPa. UHPFRC is nowadays used in many countries, mostly in the domain of new construction (Graybeal et al. 2021).

The author and his team have developed the UHPFRC rehabilitation and strengthening technology over the last 25 years by means of scientific research and applications (Bertola et al. 2021, Brühwiler 2020). In Switzerland (8,7 million inhabitants, area of 41′000 km2) there are currently more than 400 reinforced concrete structures, mainly bridges, that have been improved using the UHPFRC Technology, since 2004. This is the by far highest UHPFRC application rate in the world with respect to the size of the country.

The main reason for this successful implementation of a new technology in practice is that compared to traditional methods using concrete, mortar and epoxy coatings, the UHPFRC Technology is economic in terms of costs and material use, allows for an accelerated construction process and provides durable structures for further use reducing or eliminating maintenance costs.

*Corresponding author: eugen.bruehwiler@epfl.ch

DOI: 10.1201/9781003483755-15

By applying a UHPFRC reinforcement and waterproofing layer, the use of the existing RC bridge can continue. In this way, new requirements of use are accommodated in an economical, environmentally friendly and socially responsible manner. The UHPFRC Technology is also particularly suitable for bridges of high cultural values, since interventions are usually not visible.

2 DESIGN CONCEPTS TO IMPROVE BRIDGES

UHPFRC is used as a high-performance building material to improve existing bridges in traditional reinforced concrete with the aim of remedying, through a targeted supplement with UHPFRC, the known deficiencies of reinforced concrete.

2.1 *Basic principle of UHPFRC-concrete composite elements*

The basic idea of reinforcing structural RC bridge elements with UHPFRC is to monolithically connect, as a function of the project requirements, a 25 to 80 mm thick UHPFRC layer with the RC cross-section. The resulting UHPFRC-concrete composite element consists of a RC cross-section and a layer of UHPFRC or R-UHPFRC (incorporating steel reinforcement bars) according to Figure 1.

The term "strengthening" used here includes the increase in resistance and rigidity of structural bridge elements. At the same time, the UHPFRC layer also provides the protection function by a watertight barrier to shield reinforced concrete from direct contact with water and chloride ions.

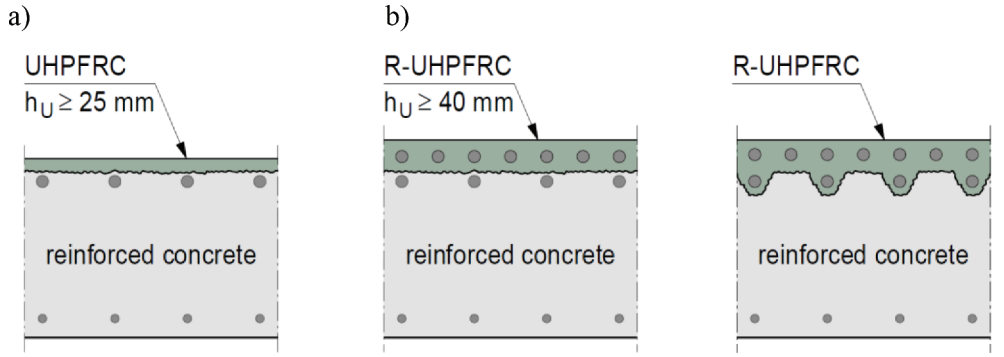

Figure 1. Basic configurations of the UHPFRC-concrete composite construction: a) protective function and increase in rigidity under service conditions, b) protective function and increase in element rigidity and ultimate resistance.

The essentials of UHPFRC-concrete composite behavior and required relevant UHPFRC material properties are summarized in (Brühwiler 2020). UHPFRC is used as material to rehabilitate and restore damaged reinforced concrete elements, thereby replacing inferior materials like repair mortars or epoxy coatings.

In the following, concepts are presented to increase structural resistance of R-UHPFRC improved RC bridges (FEDRO 2023):

2.2 *Project objective 1: Restoring and increasing the resistance of bridge deck slabs*

Bridge deck slabs made of reinforced concrete are subject to particularly high loading due to traffic loads and environmental influences. Accordingly, there is a high demand for intervention to restore and increase the structural resistance of deck slabs.

Figure 2 shows the basic strengthening concept of bridge deck slabs by applying a R-UHPFRC layer to the existing concrete slab. Bridge deck slabs carry loads and forces

mainly in the transverse direction. Correspondingly, a distinction is made between the sagging moment zone (positive bending moments) and the hogging moment zone (negative bending moments) above the webs of beams and box girders.

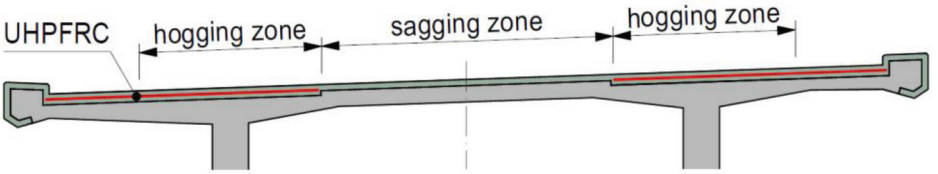

Figure 2. Concept of increasing the resistance of the original RC deck slab by means of the R-UHPFRC layer forming a strong R-UHPFRC tension chord in the hogging moment zone.

The concept is to significantly increase the flexural resistance in the hogging moment zone by forming a strong R-UHPFRC tension chord allowing for moment redistribution from the sagging to the hogging moment zone at ULS (ultimate limit state) according to the plasticity theory, given that the UHPFRC layer subjected to compressive stress in the sagging moment zone only leads to a comparatively small increase in flexural resistance.

The R-UHPFRC tension chord must be compensated by a correspondingly strong compression zone. In order to ensure the balance of the tensile and compressive forces acting in the bending cross-section, the effective concrete compressive strength is exploited, which has usually increased considerably (i.e. by 20 to 50 % compared to the 28-day compressive strength) during the bridge's service duration, often of several decades. This well-known time-dependent increase in strength is estimated using analytical expressions given in related scientific literature and standards, and verified by means of non-destructive testing on the structure. In this way, strengthening of the compression zone can usually be avoided.

By creating a R-UHPFRC tension chord, the ultimate shear resistance is significantly increased in the hogging moment zone, such that the shear force check is usually fulfilled. By the R-UHPFRC reinforcement, the slab rigidity is also significantly increased, which greatly reduces fatigue stresses in the steel reinforcement bars and concrete of the original RC element. The fatigue safety check is therefore usually fulfilled with margin.

2.3 *Project objective 2: Increasing the resistance of bridge girders*

The targeted use of R-UHPFRC, in particular as a R-UHPFRC tension chord, enables a significant increase in the load-bearing capacity of bridge girders in the longitudinal direction without significantly increasing the self-weight of the structure (by the additional R-UHPFRC layer) and without the intervention becoming visible. Also, modification of the static system is usually appropriate and highly effective. Two basic principles are described as follows.

2.3.1 *Principle 1: Reinforcement of continuous beams by means of a R-UHPFRC layer*

In statically indeterminate systems such as continuous beams, the bending resistance in the hogging moment zone is greatly increased by the creation of a strong R-UHPFRC tension chord allowing to carry out plastic moment redistribution from the sagging to the hogging moment zones at ULS, similar to the concept related to deck slabs (Figure 3).

However, this moment redistribution is only possible if the bending cross-sections are sufficiently ductile, which must be verified. For this purpose, a non-linear finite element analysis is often useful if the empirical rules of standards are not satisfied.

This principle is efficient in that an increase in the load-bearing capacity (ultimate resistance) of 15 to 30% (and in extreme cases up to 50%) can be obtained. In this way, for example, even severe damage such as failure of prestressing cables due to corrosion can be compensated without having to install costly additional tendons.

As in the sagging moment zone of a bridge girder, the R-UHPFRC layer only leads to a small increase of the flexural resistance, a need for additional reinforcement of the tension

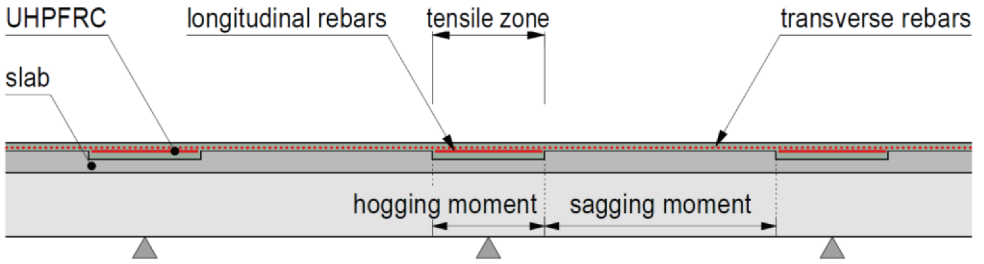

Figure 3. Principle of increasing the ultimate resistance of continuous RC bridge girders using a R-UHPFRC layer with the formation of astrong R-UHPFRC tension band in the hogging regions.

zone at the bottom side of simple and continuous beams can be accommodated for example by CFRP (carbon fiber reinforced plastic) lamellas on the underside of the bottom flange or by additional external posttensioning tendons.

2.3.2 *Principle 2: Creation of hyperstatic systems by force-locked closure of dilation joints*
For existing short and medium span RC bridges with lengths up to 80 m, all dilatation joints can be eliminated using UHPFRC. Force-fit joint closure leads to hyperstatic systems of increased structural rigidity.

Particularly, the structural behavior of the modified abutments needs to be investigated applying recent knowledge in the area of integral RC bridge structures. In the case of existing bridges, the dilation movement to be considered is limited to that due to changes in temperature alone, since girder deformation due to final shrinkage and creep of the existing concrete is negligible.

Bridges consisting of a series of simple beams that are force-fitted monolithically in the support zone by R-UHPFRC, are converted into a continuous beam and are thus analyzed like continuous beams according to Principle 1.

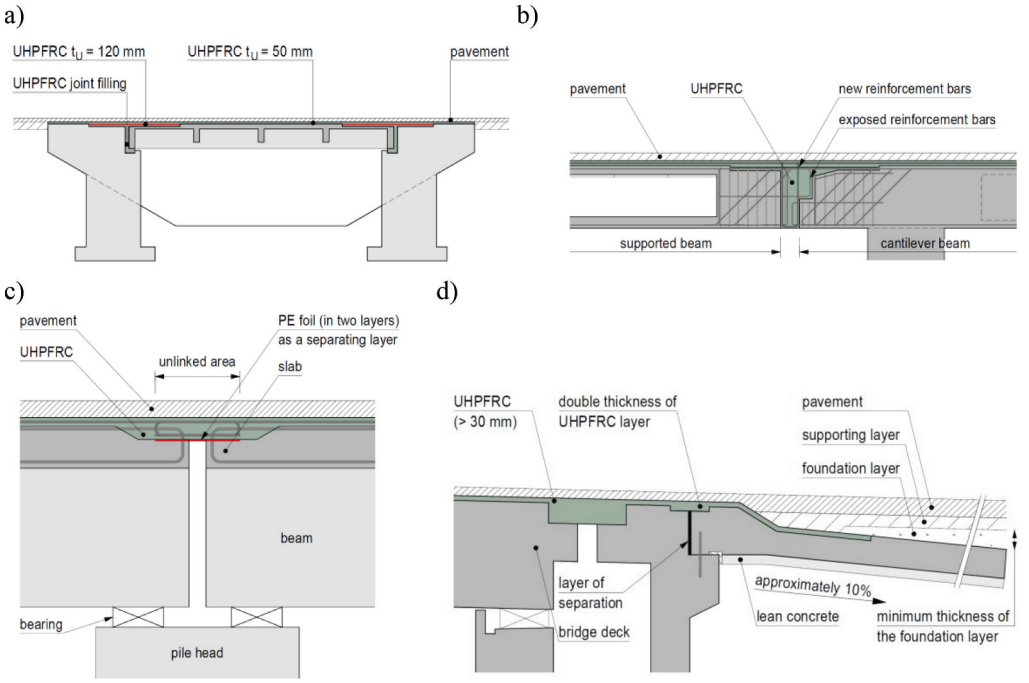

Figure 4. Principle of UHPFRC joint closure: a) in the abutment zones of a single span bridge to create a half-frame, b) force-locked girder joint, c) partial joint closure for beam chains, also called "link slab", and d) creation of a semi-integral bridge end.

Figure 4a shows the concept of joint closure in the abutment area of a single span beam. In the case of pier-like abutments with large dimensions, a semi-frame structure is created. By modifying the end zones of the beam to frame corners, the bending stress is redistributed from the sagging zone to the frame corners and thus relieved. By installing the R-UHPFRC tension chord in the abutment zones and a UHPFRC layer over the entire deck, the dilation joints are eliminated and the reinforced concrete is protected from chlorides and water. The stress flow in the frame corners has to be carefully analyzed.

Figure 4b shows the constructional detail of a force-locked girder joint, which is bending and shear resistant. The UHPFRC lock is anchored into the existing RC bridge structure with rebar inserts on both sides to connect. In the case of single span girders in series, the partial joint closure at the level of the deck slab shown in Figure 4c can be suitable. A relatively massive unbonded slab in R-UHPFRC, called "link slab", is anchored in the adjacent RC deck slabs to connect two adjacent bridge girders by a continuous deck slab. The length of the connecting UHPFRC slab is designed such that temperature related deformations are absorbed by deformation of the "link slab". The static functioning of the original simple beams is not modified by this intervention. This "link slab" principle can also be implemented in the transition from the bridge to the road for dilations up to ±10 mm.

Figure 4d shows the design of a semi-integral abutment by means of a R-UHPFRC lock connecting the bridge deck slab to the transition (or approach) slab, thereby waterproofing the bridge end zone and eliminating the dilation joint above the bridge bearing.

By forming force-locked UHPFRC connections, the structure is stiffened, which usually also increases structural resistance. Obviously, the stresses in the entire strengthened structure and in particular the UHPFRC-locked zone must be analyzed accordingly and the force flow in the modified structure must be carefully verified.

3 FOUR SELECTED RECENT APPLICATIONS

Among numerous UHPFRC application projects (Bertola et al. 2021) with involvement of the author in conceptual design, dimensioning, project proof and quality control, three recent projects are selected and briefly described in the following:

3.1 *Riddes Road Viaduct, Switzerland – Strengthening to restore structural resistance*

The 1,2 km long road viaduct (Figure 5a) consisting of a twin continuous box girder in posttensioned concrete built in 1976 is a major road overpass over a railway line, highway and a river.

a) b)

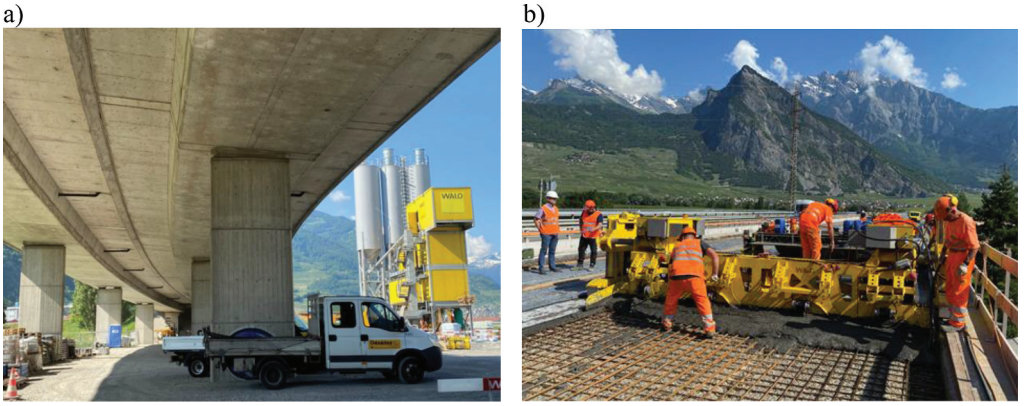

Figure 5. a) UHPFRC ready mix plant next to the Riddes Viaduct, b) UHPFRC casting on the deck slab.

RC damage including corrosion of prestressing tendons and steel rebars as well as alkali-aggregate reaction lead to a significant deficit in structural resistance. Strengthening intervention was urgently needed. The objective of the intervention was to over-strengthen the girder for flexural resistance to accommodate for (1) potential loss of 1/3 of post-tensioning, (2) 30% AAR-related and forecasted concrete strength reduction as well as (3) local damage of the deck slab.

The R-UHPFRC intervention method was found to be most cost-effective and rapid to rescue the viaduct's post-tensioned concrete structure. The concept and design of strengthening was following the principle shown in Figure 6 and the design provisions of the Swiss UHPFRC standard (SIA 2052) including detailed non-linear FE analyses (El Jisr et al. 2023). The UHPFRC layer was cast in 2021 on the deck slab of the viaduct using a casting machine (Figure 5b).

3.2 *Aare Bridge Schinznach, Switzerland – Strengthening and deck widening*

This 120 m long three span road bridge for bi-directional road traffic and with a pedestrian walkway was built in 1954. This bridge belongs to the first generation of steel-concrete composite bridges and has significant cultural and aesthetic values (Figure 6a).

The cross section consists of two main steel girders and the RC deck slab acting in composite action. The RC slab showed usual steel rebar corrosion damage, and the pedestrian walkway had to be widened to accommodate for future user demand. In addition, examination of the composite structure and the deck slab revealed deficits in structural capacity and thus structural strengthening was required.

The realized strengthening consisted in adding a 60 mm thick layer of UHPFRC incorporating steel reinforcement bars in orthogonal directions to waterproof and protect the RC slab as well as to increase the resistance of the slab in the transverse direction and the hogging moment capacity over the piers in the longitudinal direction. The UHPFRC casting works of the roadway were realized in two days in Summer 2022 (Figure 6b).

The R-UHPFRC strengthening was optimized such that strengthening of the two steel girders could be avoided, reducing the intervention on the main structure in steel to the renewal of the corrosion protection coating only.

a) b)

Figure 6. a) View of the steel-concrete composite bridge after R-UHPFRC strengthening, b) casting of UHPFRC with immediate application of curing compound.

3.3 *Viaducts Pont d'Ouche, France – Strengthening of kerb zone for impact forces*

Built as part of a vast motorway program in the 1960s, the 504 m long Pont d'Ouche twin viaducts are one of the major elements of the A6 motorway in France (Figure 7a). At the time of their construction, they were unique by its geometric characteristics, since built entirely in curves and in slope, and by the structure being made up of prestressed prefabricated isostatic beams with spans of 36 m with cast-in-place connecting slabs. This rational structural system for RC viaducts, which was very often realized in France and worldwide, allowed realization in a record time of 20 months, and the inauguration of the viaducts was in October 1970.

Installation of a robust water proofing layer in UHPFRC on the entire slab and all kerbs, repair of rebar corrosion damage and structural strengthening of the slab zone near the curbs to resist possible vehicle impact forces on the new vehicle retaining system, were the main reasons for realizing the UHPFRC project. The UHPFRC layer on the deck slab of the first viaduct was cast in 2022 using a casting machine (Figure 7b). The same UHPFRC intervention was realized in 2023 on the adjacent viaduct.

a) b)

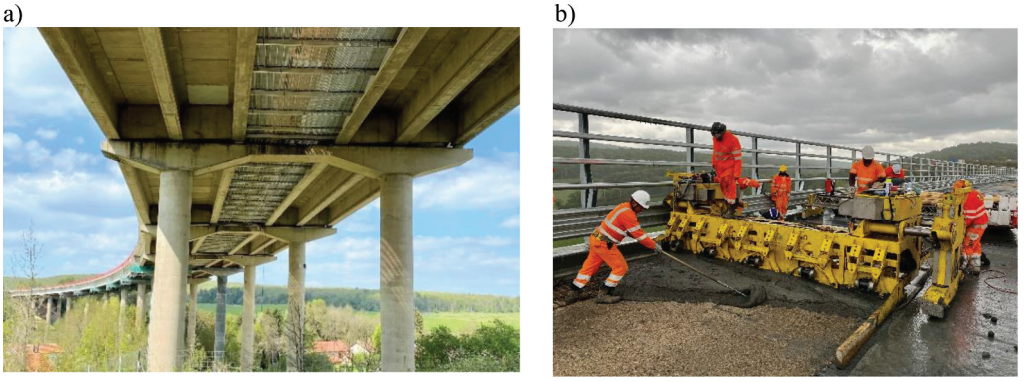

Figure 7. a) View of the twin viaduct structure with triple PC-girder cross section, b) casting of UHPFRC and curing with a plastic foil.

3.4 *Ferpecle Road Bridge, Switzerland – Strengthening and deck widening*

The Ferpècle Bridge is a prestressed reinforced concrete double-girder structure (TT cross-section) from 1958, thus belonging to the first generation of prestressed bridges. The bridge is located in the Swiss Alps. The original static system was a simply-supported beam with a 34,5-meter span, resting on abutments with side walls approximately 7 meters long (Figure 8a). With a beam height of 1,75 meters, the slenderness of 1/20 is audacious for a simple beam.

The bridge condition was acceptable, except for the usual rebar corrosion damage of the top zone of the deck slab and the kerbs.

To accommodate for future road and pedestrian/bike demands, the bridge deck was widened from 5,3 m to 7,9 m, leading to a significant demand in structural resistance of about 60% compared to the original capacity.

The widening was realized by means of a cantilevered full slab of variable thickness in R-UHPFRC, that is anchored in the existing structure. The strengthening was done following the concept shown in Figure 4a to create a half-frame structure starting from a single beam system (Bertola & Brühwiler, 2024):

- In the sagging zone (with positive bending moments in the longitudinal direction), the deck thickness was increased from 25 to 27,5 cm; i.e. 20 mm of concrete from the existing slab was removed by hydro-jetting, and a UHPFRC layer of 45 mm was cast. Transverse and longitudinal reinforcing bars (ϕ14 @ 150 mm) have been incorporated in the UHPFRC layer.
- At the beam supports, a thicker layer of R-UHPFRC (70 mm) was cast. Moreover, significant reinforcement steel bars (ϕ22 @100 mm) are included. To achieve the necessary monolithic half-frame corners, the abutment zones were force-locked, connecting the beams with the abutments. In this way, the required hogging zone of high structural resistance was realized.
- Additionally, this intervention also eliminates any costly dilation joint and its high maintenance cost.

The works were carried out in summer 2023 in two phases (upstream and downstream), enabling alternating traffic flow throughout the works. The UHPFRC casting was realized according to confirmed methods, without any particularity.

4 UHPFRC TECHNOLOGY AND SUSTAINABILITY

The two technically most efficient building materials are steel and cement. They are currently criticized as being particularly harmful to the environment. This ignores the fact that it depends on how these building materials are used. UHPFRC contains relatively high quantities of cement and steel, such that the energy input and greenhouse gas emissions per kg of UHPFRC are obviously relatively high compared to most other building materials.

Nevertheless, the principles of sustainability can be well respected through the targeted use of UHPFRC. This is because UHPFRC is a high-performance building material with which the required technical performance of structures is achieved with installing small material quantities on the existing structure, thereby preserving the existing structure.

In addition, "eco"-UHPFRC mixtures have already been developed and will be used in the near future, allowing for a reduction of the environmental impact of the UHPFRC material alone. Also, UHPFRC can be decomposed and recycled at the end of its use.

When dealing with existing structures, the use of UHPFRC follows the principle: *"Improve instead of replace!"* UHPFRC Technology is able to rehabilitate and strengthen, actually to salvage, existing RC structures. In this way, material resources and grey energy already in use are further utilized, thanks to a relatively small amount of UHPFRC. The existing structure is valorized and upgraded in an economic manner.

Estimations show that this approach has about an order of magnitude less environmental impact (and is significantly less expensive) than the still practiced demolition-replacement approach, also called "end-of-life approach", which obviously is outdated nowadays. Contrary to humans, structures don't have an end of life.

5 CONCLUSIONS

The UHPFRC Technology provides effective solutions to rehabilitate and strengthen existing bridges with little use of materials to upgrade them for future utilization. When dealing with existing bridges, the use of UHPFRC leads to: *"Improve instead of replace!"*

The UHPFRC Technology allows to rehabilitate and strengthen, actually to salvage, existing RC structures. In this way, already used material resources are further utilized. The existing bridge is valorized and upgraded in an economic manner. This follows the principle of sustainability to preserve material resources and their embodied energy, are already in use, thereby limiting greenhouse gas emissions to a minimum.

The UHPFRC Technology has already been implemented in practice. Recently, the Swiss Federal Roads Office has published a documentation to facilitate the use of the UHPFRC Technology for the preservation existing and the construction of new engineering structures of the road infrastructure (FEDRO 2023).

Interpreting monitored responses of an orthotropic steel deck using FEM

S. Ye
Arup, Hong Kong

R. Gibson
Arup, London

N. Yeung & S. Kite
Arup, Hong Kong

ABSTRACT: The actual response of a bridge deck under heavy vehicles is of great interest for bridge assessment. To better understand this, strain and displacement monitoring technologies have been deployed on many bridges around the world to measure their responses, particularly for stress histories under heavy vehicle events. For orthotropic steel decks (OSD) of highway bridges, it remains a key technical challenge to process and interpret these monitored stress responses. This is due to the uncertainties in vehicle weave (transverse axle position), axle load, axle type and vehicle configuration. Fatigue performance governs the life of OSD, and efficient processing of monitoring data would significantly improve the ease of assessing its health. In this paper, the outputs from detailed finite element modelling (FEM) are used to interpret the monitored heavy vehicle responses from the OSD of a long span suspension bridge. The FEM investigates the effects of different weave positions and axle arrangements on stress histories at locations equivalent to those monitored on the bridge. Responses from heavy vehicle events are also extracted from the high frequency strain gauge monitoring data. Through engineering interpretation, key features of the generated responses under different types and locations of heavy vehicles are identified. It is envisaged that this interpretation could be automated through machine learning, which ultimately could be linked back to local fatigue assessments and bridge inspections to correlate processed monitoring data with fatigue health.

1 INTRODUCTION

1.1 *Background and motivation*

Orthotropic steel decks (OSD) are adopted for many bridges around the world as it is a highly efficient method for providing a lightweight deck, particularly for long span bridges. It has been used since 1950s and has remained relatively unchanged, incorporating only a small number of variations. The OSD system uses steel only where it is necessary, with the main stiffness required in the longitudinal direction. The system consists of a flat deck plate with U-shaped longitudinal trough stiffeners welded to the underside. The deck plate and troughs sit on regularly spaced cross girders. The trough spacing is typically 600 mm and the cross girders at 3-4 m spacing.

The design of OSD is governed by fatigue rather than strength. The continuous passage of heavy trucks and buses provides the most onerous condition for fatigue local to the tyre tracks. Small vehicles such as cars do not have a significant effect. Looking at

DOI: 10.1201/9781003483755-16

existing steel bridges, a significant amount shows signs of fatigue cracking after only 10-30 years of service life. This suggests a lack of understanding of the fatigue effects in OSD in the past. Detailed analysis techniques have been developed by Arup, which calculate a representative level of stress that results in damage predictions correlating well with cracking found on the bridges in this timescale. The fatigue assessment uses a detailed finite element (FE) model of the bridge deck to generate stress histories of heavy vehicle passage events at different vehicle weaves (transverse axle positions) at each weld location. The stress histories are then cycle counted in order to perform damage prediction calculations.

However, the current fatigue assessment process is time-consuming and requires a very detailed and sophisticated approach. We propose a new approach of assessment which involves interpreting strain monitoring data of OSD to enable more efficient assessment of fatigue health. The strain gauge data taken from the OSD is interpreted by comparing with the stress histories obtained from the finite element method (FEM). Each vehicle type, such as double-decker bus (DDB) and heavy goods vehicle (HGV), will have a signature stress history.

The proposed approach also requires some historic correlation with actual damage found on bridges in order to provide validation and calibration of assessment results. As the strain gauge measurements are not taken from the weld itself, there is no fatigue calculation that can be directly performed. Therefore, to make best use of the interpreted data requires correlation with the performance data of similarly configured OSD (e.g., plate thickness and trough stiffener shape). This must be based on normalised truck numbers to remove differences in demand between bridges.

In this paper, we present the identification of double-decker bus (DDB) passage events and their weave positions using FEM results. This is carried out through manual comparison with FEM outputs and engineering interpretation. It is envisaged that ultimately this can be automated through machine learning in order to perform the interpretation on thousands of heavy vehicle events.

1.2 *Long Span Bridge and its structural monitoring*

The paper uses the OSD of a long span suspension bridge as the case study, hereinafter referred to as the Long Span Bridge (LSB). The bridge deck of the LSB consists of orthotropic deck plates, and carries multiple road traffic lanes in each direction.

On the LSB, a structural health monitoring (SHM) system has been deployed, with sensors such as strain gauges, displacement transducers, GPS rover stations, accelerometers, anemometers and temperature sensors. The SHM system was designed to measure input loadings (e.g., wind, temperature, traffic), output responses (e.g., strain, displacement) and structural properties (e.g., modal frequencies, mode shapes).

1.3 *Data used in this study*

In this study, data collected from five strain gauges at the OSD of upper deck was used, referred to as Strain Gauge 1 (SG-1) to Strain Gauge 5 (SG-5). The sensor layout is shown in Figure 1. These five sensors are located under the slow lane where heavy vehicles travel. SG-1, SG-3 and SG-5 measure strain in the longitudinal direction, and SG-2 and SG-4 measure strain in the vertical direction. Each strain gauge collects data continuously at around 50 Hz, which gives over 4 million data points per day. To facilitate the data analysis and interpretation, strain data was converted to stress data using $\Delta\sigma = E\Delta\varepsilon$, assuming E = 210 GPa for steel.

Ideally, 100 Hz is adopted for fully capturing the stress history under each heavy vehicle event, but 50 Hz may be good enough. In addition, as shown in Figure 2, it has been discovered that SG-1 has relatively large data noise (about ± 4 με). These factors need to be considered when interpreting the monitored heavy vehicle responses.

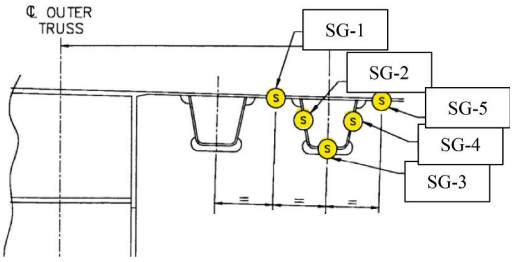

Figure 1. Five strain gauges at orthotropic steel deck.

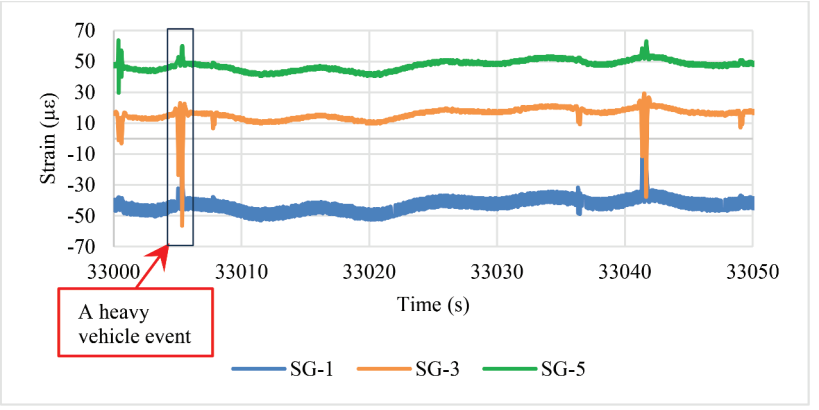

Figure 2. Example plot of collected strain data (at 33000-35000 s of a day).

2 METHODOLOGY

2.1 *Extraction of heavy vehicle events from strain monitoring data*

Individual heavy vehicle events were first extracted from the strain monitoring data using machine learning (support vector machine) and statistical methods (moving average-based algorithms). More information on the methods was provided in Ye et al. (2023).

2.2 *Finite element modelling and analysis*

The fatigue assessment of the LSB OSD was performed using a detailed local 3D linear elastic FE model. It was analysed using *MSC Nastran*, and the fatigue calculation was performed using software written by Arup specifically for assessing bridge decks. For the purpose of this study, the fatigue software was used to generate stress histories of double-decker buses (DDB) passing over the deck for comparison with the strain monitoring data.

The FE model was a multi-scale model. A detailed local region of the bridge deck section, which consisted of shell elements, was embedded into the global region, as shown in Figure 3. The global model consisted of beam elements with equivalent shell elements for the deck.

The local region was 27 m long and included six 4.5 m cross frame bays. The full width of the bridge was included. The "cut-section" ends of this local region were rigidly constrained to the global region. The mesh density in the fine detailed region was such that stress concentrations (other than those generated by the weld profiles) were adequately predicted. This means a mesh size in the order of the thickness of the deck plate or trough.

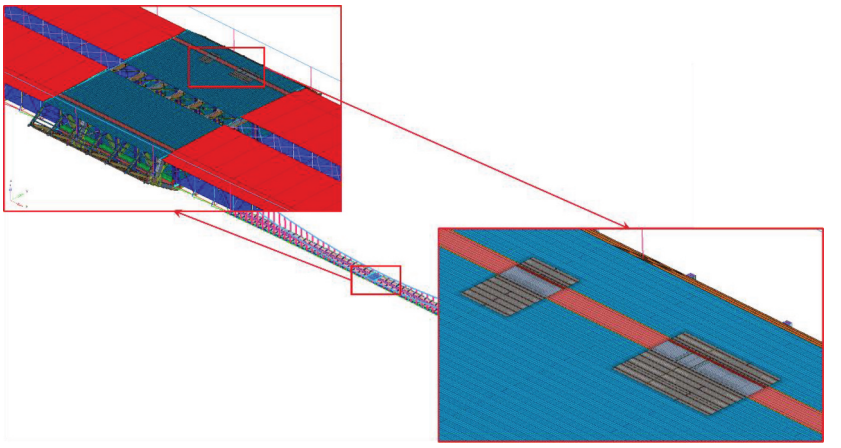

Figure 3. Finite element model of orthotropic steel deck in NASTRAN.

Fatigue damage in OSD is caused by the passage of heavy trucks and buses. There are many variations of truck configuration, however, there are not many bus types that travel on the LSB. To keep the process straightforward, this initial study was based on the type of double-decker bus (DDB) which was prevalent at the time of monitoring data collection. The DDB consists of three axles (see Figure 4). The front steering axle has a single tyre each side, known as an A-axle. The rear two axles have pairs of tyres each side, known as a B-axle. This study assumed the maximum bus weight of 27 tonnes, as specified by the manufacturer. The load was positioned so that the second axle was longitudinally in-line with the strain gauges.

In order to find matching responses between the detailed FE model and monitoring data, the analysis was run for ten different transverse bus positions, or weaves, relative to the strain gauges (see Figure 5). The bus load was incrementally moved along the model to generate stress histories from elements at each gauge location, one bus passage per weave.

The strain gauge locations are previously shown in Figure 1. They are attached to the underside of the deck plate (SG-1 and SG-5), sides of the trough stiffener (SG-2 and SG-4)

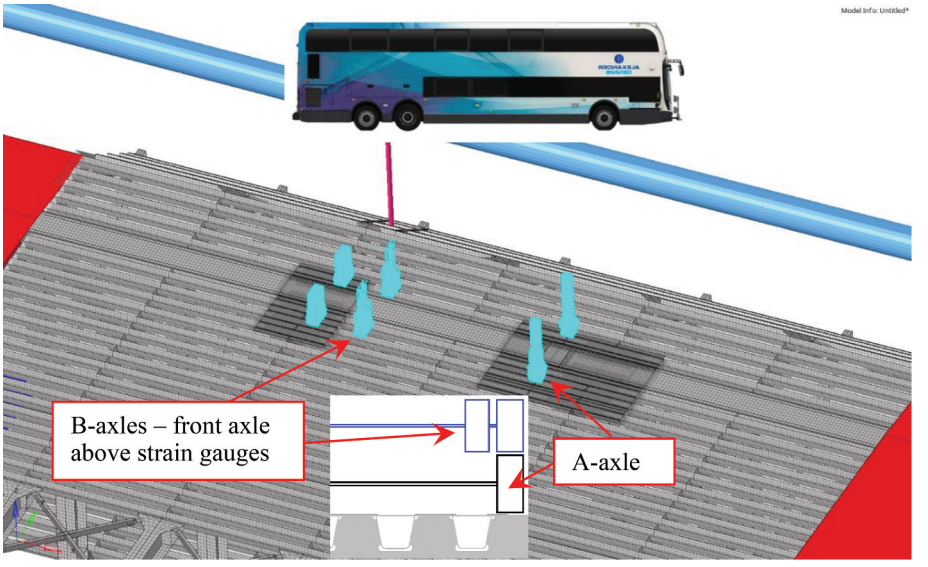

Figure 4. Application of environ 500 bus loading on orthotropic steel deck.

and beneath the trough (SG-3). Outputs from SG-2 and SG-4 were not used, as they are not typical of OSD behaviour. The main outputs were taken from SG-1 and SG-5, as they show distinctive stress patterns, with clear indications of bus location. SG-3 was found to be less sensitive to bus location but useful for correlation.

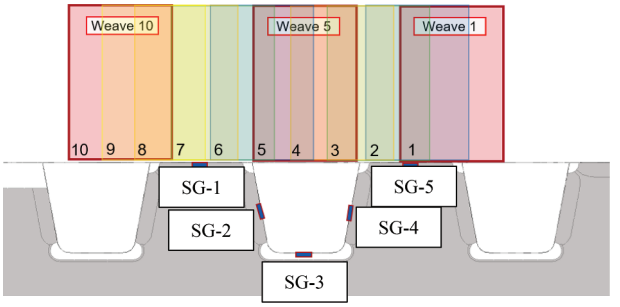

Figure 5. Application of bus load at different weave positions.

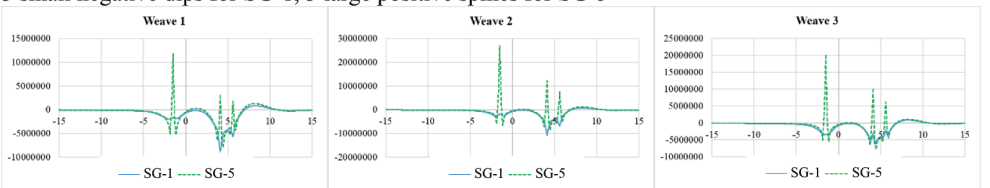
3.3 *Interpretation of monitored responses using FEM output*

Looking at the strain monitoring data alone from the bridge, it is unknown what vehicles passed or where they passed over. However, the stress histories from the FE model, at different weave positions, are known. They can be compared with the monitored responses (i.e., matching response patterns) to ascertain the bus passage event and bus location.

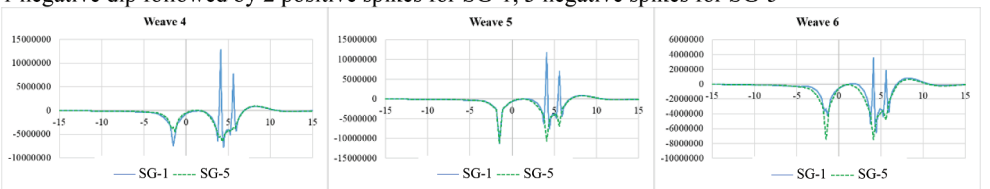
3 RESULTS AND INTERPRETATION

3.1 *FEM outputs*



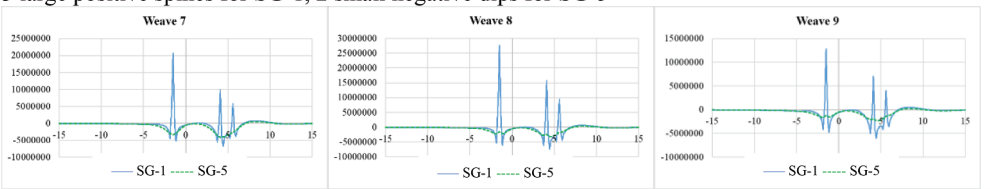
The stress histories from the FE model, under the DDB nominal loading at different weave positions (weaves 1 to 10), are summarised in Table 1, which shows that four distinctive response patterns can be identified. As for the relationship between weave positions and sensor locations, as shown previously in Figure 5, weave 2 is directly above SG-5, weave 8 is approximately directly above SG-1, and weave 5 is directly above the trough stiffener.

A number of observations and interpretations can be made from the response patterns:

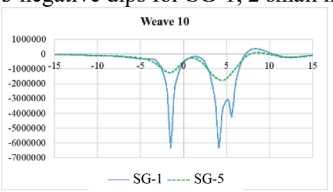


- The stress history includes global response of the deck and local response of the deck plate or trough stiffener, with an influence length approximately the distance between cross frames.
- For A-axle (single tyre), when the tyre is directly above SG-5 (refer to response pattern 1), which is located at the deck plate between two adjacent trough stiffeners, it results in a tension response due to local bending (large positive spikes) of the deck plate. Likewise for SG-1 (refer to response pattern 3).
- For A-axle, when the tyre is slightly away from SG-5 (refer to response patterns 2-4), it results in a global compression response (relatively small negative dips) of the deck. Likewise for SG-1 (refer to response patterns 1, 2 and 4).
- For response pattern 10, the tyres are much closer to SG-1 than SG-5. This is illustrated by the higher in magnitude and the definition of dips for each axle for SG-1.
- For B-axle (double tyres), it results in a combination of the above-mentioned two types of response. For example, for SG-1 in response pattern 2, the front A-axle results in global compression response while the rear B-axles results in a combination of global compression (due to the outer tyre) and local tension (due to the inner tyre).

Table 1. Different response patterns from FEM outputs.



FEM response pattern 1 (weaves 1 to 3):
3 small negative dips for SG-1, 3 large positive spikes for SG-5



FEM response pattern 2 (weaves 4 to 6):
1 negative dip followed by 2 positive spikes for SG-1, 3 negative spikes for SG-5

FEM response pattern 3 (weaves 7 to 9):
3 large positive spikes for SG-1, 2 small negative dips for SG-5

FEM response pattern 4 (weave 10):
3 negative dips for SG-1, 2 small negative dips for SG-5

3.2 *Interpretation of monitored responses using FEM output*

The following graphs show examples of monitored responses (refer to Figures 6–9). As discussed in the previous section, the deck plate strain response spikes very sharply when the tyre is directly above the gauge. This provides a guidance as to where the vehicle is located. Also, the number and spacing of spikes provides an indication of axle arrangement. It should be noted that the data frequency is around 50 Hz, and the SG-1 response contains relatively large noise, as previously explained in section 1.3.

The monitored response pattern I in Figure 6 has sharp peaks in SG-1 response, indicating that the vehicles are located around weaves 7-9. The peaks suggest the vehicles have two axles. Although the axle count is different, the shapes are similar to response pattern 3 in Table 1. SG-5 shows negative dips which represent the global response from axles further away. SG-3 at the bottom of the trough is less sensitive to sharp peaks, but the response indicates that the rear axle is heavier than the front axle.

The monitored response pattern II in Figure 7 has sharp peaks in SG-5 for the rear tyre only, suggesting a B-axle located outside of weave 1. The inner tyre generates the large stress response in SG-5. The peaks suggest that the vehicles have two axles. SG-1 shows negative dips which represent the global response.

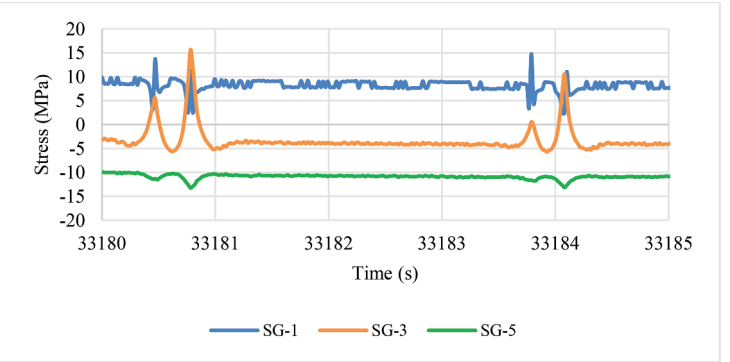


Figure 6. Monotored response pattern I.

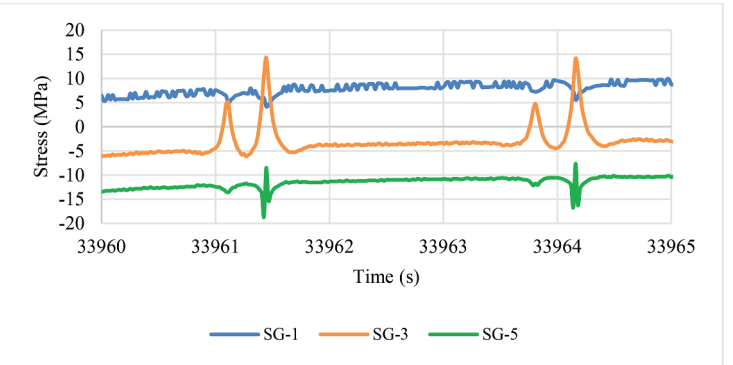

Figure 7. Monotored response pattern II.

The monotored response pattern III in Figure 8 has sharp peaks in the SG-1 response, but only for the rear tyres. This indicates that the vehicles are on weaves 4-6, for which only the B-axle with inner tyres generate the large spiked stress response in SG-1. The response shows a double peak which means the vehicles have three axles. Again, SG-5 shows negative dips with no peaks which represents the global response. SG-3 at the bottom of the trough has a larger rear peak as there are two closely spaced axles.

The monotored response pattern IV in Figure 9 has sharp peaks in the SG-5 response, indicating that the vehicles are located around weaves 1-3. The peaks suggest the first vehicle has three axles and the second has four. SG-1 shows negative dips which represent the global response.

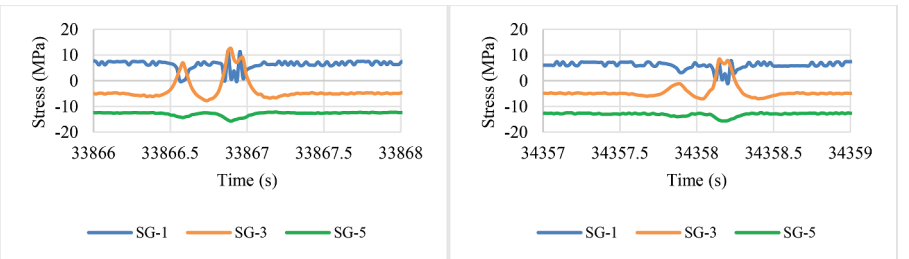

Figure 8. Monotored response pattern III.

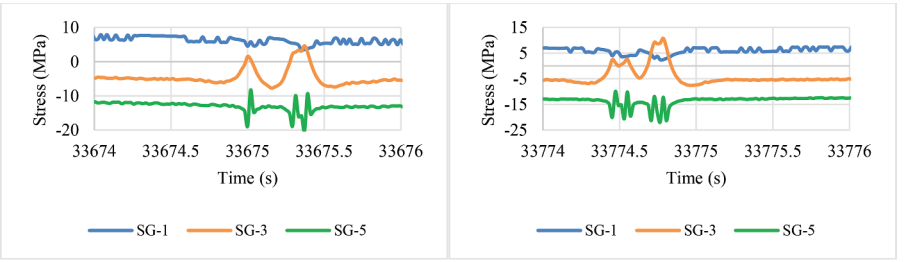

Figure 9. Monitored response pattern IV.

4 DISCUSSION

This study has demonstrated the technical feasibility of interpreting monitored heavy vehicle responses using FEM outputs, and in particular, inferring axle arrangement and vehicle weave from the response data. It is envisaged that the outcomes of this study can be used to develop a physics-guided machine learning algorithm for recognising the responses of different types of heavy vehicles at different weave positions, which is useful information in fatigue assessment. This could become a general tool for analysing the monitoring data under heavy vehicles, linking input loading data to output response data, and thus better understanding the behaviour and response of OSD. Ultimately, this could be linked to local fatigue assessments and bridge inspections to correlate processed monitoring data with fatigue health.

5 CONCLUSIONS

In this paper, we have demonstrated the technical feasibility of interpreting monitored heavy vehicle responses of orthotropic steel deck (OSD) using finite element method (FEM) analysis results, and in particular, the identification of axle arrangement and vehicle weave (transverse axle position). The study has used the OSD of a Long Span Bridge (LSB) as the case study, which has strain gauges installed at the deck plates and trough stiffeners, with continuous data collection at around 50 Hz. The FEM results of stress response under the type of double-decker bus (DDB) that travelled frequently on the LSB, at 10 different weave positions were generated using a detailed FE model. Four distinctive response patterns were identified from the FEM outputs, which were interpreted from a structural behaviour perspective. These FEM response patterns served as the reference patterns to interpret the monitored heavy vehicle responses. It is envisaged that this interpretation could be automated through machine learning in order to perform the interpretation on thousands of heavy vehicle events and enable more efficient and accurate fatigue assessment.

Predicting time history response of bridges under vehicle load using CNN

Huile Li & Tianyu Wang
Key Laboratory of Concrete and Prestressed Concrete Structures of the Ministry of Education, School of Civil Engineering, Southeast University, Nanjing, China
National and Local Joint Engineering Research Center for Intelligent Construction and Maintenance, Southeast University, Nanjing, China

ABSTRACT: Vehicles represent the main operational loadings of bridge structures since they are designed and constructed to sustain passing vehicles. Among others, structural responses due to the moving vehicles play a crucial role in bridge health monitoring, condition assessment, maintenance. Traditionally, vehicle-induced dynamic responses can be obtained through a variety of numerical computational models. Depending on the complexity of existing models, they could become either computationally expensive or hard to be implemented in regular engineering practice. Moreover, as physical-based methods, a good number of parameters associated with materials, mechanics, and geometry are required to establish a reliable model reflecting the physical structure behaviour. Recently, the literature has seen an increasing research efforts in dynamic response estimation of civil structures subjected to vehicle, seismic, or wind load using machine learning techniques. This paper presents an investigation of predicting dynamic responses of bridges by neural network under vehicle loadings. Representative analysis model is employed to create training data pairs for learning parameters in the network. The state-of-art deep learning technique, namely, convolutional neural network is adopted to develop the metamodel of the vehicle and bridge system, capable of delivering time history response to be compared with results from numerical experiments. The results show that the predictive model yields high prediction accuracy and is robust to data noise.

1 INTRODUCTION

Structural dynamic response of bridges plays a crucial role in the entire bridge life cycle, such as planning, design, operation & maintenance, inspection, and monitoring. These responses can be obtained by field measuring or numerical computation. For vibration measurement, sensors need to be installed in the structural components or cross-sections of interests (Carey et al., 2017; Mostafa, 2021; Xia et al., 2013). However, the campaign is still labor intensive and cost-ineffective. Although long-term bridge health monitoring can provide continuous data of bridges (Hu et al., 2013; Cahill, 2016; Sun et al., 2020), this type of monitoring system is rarely applied to the bridges with regular spans. These bridges account for the vast majority of the bridge inventory.

Recently, artificial neural network (ANN) has been regarded as a quite promising soft computing algorithm in dynamic analysis of large-scale civil structures (Adeli, 2001; Adeli, 2020; Vaidyanathan et al., 2005). The development of deep learning techniques provides new tools for structural response prediction due to dynamic loadings (Adeli, 2020; Feng et al., 2021; Kim et al., 2020). As a data driven approach, ANN models can be constructed by using labeled data as input and output respectively. For example, Lagaros & Papadrakakis (2012) used neural network for dynamic response prediction of buildings under seismic load.

DOI: 10.1201/9781003483755-17

Joghataie & Farrokh (2008) used a feedforward neural network to perform dynamic analysis involving seismic excitation. Oh et al. (2020a) realized the prediction of the maximum response of structures based on conventional multi-layer perceptron under artificial earthquakes. In addition, many researchers have studied the application of deep neural networks in estimating the dynamic response of structures caused by ground motion (Xu et al., 2021; Wu et al., 2019; Kim et al., 2019; Peng et al., 2021; Oh et al., 2020b; Torky & Ohno, 2021;).

While ANN based surrogate models have gained more and more attention in the literature related to earthquake-induced structural dynamic response analysis, limited research has been reported focusing on the response prediction of bridges under vehicular loads by the neural network algorithms (Li et al., 2020, 2021, 2022, and 2023a). To this end, this work aims to present an investigation of adopting deep neural networks to analyze vehicle-induced bridge vibrations and the efficacy of the state-of-art machine learning techniques under consideration. A representative model namely, moving load model is established in this study. The model is able to capture the main dynamic characteristics of the vehicular loads. A deep convolutional neural network (CNN) model is proposed to predict the time-histories of bridge dynamic response. The deep learning architecture is developed based on the bridge equation of motion governing the structural vibration in generalized coordinates. A comparison of time-history curve and peak error are carried out to evaluate the estimation capacity of proposed model.

2 MOVING LOAD MODEL

In this paper, a simple model of vehicular loads, namely moving load model, is considered to simulate the dynamic responses. As shown in Figure 1, the inertia force of vehicle can be ignored and the vehicular load can be simplified as a moving concentrated force *P*. Additionally, the track irregularity excitation is also neglected herein (Li et al., 2023b). When the force P passes the bridge at the speed of v, the partial differential equation of the bridge vibration can be written as

$$EI_{\mathrm{b}}\frac{\partial^4 Z_{\mathrm{b}}(x,t)}{\partial x^4}+\bar{m}\frac{\partial^2 Z_{\mathrm{b}}(x,t)}{\partial t^2}+c\frac{\partial Z_{\mathrm{b}}(x,t)}{\partial t}=P\delta(x-vt) \tag{1}$$

Where Z_{b} is the bridge displacement; I_{b}, $\bar{m}$, and c are the moment of inertia, mass per unit length, and damping coefficient of the bridge respectively; E is the modulus of elasticity; and δ is the Dirac delta function.

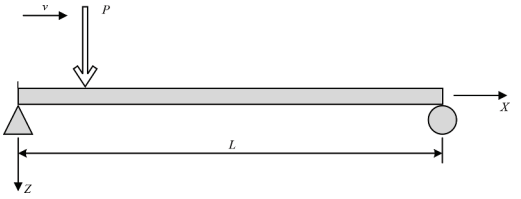

Figure 1. Moving load model.

Equation (1) can be solved through modal decomposition technique. Accordingly, the solution of Equation (1) is expressed in the following form (Li et al., 2023c):

$$Z_{\mathrm{b}}(x,t)=\sum_{i=1}^{\infty}q_i(t)\phi_i(x) \tag{2}$$

where $q_i(t)$ is the generalized mode coordinates and $\phi_i(x)$ is the function of the ith vibration mode. For a simply-supported bridge, the function of vibration mode can be written as

$$\phi_i(x) = \sin\frac{i\pi x}{L} \tag{3}$$

Then, the ith order generalized equation of motion of the simply-supported beam is given by

$$\ddot{q}_i(t) + 2\varsigma_i\omega_i\dot{q}_i(t) + \omega_i^2 q_i(t) = \frac{2}{\bar{m}L}P\sin\frac{i\pi vt}{L} \tag{4}$$

where ω_i and ς_i are the ith frequency and damping ratio. The solution of Equation (4) can be written as

$$q_i(t) = e^{-\varsigma_i\omega_i t}(A_i\cos\omega_{id}t + B_i\sin\omega_{id}t + D_i\cos\omega_{iv}t) \tag{5a}$$

$$C = \frac{2P}{\omega_i^2\bar{m}L}\frac{1-(\omega_{iv}/\omega_i)^2}{\left[1-(\omega_{iv}/\omega_i)^2\right]^2 + [2\varsigma_i(\omega_{iv}/\omega_i)]^2} \tag{5b}$$

$$D = \frac{2P}{\omega_i^2\bar{m}L}\frac{-2\varsigma_i(\omega_{iv}/\omega_i)}{\left[1-(\omega_{iv}/\omega_i)^2\right]^2 + [2\varsigma_i(\omega_{iv}/\omega_i)]^2} \tag{5c}$$

where $\omega_{iv} = i\pi v/L$ and $\omega_{id} = \omega_i\sqrt{1-\varsigma_i^2}$. A_i and B_i are the undetermined constants which can be identified by the initial condition. Therefore, the response of bridge can be expressed as

$$Z_b(x,t) = \frac{2P}{\bar{m}L}\sum_{i=1}^{\infty}[e^{-\varsigma_i\omega_i t}(A_i\cos\omega_{id}t + B_i\sin\omega_{id}t) + C_i\sin\omega_{iv}t + D_i\cos\omega_{iv}t]\sin\frac{i\pi vt}{L} \tag{6}$$

3 DEEP CNN FOR RESPONSE PREDICTION

Deep CNN is a type of classical deep learning model which is specialized in processing data with grid structure. In this paper, the time history data of the generalized force is adopted as input. A deep CNN model is proposed to predict the time history response of the bridge.

3.1 *CNN*

Since the input of the neural network is usually considered to be high-dimensional, resulting in large model size and thus considerable computational burden, the feature extraction layers are introduced into the deep learning model to reduce the dimensionality of data and to improve the fitness of model. Convolutional layer is a widely used feature extraction layer in deep learning models. In a convolutional layer, the convolutional operation and nonlinear activation function are used together to extract the feature from the input $\mathbf{X}$. Convolutional operation can be expressed as

$$\mathbf{O}_{i,j,k} = (\mathbf{X} * \mathbf{V})_{i,j,k} = \varphi\left(\sum_{m,n,l} X_{(i-1)s+m,(j-1)s+n,l}V_{m,n,l,k}\right) \tag{7}$$

where $X_{i,j,l}$ is the input component at the i^{th} row, j^{th} column, and l^{th} input channel; $V_{m,n,l,k}$ is the component of convolutional kernel $\mathbf{V}$ at the m^{th} row and n^{th} column, connecting the l^{th} input

channel and k^{th} output channel; $\mathbf{O}_{i,j,k}$ is the output component at the i^{th} row, j^{th} column, and k^{th} output channel; s is strides defining that the convolutional operation is carried out every s data point in each direction; $\varphi()$ is the activation function; and $*$ is the convolution operator. As shown in Figure 2, several convolutional operations are usually carried out in parallel, each of which can be regarded as a linear filter.

To extract advanced features from the input data, nonlinear activation functions such as sigmoid function, hyperbolic tangent function, and rectified linear unit (ReLU) are usually used after the convolutional operation to improve the ability of nonlinear mapping. The expressions of the activation functions, sigmoid, tanh, and ReLU are given as

$$Sigmoid(x) = \frac{1}{1+e^{-x}} \tag{8}$$

$$tanh(x) = \frac{e^{x}-e^{-x}}{e^{x}+e^{-x}} \tag{9}$$

$$ReLU(x) = \begin{cases} x & x>0 \\ 0 & x \le 0 \end{cases} \tag{10}$$

Another operation in CNN is the pooling operation which includes mean pooling and max pooling to calculate the mean value or max value of all the data in the pooling domain respectively. Figure 2 shows how the mean pooling can reduce the input data size.

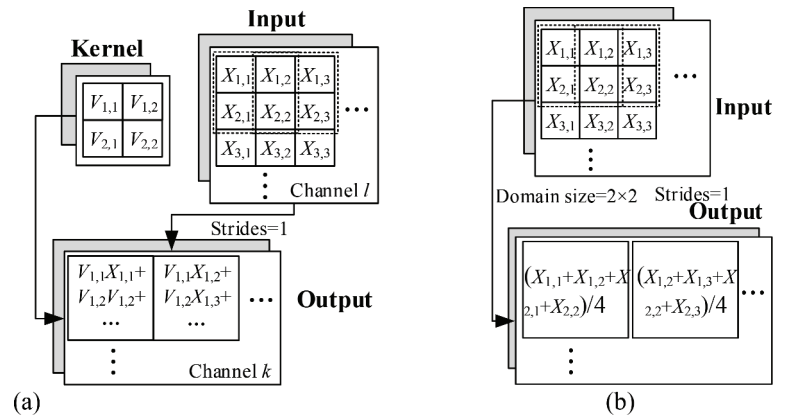

Figure 2. The CNN algorithm: (a) convolutional operation; and (b) pooling operation.

3.2 *Proposed CNN model for time history prediction*

According to Equation (4), the input of the CNN model is determined as the generalized force associated with the ith mode of vibration. To predict the dynamic bridge response in terms of discrete time, the network input can be expressed as

$$X_{i,j} = \sin\left(\frac{i\pi v t_j}{L}\right), \quad i = 1,2\ldots n, \quad j = 1,2\ldots m \tag{11}$$

where $X_{i,j}$ is the element in the input matrix $\mathbf{X}$ at the ith column and jth row; $t_j = j\Delta t \in [0, T]$; n is the number of vibration modes considered in response calculation; Δt is a constant which represents the time interval related to the sampling frequency; T is the time needed for the vehicle

to cross the bridge in the present analysis; and $m=T/\Delta t$ is the number of data points associated with one vehicle passing event.

The deep CNN model with the architecture shown in Figure 3 is proposed to realize the time history response prediction of bridge displacement, velocity, and acceleration.

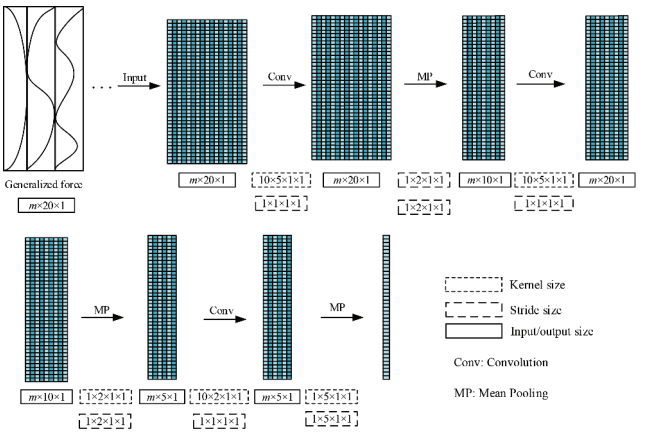

Figure 3. Architecture of the proposed deep CNN model for time history response prediction.

4 NUMERICAL EXAMPLE

To validate the proposed deep CNN model in time history response prediction, a numerical example is used. A vehicle-bridge system in the railway (Li et al., 2021) is simplified as the moving load -bridge model. The model parameters are shown in Table 1.

Table 1. Parameters of the vehicle-bridge system.

Parameter	Value
Bridge span L	23.1 m
Mass per unit length $\bar{m}$	2.12×10^4 kg
Elastic Module E	3.45×10^4 MPa
Moment of inertia I_b	6.78 m^4
damping ratio	0.02
Central force P	5.49×10^5 N

4.1 *Bridge response*

Figure 4 shows the displacement, velocity, and acceleration response of the bridge mid-span when the train speed is 300km/h.

4.2 *CNN training*

In this paper, 600 samples are generated by the moving load with random vehicle speeds between 250 km/h to 300 km/h. Among these examples, 500 samples are selected as training samples and the remaining 100 samples are used as validation datasets. For the model input, modal forces associated with 20 vibration modes are considered in this example. Mean square error (MSE) is utilized as the loss function given by

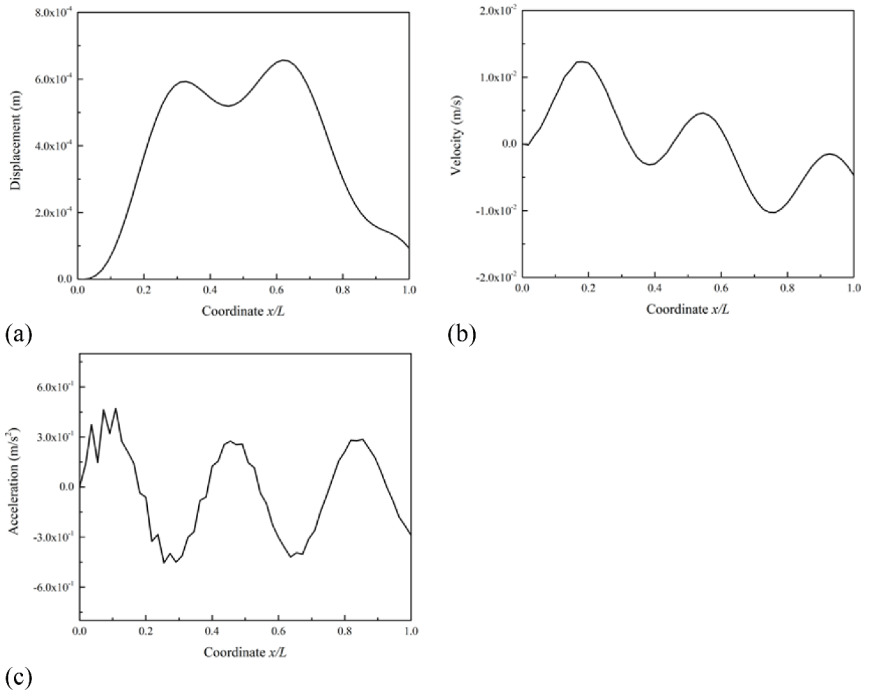

Figure 4. Sample of bridge response at mid-span with train speed of 300km/h: (a) displacement; (b) velocity; and (c) acceleration.

$$MSE = \frac{1}{M_{\mathrm{b}}} \sum_{i}^{M_{\mathrm{b}}} \left(X_i - \hat{X}_i \right)^2 \tag{12}$$

where X_i and $\hat{X}_i$ are the predicted value and target value of deep learning model; and M_{b} is the number of samples in a training batch.

In this example, root mean square prop (RMSprop) algorithm with initial learning rate of 0.0001 is utilized to train the proposed deep neural network model. The MSE of training samples and validation samples varying with the training epochs are presented in Figure 5.

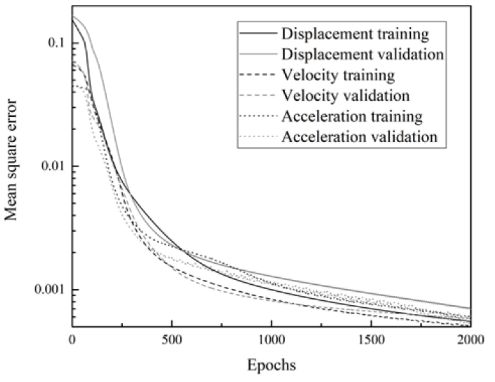

Figure 5. The variation of MSE with training epochs.

4.3 *Response prediction results*

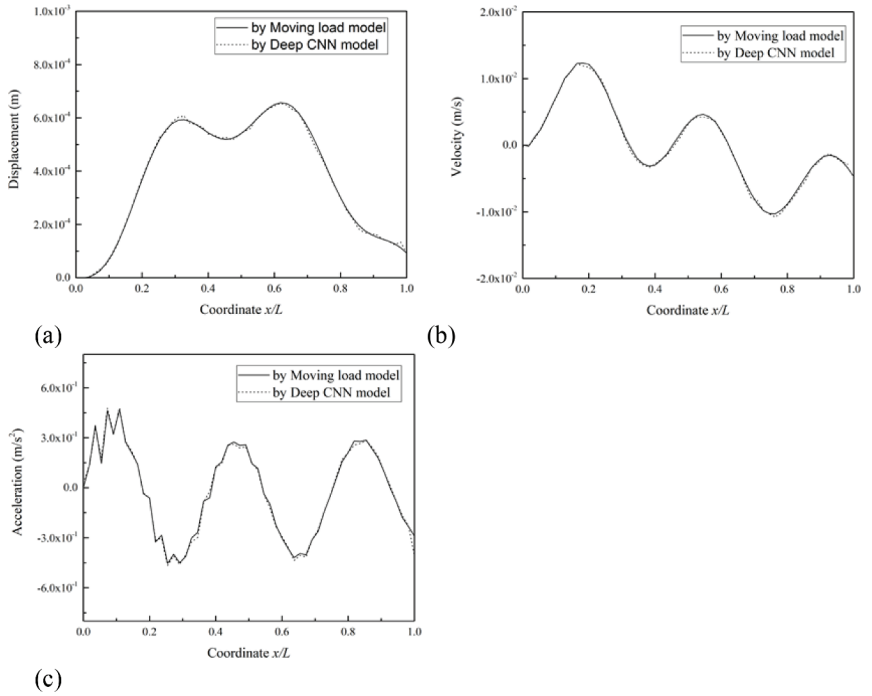

Figure 6. Comparison of time history response resulting from the deep learning model and moving load model: (a) displacement; (b) velocity; and (c) acceleration.

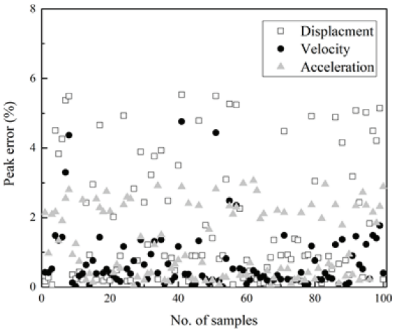

Figure 7. The peak error of predicted response prediction.

Figures 6 (a)-(c) present the comparison of time history response of the bridge under moving load while the moving speed is 300 km/h. One can observe from the figures that the prediction result is close to the analysis result from the moving load model.

Figure 7 displays the peak error (PE) of response prediction result of 100 new samples. As it is shown, for most samples, PE is less than 3%. Some samples have a larger value in PE and yet all the PE of tested samples are less than 6%. Therefore, the results show that the proposed deep learning model can make the response prediction under different moving speeds.

To examine the robustness of the proposed deep CNN model, different levels of noise, namely 1%, 2%, 5% and 10% are added to the input generalized force. The data noise can also

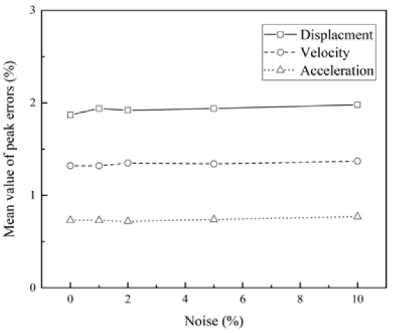

Figure 8. Mean value of peak errors varies with input noise.

be regarded as the inaccuracy of the input data. Figure 8 shows the variation of the mean PE of 100 samples with the input data. From the figure, it can be seen that the mean PE slightly increases with the rise of the noise level. Even under 10% noise, the PE value of the predicted result is less than 2%. Therefore, the developed prediction model is adaptable to varying input data quality.

5 CONCLUSIONS

In this paper, a deep CNN model is proposed to predict the bridge response under vehicular loads. Moving load model is used to obtain the bridge dynamic response samples. The generated samples are utilized to train the proposed deep CNN model for response prediction. The following conclusions can be drawn.

(1) Time-history responses including displacement, velocity, and acceleration can be predicted by the proposed CNN model.
(2) The peak error of response prediction result can be controlled to below 6%. Therefore, the proposed CNN model can be utilized to predict the peak response with satisfactory accuracy.
(3) The proposed deep CNN model is robust. Under the noise level up to 10%, the proposed model can predict the peak value of the response.

Behavior of CFST piers with compound concrete under cyclic lateral loading

Ji-Ji Wang*, Jun-Lei Fu, Su-Gong Cao, Hao Hu & Hao Tian
Zhejiang Scientific Research Institute of Transport, Hangzhou, China

ABSTRACT: Compound concrete, which refers to fresh concrete partly replaced with coarsely crushed demolition concrete (recycled concrete lumps or RCLs hereafter), is a simpler recycling process than the reuse of recycled concrete aggregates. The inherent weakness of the interface between RCLs and fresh concrete can be suppressed when a substantial amount of confinement can be provided as that in concrete-filled steel tubular (CFST) columns. The local buckling of CFST columns can be further delayed or suppressed when fibre-reinforced polymer (FRP) is used to jacket the steel tubes. The potential use of the composite column is as piers in rebuilt bridges. The paper presents and interprets the results of an experimental study on the mechanical behavior of CFST piers with compound or normal concrete subjected to combined axial compression and cyclic lateral loading. Four large-scale piers were tested, including a reinforced-concrete (RC) pier, a CFST pier, two GFRP-jacketed CFST piers with or without RCLs, to investigate the influence of parameters such as confinement types and concrete types. The test results indicate that the seismic behavior of the GFRP-jacketed CFST pier with compound concrete is comparable to that of fresh concrete; the use of GFRP jackets is effective in delaying the local buckling failure at the end of a cantilevered pier; the ductility and lateral load-carrying capacity of the RC pier can be significantly enhanced due to confinement.

1 INTRODUCTION

Compound concrete, which refers to fresh concrete partly replaced with coarsely crushed demolition concrete (recycled concrete lumps or RCLs hereafter), is a relatively new technique for recycling concrete. It has several advantages over traditional ways of recycling concrete aggregates, including its simplicity, cost-effectiveness and increased recycling ratio of demolition concrete. However, the non-uniformity and weak interfaces between RCLs and fresh concrete have detrimental effect on the mechanical performance of the compound concrete. Teng et al. (2016) conducted an experimental study on the compressive behavior of fibre-reinforced polymer (FRP) tubes filled with compound concrete. They found that with a significant level of confinement, the ultimate axial stress and the ultimate axial strain of the compound concrete with RCLs are comparable to those of the fresh concrete, regardless of the strength of the old concrete. Thereafter, many studies have been conducted experimentally and analytically on compound concrete with different type of confinements (Yu and Wu 2019; Zhao et al. 2020; Zhou et al. 2021; Chen et al. 2022, .etc).

Concrete-filled steel tubular (CFST) columns are widely used in new construction and can provide superior ductility over traditional reinforced concrete columns under seismic loading, especially when the local buckling issue can be delayed or suppressed by wrapping FRP sheets over steel tubes (Hu et al. 2011). The FRP-confined CFST columns with compound concrete has the potential to be used as bridge piers where low-capacity bridges should be demolished and rebuilt. Zhao et al. (2020) conducted axial compression tests on this kind of composite

*Corresponding author: wangjiji2009@qq.com

DOI: 10.1201/9781003483755-18

columns and obtained the axial stress-strain behavior of the compound concrete. The seismic performance of this kind of columns has not been studied yet.

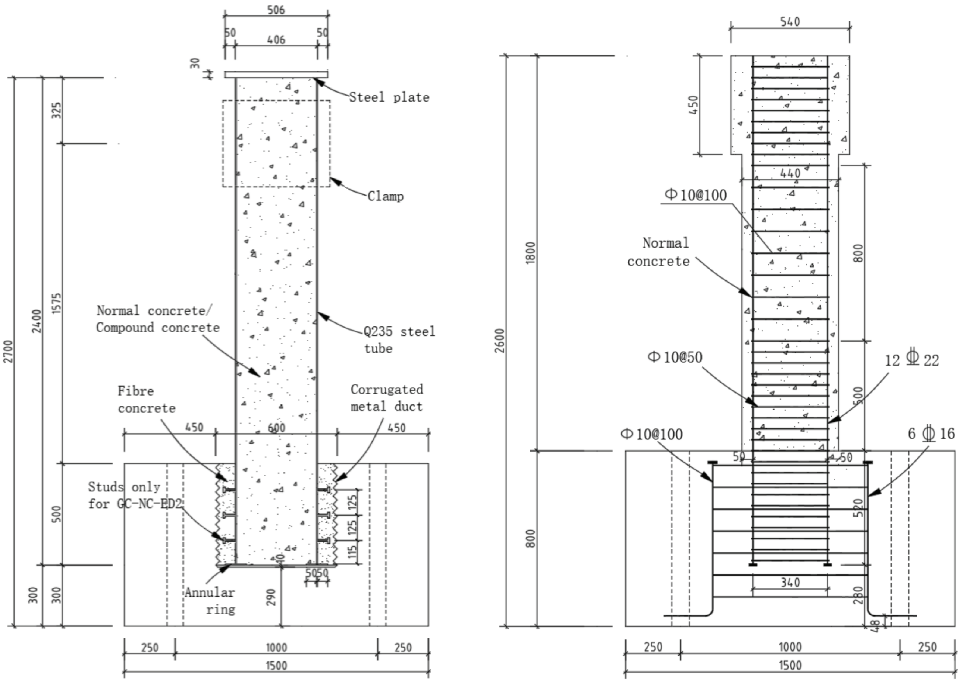
The paper presents and interprets the results of an experimental study on the behavior of CFST columns with compound or normal concrete subjected to combined axial compression and cyclic lateral loading. Four large-scale piers were tested, including a reinforced-concrete (RC) pier, a CFST pier, two GFRP-jacketed CFST piers with compound or normal concrete, to have a deeper understanding on the seismic performance of the composite column and investigate the influence of parameters such as confinement types and concrete types.

2 EXPERIMENTAL PROGRAM

2.1 *Specimen details*

The experimental program consisted of four large-scale test specimens, one CFST column, one reinforced concrete (RC) column and two GFRP-jacketed CFST columns with compound concrete or normal concrete. All the specimens had a circular section with a diameter of 406 mm, except that the RC column was 440 mm in diameter and its concrete cover was 40 mm measured from the outer side of longitudinal steel bars. All the specimens were 1575 mm in length from the point of lateral loading to the top of the reinforced concrete (RC) footing with a dimension of $1500\times1500\times800$ mm. The steel tubes were rolled from Q235 steel plate with a longitudinal seam weld. All steel tubes had an outer diameter of 406 mm and a thickness of 6 mm. Each specimen was given a name, which starts with "GC/SC/RC" to represent the GFRP-confined CFST column, CFST column, or RC column, respectively, followed by "NC/CC" to represent normal or compound concrete. For instance, specimen GC-NC was a GFRP-confined CFST column that filled with normal concrete. Specimen details were summarized in Table 1.

Table 1. Specimen details.



Specimen label	Concrete type	Number of GFRP layer	Type
GC-NC	Normal concrete	2 plies	GFRP-jacketed CFST columns
GC-CC	30% RCLs (volume ratio)	2 plies	GFRP-jacketed CFST columns
RC-NC	Normal concrete	N/A	RC columns
SC-NC	Normal concrete	N/A	CFST columns

The three specimens with steel tubes were embedded in the footing 500 mm in depth. The corrugated metal duct was used to increase bonding force and provide confinement to concrete in the connection region, in which fiber-reinforced concrete was filled after the steel tube was temporarily supported in the footing. Studies found that welding annular rings at the bottom of steel tubes significantly increased the shear resistance of joints when the extending width was between 8 to 16 times the thickness of the steel tube (Stephens et al. 2015; Zhu 2017). This design detail was adopted in the present study, with the annular ring extending a width of 50 mm to both inside and outside of the steel tube (Figure 1a).The RC specimen was connected to the footing with longitudinal reinforcement. Totally 12 evenly distributed 22 mm HRB400 steel bars were fixed by steel wire to the steel cages in the footing.The anchoring length of the longitudinal reinforcement extending into the column and footing was 520 mm according to the requirements in GB 50010-2010 for headed steel bar (see Figure 1b).

2.2 *Preparation of specimens*

Specimens were constructed in sequence of footings, connections and columns (see Figure 2).

(a) Firstly, the steel cages of the footing were put in the molds. Corrugated metal ducts or steel cages of the connection were temporally supported in the footing, and the footings were cast with C30 normal concrete.

(a) Specimens with steel tubes (b) RC specimen

Figure 1. Design details of specimens.

(b) For specimens with steel tubes, steel tubes were put in the ducts and temporarily supported with 4 steel bars, after which fiber-reinforced concrete was cast in the ducts. For the RC specimen, the steel tube mold was put above the footing and was adjusted to vertical state with four steel bars.

(c) Steel tubes or the steel mold were poured with concrete in three layers and each layer was carefully vibrated. For specimen with compound concrete, the RCLs were made from C30 steel cubes and were put in water to absorb water for over 24 hours. For each layer, the RCLs were thrown into the steel tube together with the normal concrete.

(d) Thick steel plates were welded on top of the steel tubes to sustain axial compression. Two layers of GFRP sheets were horizontally wrapped on the steel tubes in the lab.

(a) Steel cages installed with strain gauges (b) Concrete casting (c) FRP wrapping and top plates welding

Figure 2. Preparation of specimens.

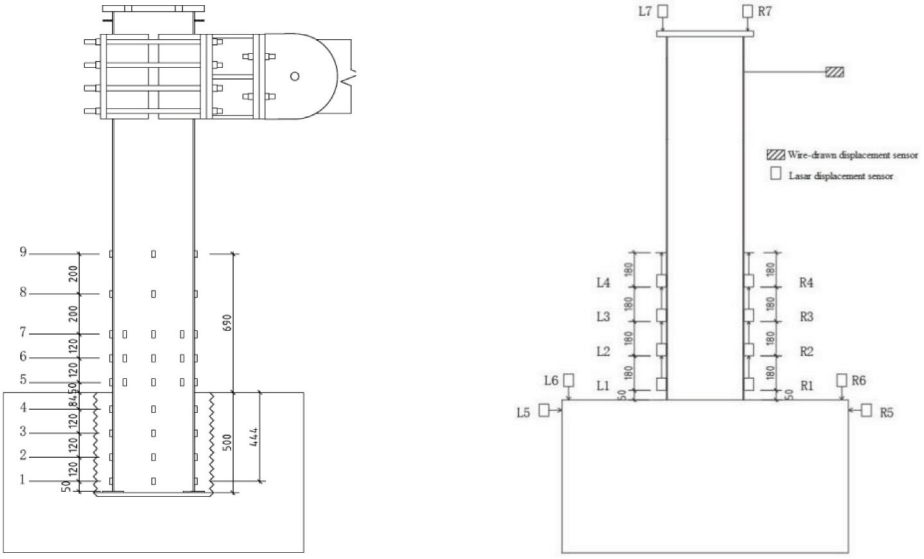
2.3 *Material properties*

In total, three batches of concrete were prepared for the footings, columns and the connections, respectively. 6 mm-length PVA fiber with a content of 1.8kg/m^3 was added in the concrete batch for the connection. For each batch of concrete, at least three 150 mm cubes were prepared and tested in accordance with GB/T 50081-2019. The average compressive strengths of 150 mm cubes were 47.3 MPa, 61.3 MPa, and 49.0 MPa for concrete in the footings, the columns and the ducts, respectively, at the age of about three months. Compound concrete with recycled concrete volume ratio of 30% was used in specimen GC-CC. The RCLs were crushed from 150 mm cubes whose average compressive strength was 59.2 MPa at the age of 28 days. The characteristic length of the RCLs was 50~150 mm. Cylinders 200 mm in diameter and 400 mm in length were also prepared for the compound concrete and the normal concrete (the same batch concrete for columns), whose average cylinder compressive strengths were 36.8 MPa and 45.8 MPa, respectively.

Three steel coupons were cut from a steel tube which was exactly the same as those in the columns. The steel tube had an elastic modulus of 201 GPa, a yield stress of 275.4 MPa, and an ultimate stress of 390.1 MPa. The steel reinforcement has an elastic modulus of 203 GPa, a yield stress of 441.1 MPa, and an ultimate stress of 654.1 MPa. The GFRP jacket used had an elastic modulus of 100 GPa and an ultimate strain of 2.5% according to the manufacturer.

2.4 *Instrumentation*

Strain gauges and transducers were employed to monitor the behaviour of specimens (see Figure 3a). A number of bi-directional strain gauges were used to measure the axial and hoop strain distributions of the column at 9 different column heights, namely, the circumferences at 50 mm, 170 mm, 290 mm and 410 mm from the column bottom surface, and 50 mm, 170 mm, 290 mm, 490 mm and 690 mm from the column footing top surface, respectively. For No. 5~7 layer of strain gauges, eight strain gauges were evenly installed around the circumference. The other heights were expected to be outside the plastic hinge region, so a smaller number (i.e. four) of strain gauges were used for each circumference. The gauge length of the strain gauges attached to the steel tubes was 10 mm while that of the strain gauges attached onto the FRP jackets was 20 mm.



Eight linear variable displacement transducers (LVDTs) were installed on the two sides of the loading plane (i.e. the western side and the eastern side, see Figure 3b) of the column at intervals of 180 mm starting from the column end (i.e. the top surface of the footing). These LVDTs were installed on the column surface through pre-fixed nuts. In addition, two pairs of LVDTs (each pair consisted of one vertical and one horizontal transducer) were used on the two sides of the foundation to monitor the movement it could experience during the test. A wire-drawn displacement sensor was installed at the center of the clamp connected to the lateral laod actuator to measure the lateral displacement. The rotation of the column head and the shortening of the column were measured by two LVDTs on the top steel plate.

2.5 *Testing frame*

All the tests were conducted using a testing frame at the Structural Engineering Laboratory of Zhejiang Scientific Research Institute of Transport. Figure 4 shows a photo of the testing frame. The testing frame includes a vertical actuator (capacity: 1000 kN) connected to a relatively large steel beam and rollers are provided between the actuator and the beam so that during the test the horizontal locations of the actuator can be adjusted. In addition, a horizontal actuator (capacity: 500 kN in tension and compression) is provided which can apply horizontal loading through a hinge joint. The positions of both actuators can be controlled manually. Both actuators can apply not only compression but also tension forces. In the test, the specimen was fixed to a strong floor using eight sets of screws (80 mm in diameter) and nuts.

2.6 *Loading scheme*

Pre-loading procedure was conducted before formal loading to reduce the gap between the specimens, basement and actuators, and to make sure the measuring instruments were in

(a) Strain gauges installed on tubes (b) Transducer layout

Figure 3. Preparation of specimen.

Figure 4. Testing frame

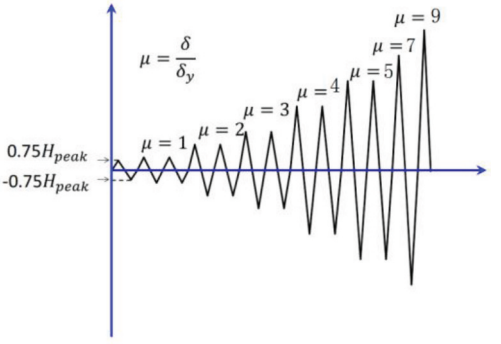


Figure 5. Loading scheme

correct status. After pre-loading, a constant axial load of 700 kN was applied to each column. The lateral load scheme was conducted following the practice of existing studies (Yamao et al. 2002; Zhang 2014). The yield displacement was used to control the lateral cyclic loading. The yield displacement of the column was defined in the following way: (1) load the column to a level which is 0.75 times the maximum lateral load H*peak*; *Hpeak* was estimated through a sectional analysis method and was found to be 350 kN; (2) the yield displacement δ_y is defined as the elastic limit of an equivalent elastic-perfectly plastic curve with a reduced stiffness being equal to the secant stiffness at 75% of the peak lateral load. The lateral load was applied in the following scheme (see Figure 5):

(a) Before 0.75H*peak*: the specimens were pushed to one side with a loading rate of 100 kN/min and stopped when the lateral force was 250 kN. Calculate the displacement δ_{y1} at H*peak*. Reverse the loading direction and obtain the displacement δ_{y2}. The yield displacement used to control the following lateral loading scheme was the average of the absolute value of two displacements.

(b) After 0.75H*peak*: the lateral cyclic loading was controlled by a maximum displacement of $\pm\delta_y$, $\pm 2\delta_y$, $\pm 3\delta_y$, $\pm 4\delta_y$, $\pm 5\delta_y$, $\pm 7\delta_y$, etc., and consisted of two cycles at each displacement level before $5\delta_y$. The loading rate was 9 mm/min. Loading was stopped for 5 minutes at each maximum displacement before observing the status of the specimen.

3 EXPERIMENTAL RESULTS AND DISCUSSIONS

3.1 *Test observations*

The failure mode of GFRP-confined CFST column specimens GC-NC/CC: firstly, transverse inter-layer cracks appeared at the bottom of the column in GFRP, and then the steel pipe bulged at the bottom of the column. The composite material gradually fractured near the bulge of the steel pipe, and finally the steel pipe buckled at a distance of 50mm from the bottom of the column, resulting in a significant decrease in bearing capacity.

The failure mode of CFST column specimen SC-NC: The steel tube is bulging and bending at the bottom of the column. Due to weld defects, the tensile test weld of the steel tube breaks prematurely, and there is no tearing failure of the steel tube.

The Failure mode of RC column specimen RC-NC: The concrete protective layer at the bottom of the column peels off extensively, the exposed longitudinal bars buckle, the core concrete at the bottom of the column falls off, and the test is terminated when the horizontal force drops by more than 15%.

Take specimen GC-NC as an example to introduce the failure process in detail. The specimen experienced GFRP damage in the tensile side first, after which the steel tube buckled. There was a sharp drop in horizontal force for specimen GC-NC during the first positive cycle of $7\delta_y$ when the steel tube on the tensile side was damaged (see Figure 6).

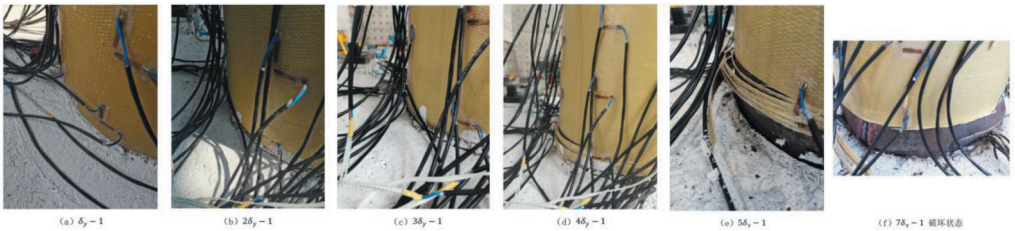

Figure 6. Failure process of specimen GC-NC.

3.2 *Lateral load–lateral displacement curve*

The envelope lateral load-lateral displacement curve was shown in Figure 7. Several observations can be drawn from the figure:

(a) The horizontal bearing capacity and ductility of CFST specimen or GFRP confined CFST specimens are greater than those of reinforced concrete pier column specimens. The experimental phenomenon shows that the concrete in the plastic hinge area at the bottom of RC column specimen peeled off and was damaged severely. Although the concrete in the plastic hinge area of other specimens also showed crushing failure, due to the constraints of steel pipes and composite materials, the concrete inside the column still maintained vertical compressive bearing performance.
(b) The seismic behavior of the GFRP-jacketed CFST pier with compound concrete is comparable to that of fresh concrete. The bearing capacity of specimen GC-CC is a little weaker than its counterpart, as the cylinder test showed that the compressive strength of the compound concrete was 36.8 MPa, smaller than that of normal concrete (45.8 MPa).

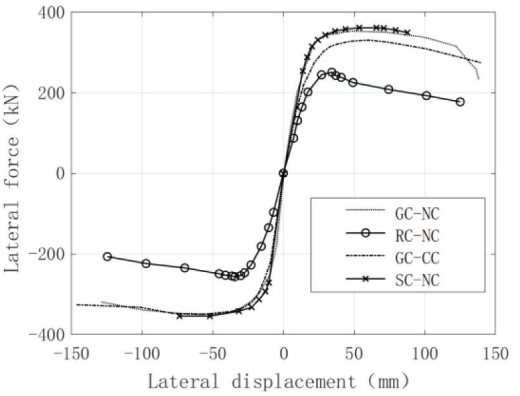

Figure 7. Envelope lateral load-displacement curve.

3.3 *Ductility*

Table 2 shows the ductility factor of each specimen. The ductility factor of specimen RC-NC is the smallest, indicating that the ductility of RC columns is worse than that of composite column specimens. The reason for the low ductility of specimen SC-NC (CFST column) is due to earlier failure in the weld seam compared to those in GFRP-confined CFST columns.

Table 2. Ductility of specimens.

Specimen		Yield displacement (mm)	Yield load (kN)	Ultimate displacement (mm)	Load at ultimate displacement (kN)	Ductility factor μ	Ductility factor (Mean)
GC-	+	22.0	326.7	121.9	316.1	5.54	5.60
NC	-	22.8	317.3	128.9	319.2	5.66	
RC-	+	17.8	210.0	66.9	221.4	3.90	4.26
NC	-	23.1	219.4	106.6	209.9	4.62	
GC-	+	21.9	275.1	132.7	280.8	6.07	6.35
CC	-	22.1	319.2	146.5	326.0	6.62	
SC-NC	+	20.1	315.4	87.6	349.2	4.36	4.31
	-	17.3	313.0	73.8	354.1	4.26	

4 CONCLUSIONS

The paper presents and interprets the results of an experimental study on the mechanical behavior of CFST piers with compound or normal concrete subjected to combined axial compression and cyclic lateral loading. By comparing and analyzing the failure mode, bearing capacity and ductility of each specimen, the influence of confining type and concrete type on the seismic performance of the specimens is studied. Through the analysis of experimental phenomena and results, the following conclusions can be drawn:

(1) GFRP-confined CFST columns have superior ductility over RC and CFST columns. The ductility and lateral load-carrying capacity of the RC pier can be significantly enhanced due to confinement.
(2) The seismic behavior of the GFRP-jacketed CFST pier with compound concrete is comparable to that of fresh concrete. The use of GFRP jackets is effective in delaying the local buckling failure at the end of a cantilevered pier.

Extending the service duration of bridges by means of (R-)UHPFRC

S. De Maria & D. Briccola
University of Applied Sciences and Arts of Southern Switzerland (SUPSI), Mendrisio, Switzerland

ABSTRACT: Ultra-High-Performance Fiber Reinforced Cementitious Composite (UHPFRC) and Reinforced UHPFRC (R-UHPFRC) are mainly used to improve the performance of aging bridge structures against increasing traffic, aggressive environmental scenarios, and demanding operational conditions. The growing number of applications in this field requires a robust numerical modeling technique to quantify the load carrying capacity and ductility response of arbitrary-shaped cross-section reinforced with (R-)UHPFRC layers under axial load and bending moments. The application of a well-codified approach, based on (i) the discretization of a cross-section in iso-parametric subdomains, (ii) equilibrium and compatibility equations, and (iii) numerical integration to solve (ii), allows to easily evaluate the frontier of interaction domains and moment-curvature diagrams. In this way, different refurbishment solutions can be compared highlighting the advantages of each of them in terms of load-carrying capacity and durability. This approach can aid practicing engineers, breaking down the last barrier to the widespread use of this promising material.

1 INTRODUCTION

Reinforced and prestressed concrete structures such as existing bridges and viaducts, when subjected to large stresses or cyclic actions, as well as to severe environmental conditions, show deficits in terms of mechanical strength and durability. Traditionally, numerous rehabilitation works have been carried out using ordinary concrete. Despite its wide use, the limited durability of concrete combined with the harsh exposure conditions jeopardize the effectiveness of traditional renovation techniques, resulting in the need to intervene again few years after.

Research in the field of engineered materials for use in civil engineering structures has brought to the development of Ultra-High-Performance Fiber Reinforced Concrete (UHPFRC). Thanks to its extraordinary mechanical properties, UHPFRC is nowadays in Switzerland the first choice for carrying out rehabilitation works on existing reinforced concrete (RC) and prestressed concrete (PRC) structures.

The material exhibits outstanding mechanical properties: extremely high compressive and tensile strengths respectively in the range of 150 - 200 MPa and 7 - 10 MPa in the elastic range, up to 14 MPa in the strain hardening domain as reported in Brühwiler, E. (2019). More in detail, 10-15 mm steel fibres, added in a dosage of at least 2- 3 % in volume to a specific mixture of cement, minerals, and water, are responsible of the increased tensile capabilities of the material. Moreover, thanks to its composition, UHPFRC exhibits an ultra-low permeability with a permeability coefficient in non-cracked conditions about 50 times lower than that of ordinary concrete, as reported in Charron, J.P. (2006). That ensures an increased performance in terms of durability.

For these features, UHPFRC represents a valuable method both to create a protective layer for reinforced concrete elements and to increase the load carrying capacity of existing bridges

DOI: 10.1201/9781003483755-19

and viaducts. Therefore, an extensive laboratory and on-field research carried out over the past 20 years mainly in Switzerland have led to a comprehensive knowledge of UHPFRC and a reduced time-to-market. It has been demonstrated in Habert, G. (2012) that producing UHPFRC generates half of the amount of CO2 emissions than ordinary concrete. To aid practitioner engineers in their daily activities in 2016 the Technical Leaflet SIA 2052 was published. An additional aid to the widespread use of such an innovative material in rehabilitation and strengthening of existing RC and PC bridges could be an easy-to-use sectional analysis program to evaluate the strength and ductility of (R-)UHPFRC-RC/PC cross-sections under bending and axial forces. Therefore, the goal of this research is to apply the numerical approach presented in Quagliaroli, M. (2015) to determine the interaction domains and moment-curvature diagrams of R-UHPFRC-RC sections subjected to axial load and bending moment. A critical comparison of interaction domains and moment-curvature diagrams can help identifying effective methods to extend the service duration of existing bridges based on materials data durability and structural properties.

2 A CONVENIENT APPROACH TO ASSESS THE BEHAVIOR OF (R)UHPFRC-RC CROSS SECTIONS

To highlight the advantages UHPFRC can offer to existing bridges and viaducts in terms of extended service duration, e.g. increased durability and load carrying capacity, multiple layer/ reinforcement configurations based on two different cross-section geometry have been scrutinized.

The configurations exploited can be grouped into two main categories: solutions for (a) protection, where only a thin layer of material is placed on the top of the cross-section to secure it from aggressive environments thanks to UHPFRC outstanding permeability characteristics, avoiding the penetration of chlorides due to deicing agents; (b) strengthening, where the additional UHPFRC layer is reinforced with steel bars to increase both resistance and ductility of cross-sections. For each arbitrary-shaped composite cross-section made of UHPFRC applied as a protective or strengthening layer on existing RC sections, the kinematic assumption valid for slender elements and the perfect bond of materials allow to assess their structural response.

The presence of multiple materials characterized by different constitutive laws makes it convenient to apply the subdomain discretization approach introduced by Malerba, P.G. (1984). According to Briccola, D. (2013), two types of scenarios allow to numerically assess its structural response (strength and ductility): (i) given a deformation state, determine the corresponding stress state (direct problem); (ii) given the stress state, determine the cross-section kinematics. The first scenario allows drawing the axial force- bending moment interaction envelope for limit state design by iteratively changing the applied deformation state. Instead, the second problem allows determining the moment-curvature diagrams under service condition given a defined axial force. Sectional equilibrium and compatibility equations, written in a general matrix form, enable handling both scenarios.

From the numerical point of view, the first problem, written explicitly, involves a simple quadrature approach to solve the stress functions integral over the cross-section. Instead, the second one involves a numerical strategy for solving systems of nonlinear equations, namely the Newton- Raphson procedure.

The kernel of the problem is the integration of the terms of the stiffness matrix of the section arising from the algebraization of the abovementioned equations. By subdividing the cross-section into parametric subdomains and using different types of Gauss integration rules, an effective numerical integration strategy allows for solving the problems and drafting interaction domains and moment-curvature diagrams. Figure 1 shows graphically the subdivision and integration steps of the numerical procedure. For details on the numerical integration procedure and the analytical formalism, the reader can rely on Quagliaroli, M.(2015).

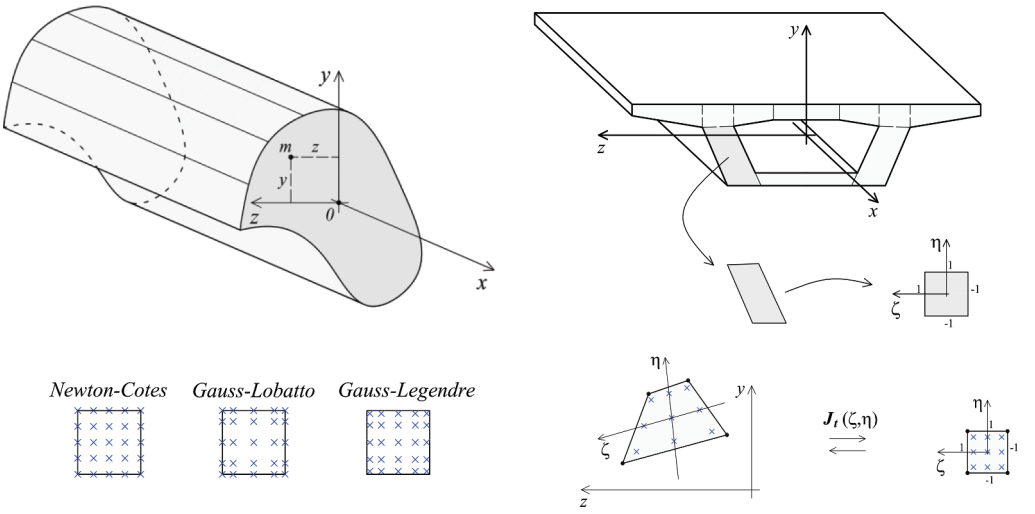

Figure 1. Integration strategies. The section is divided into subdomains and the integration works sampling in a parent domain by using parametric transformations.

3 APPLICATIONS AND MAIN FINDINGS

The numerical approach described has been applied to: (i) a reinforced concrete square section [RCsq] strengthened with a 40mm-depth UHPFRC layer with [RU-RCsq] or without [U-RCsq] reinforcing bars or, in alternative, with a traditional concrete layer with [RC-RCsq] or without [C-RCsq] reinforcing bars; (ii) a reinforced concrete two-cell box girder section [RCbg] strengthened with a 40mm-depth UHPFRC layer with [RU-RCbg] or without [U-RCbg] reinforcing bars or, in alternative, with a traditional concrete layer with [RC-RCbg]

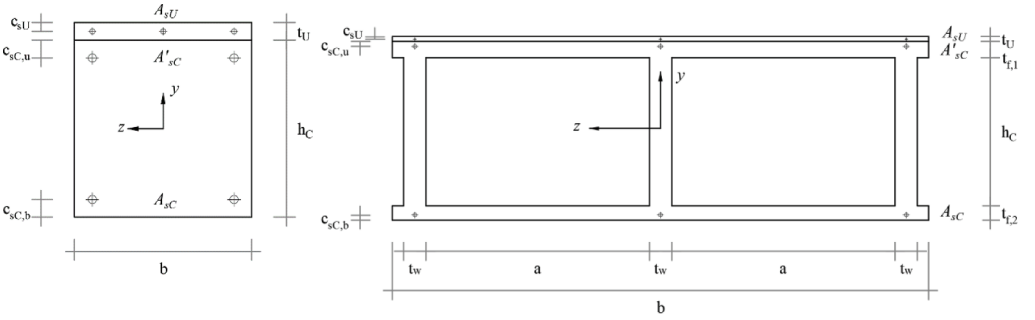

Figure 2. Square section (left) and two-cells box girder deck section (right).

or without [C-RCbg] reinforcing bars as in Figure 2. More in detail, 8 subdomains have been used for section (i) and 42 for (ii). As per the integration points a Gauss-Lobatto scheme was selected and with 7 sampling points on each subdomain, considering the outcomes in Quagliaroli, M. (2015).

3.1 *Bending moment – axial force interaction envelope*

Figure 3 shows the frontier of the bending moment-axial force interaction envelope for both the square (left) and box-girder (right) cross section considering different strengthening configurations.

By adding a UHPFRC strengthening layer, even unreinforced, for both sections, the bending moment-axial force interaction envelope assume a pronounced asymmetric shape with a remarkable positive bending moment-negative axial force region. The application of a 40mm-layer of UHPFRC on the top of a RC cross-section significantly increases the positive bending moment for limit state design under compressive axial force due to the UHPFRC high resistance under compression. Reinforcing the layer of UHPFRC with steel bars, for instance adding 3ϕ10 to the reinforced square concrete section, does not provide a meaningful strength increase to the positive bending moment under compression with respect to the unreinforced UHPFRC strengthening option. Indeed, the additional (R-)UHPFR-layer provide a remarkable strength gain in negative bending moment under compressive and tensile axial force.

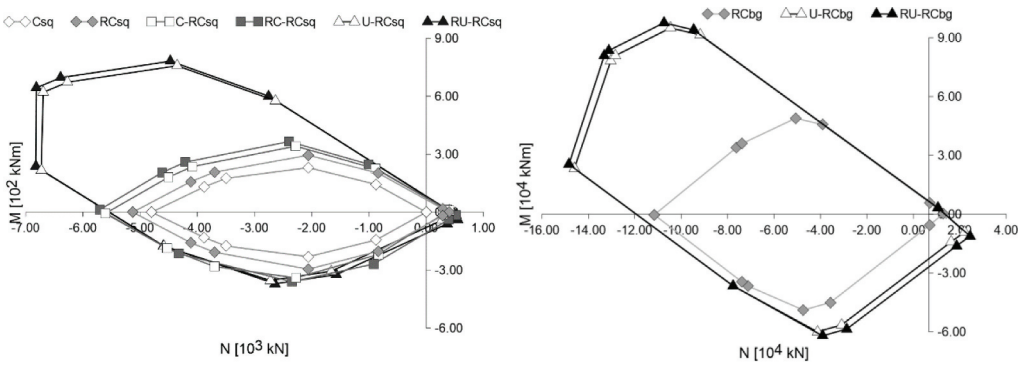

Figure 3. Bending moment - axial force interaction envelope of square cross-section (left) and of two-cells box girder deck section (right) for different strengthening configurations.

3.2 *Moment – curvature diagrams*

Figure 4 shows bending moment-curvature diagrams referring to different configurations of the square section under several levels of axial force for comparing strength and ductility values. Point A, B, C belong to the Csq section bending moment-axial force interaction envelope corresponding to the following failure conditions: point A) $\varepsilon = \varepsilon_{cu}$ at the top fiber, $\varepsilon = 0$ at the bottom reinforcement line; point B) $\varepsilon = \varepsilon_{cu}$ at the top fiber, $\varepsilon = \varepsilon_{sy}$ at the bottom reinforcement line; point C) $\varepsilon = \varepsilon_{cu}$ at the top fiber, $\varepsilon = \varepsilon_{su}$ at the bottom reinforcement line.

An additional level of axial force (N = -2400 kN), far away from failure of Csq section, was selected for further investigations. For all levels of axial force, it is evident that by adding a layer of UHPFRC, reinforced or unreinforced, the section becomes stiffer as the observed

reduction in curvature demonstrates. Moreover, the higher the material strength, the greater the sectional strength.

Conversely, for all levels of axial force and cross-section configurations, it is evident that the maximum bending moment a section can withstand decreases drastically with respect to the ultimate bending moment attained by (R-)UHPFRC-RC section. That highlights the great contribution in terms of strength that even a thin layer of UHPFRC provides to a reinforced concrete cross-section.

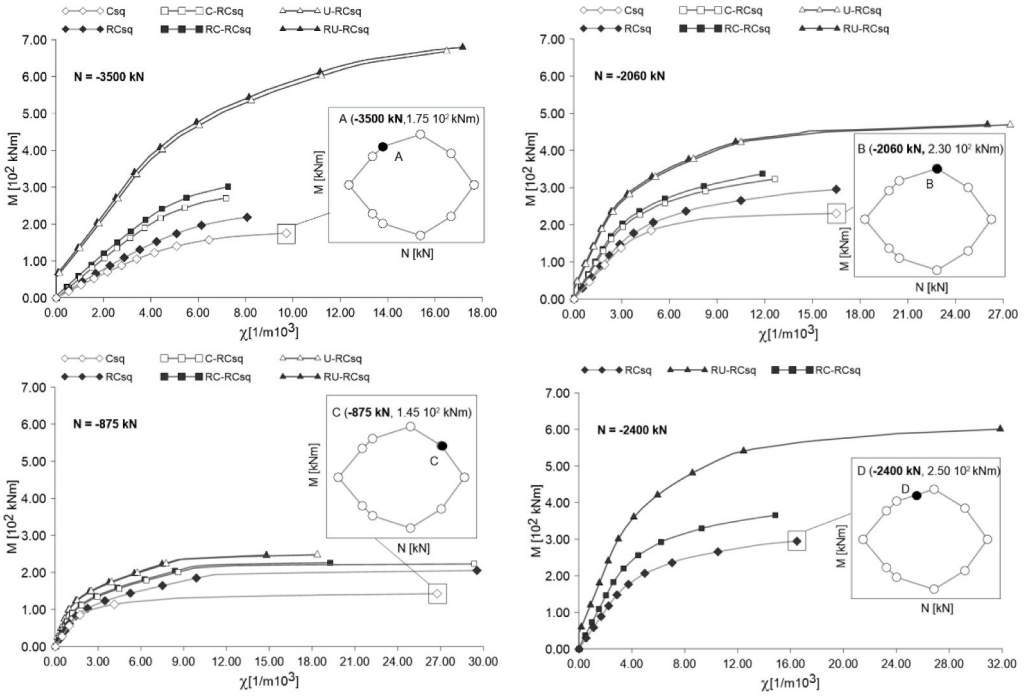

Figure 4. Moment - curvature diagrams comparison for the square section under different level of axial force for several strengthening configurations.

4 DISCUSSION

By further elaborating the results obtained, a synthetic measure of the load carrying capacity gain on average according with limit state design philosophy can be introduced. This measure, named α, shown in Figure 5 and 6 respectively for the square and box-girder deck section, corresponds to the ratio between the area beneath the bending moment-axial force interaction envelope in case of (R)UHPFRC-RC section and that beneath the bending moment-axial force interaction envelope of the original RC section.

The parameter α enables a fast comparison among different UHPFRC solutions under several loading scenarios. It is easy to note that this load carrying capacity gain is more pronounced where UHPFRC mechanical properties are best adapted, that is under positive/negative or negative/positive axial force and bending moment. In fact, in the N+/M- field of interaction the added layer of UHPFRC is stretched and can manifests its higher strength in tension with respect to traditional concrete. Similarly, in the N-/M+ field of interaction the added UHPFRC layer is shortened and can manifests its higher strength in compression with respect to traditional concrete.

As a result, it is evident that even in its protective version UHPFRC increase the load-carrying capacity of the original section, but of course this beneficial effect is even more evident in case of R-UHPFRC.

By comparing Figure 5 and 6 the impact of this increase depends on the cross-section shape and geometry, and on the amount of reinforcement steel. Considering the bending moment-axial force interaction envelope of the RC square cross-section under N+/M- the load carrying capacity gain is about 75% and for the RC two-cell box girder deck section is about 26%. Similarly, under N-/ M+ the load carrying capacity gain is about 3.6% for RC square section, and about 3.5% for the two-cell box girder deck section.

Of course, if material degradation was considered, the load carrying capacity gain magnitude would be different. Nevertheless, in case of structures with a good condition state the values obtained in this study represent a good esteem of the increased structural performance. As a result, it appears evident that UHPFRC repair and/or strengthening strategies to cope with more demanding future traffic conditions is a rewarding source of benefits for extending the service duration of road networks.

A numerical assessment considering different mechanical reinforcement ratios is out of the scope of this study but potentially can affect the load carrying capacity gain jeopardizing the effectiveness of UHPFRC strengthening configurations on protective ones.

5 CONCLUSIONS

The application of a well-codified computational approach to derive bending moment-axial force interaction envelopes and moment-curvature diagrams can aid practicing engineers and favoring the widespread use of this promising material. The procedure adopted can be easily extended to incorporate the contribution of prestressing steel and/or other kind of material. Additionally, biaxial bending moment-axial force interaction domain helpful for instance to

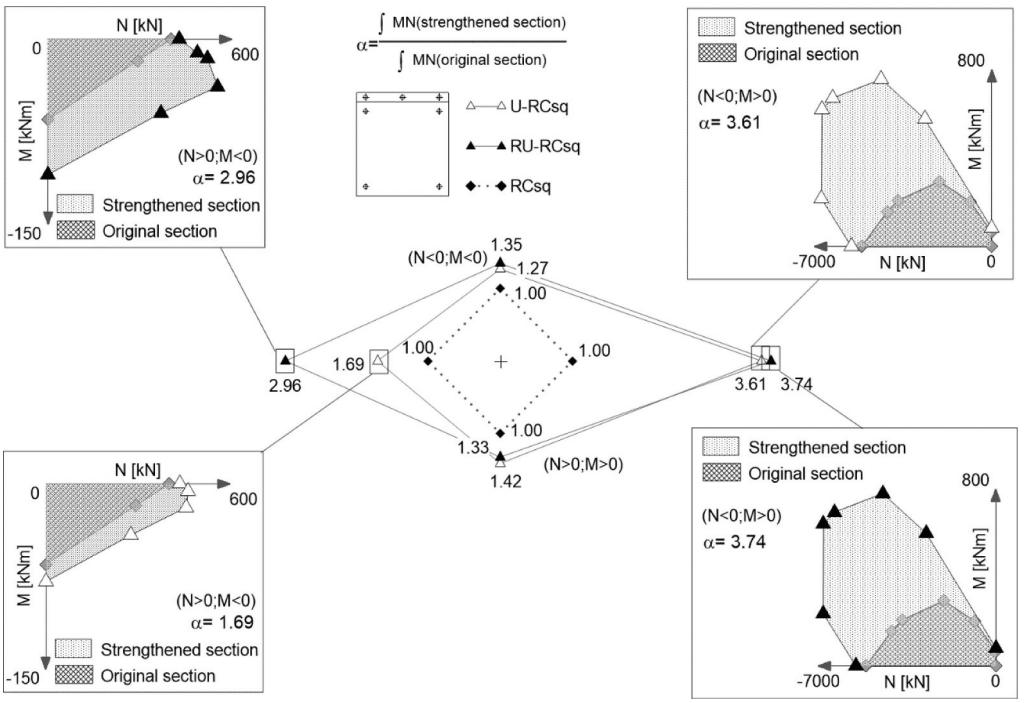

Figure 5. Load carrying capacity gain on average measure according with limit state design philosophy for RC, U-RC and RU-RC square section configurations.

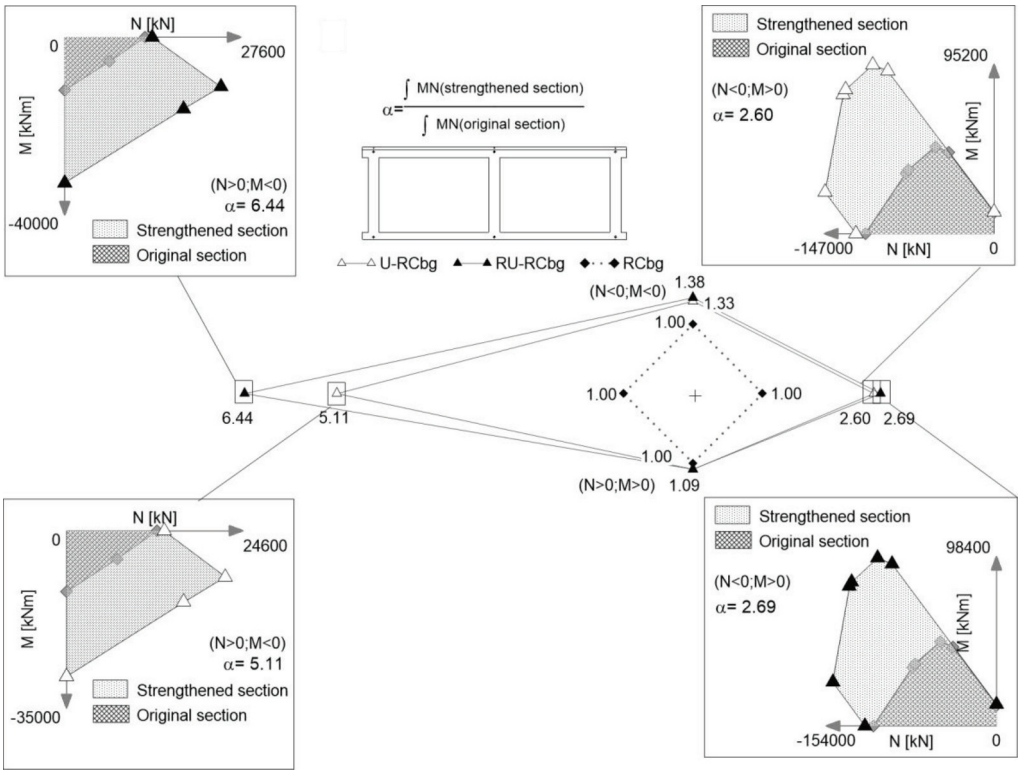

Figure 6. Load carrying capacity gain on average measure according with limit state design philosophy for RC, U-RC and RU-RC two-cells box girder deck section configurations.

study the load carrying capacity of stressed-ribbon footbridges can be straightforward derived by imposing cross-sectional equilibrium and compatibility, relying on perfect bond between different materials.

UHPFRC represents an advantageous material for strengthening aging infrastructures while increasing their durability, therefore achieving the goal of extending the service duration of existing bridges and viaducts. The technology has been implemented and widely used in Switzerland, but it worth to further application in other countries where prestressed reinforced concrete bridges and viaducts represent a huge portion of the total road infrastructural network.

Moreover, it has been demonstrated that besides its noticeable durability due to its incredibly low permeability, this innovative material is more sustainable than traditional one, representing a good candidate for repairing works.

The study carried out support several interesting reflections highlighting the structural performance advantages due to the application over a RC cross-section of a UHPFRC layer both for protective and strengthening purposes. These advantages can be summarized as follow:

- high load carrying capacity and exceptional ductility can be easily achieved on average.
- increasing axial force due to external loads do not drastically reduce ductility and strength.
- the load-carrying capacity gain is higher if the cross-section undergoes positive/negative or negative/positive axial force and bending moment.

Finally, further developments on the topic can be drafted. A rigorous approach to define the actual load carrying capacity of existing bridges must necessarily consider the material

degradation mechanism induced by carbonation, corrosion, exc. The implementation of such degradation models could reveal a limited rotational capacity at the sectional level jeopardizing the benefits of the added protective/strengthening UHPFRC layer.

Moreover, given the advancement in UHPFRC technology, it could be interesting to exploit the material not only where its mechanical properties are best adapted (that means when N +/M- or N-/M+) but everywhere across the deck to profit of the limited displacement of (R) UHPFRC-RC cross-section with respect to RC ones as it can be inferred by looking at the moment-curvature diagrams for fixed internal actions. In fact, the lower the curvature under a given axial force and bending moment, the lower the structural deflection.

Optimization study on wet joints construction of steel plate composite beams

B. Wang
Anhui Transportation Holding Group Co., Ltd, Anhui, China

Z.Q. Liu
Tongji University, Shanghai, China

ABSTRACT: To improve the construction efficiency of the steel plate composite beam bridge deck and reduce the construction steps of wet joints, this paper proposes a method to eliminate shear studs and internal prestressing in wet joints of steel plate composite beams. This significantly enhances the construction efficiency of the steel plate composite beam bridge. By establishing a spatial finite element analysis model and comparing it with a traditional bridge deck in terms of stress analysis, the results show that the two optimized structures have minimal impact on the stress distribution of the bridge deck. In particular, the stress increase in the bridge deck with eliminated wet joint shear studs is less than 4%, and the reduction in stress reserve due to the absence of transverse prestressing in wet joints is only 1 MPa.

Keywords: Wet joints, steel plate composite beam, finite element simulation, structural optimization

1 INSTRUCTIONS

Due to its simple structure, clear force transmission, and efficient construction, the steel plate composite beam bridge has the potential for standardized and industrialized construction, and is often used in the construction of municipal bridges(Zhang, Y., et al. 2020; Tawfic, Y. R., et al. 2021; Hassan, A. D. M., et al. 2020; Du, H., et al. 2020).

In urban bridge construction, the construction of steel plate composite beam bridges often involves the prefabrication of steel main beams and segmental bridge decks in factories, followed by on-site hoisting. Subsequently, wet joints are cast on-site, and prestressing is applied to the bridge deck. While the prefabrication of most components in factories and the mechanized hoisting construction greatly enhance construction efficiency, the welding of shear studs on steel main beams and the subsequent tensioning of prestressing in bridge decks usually require a large workforce, posing a key challenge to the standardization and industrialization of steel plate composite beam construction(Nie, J., et al. 2019; El-Sisi, et al. 2021; Zhao, Y. et al. 2020; Wang, Y. H., et al. 2020).

To further advance the construction efficiency of steel plate composite beam bridges, many scholars have explored the structural construction in-depth. For instance, Huang D and others (Huang, D., et al. 2023) proposed the U-shaped reinforcement wet joint construction, which involves setting the internal straight overlapping reinforcement in wet joints as U-shaped reinforcement, eliminating the need for welding and significantly improving construction efficiency. Additionally, He Shuan-Hai and others (Shuan-hai, H. E., et al.2021) directly improved structural construction efficiency by eliminating wet joints in composite beams. They used high-strength concrete as the bridge deck for I-shaped composite beams, enhancing the structural strength of the bridge deck and eliminating the wet joint construction. Full-scale model tests showed reasonable force distribution and feasible construction.

DOI: 10.1201/9781003483755-20

Based on the comprehensive analysis of the above studies, wet joint construction, due to its complexity, is indeed one of the key research objects affecting the construction efficiency of steel plate composite beams. This paper proposes an optimized method by studying and analyzing the shear studs and transverse prestressing inside wet joints, suggesting the elimination of shear studs and transverse prestressing at wet joint locations, significantly improving the construction efficiency of steel plate composite beams.

2 OPTIMIZATION OF WET JOINT SHEAR NAILS

2.1 *Model establishment*

The study focuses on a 3×40m double main beam steel plate composite beam bridge with a bridge width of 12.5m. A three-dimensional finite element model was established using finite element analysis software. The steel beam element type is SHELL63, and the concrete bridge deck element type is SOLID45. The steel material is Q345, with an elastic modulus of 2.1×10^5 MPa, density of 7850 kg/m³, Poisson's ratio of 0.3, and linear expansion coefficient of 1.2×10^{-5}. The concrete is C50, with an elastic modulus of 3.45×10^5 MPa, density of 2600 kg/m³, and Poisson's ratio of 0.2. Additionally, it is considered that there might be some bonding slip between the concrete bridge deck and the steel beam. This interaction is simulated by establishing spring elements COMBIN14 to model the elastic connection between them.

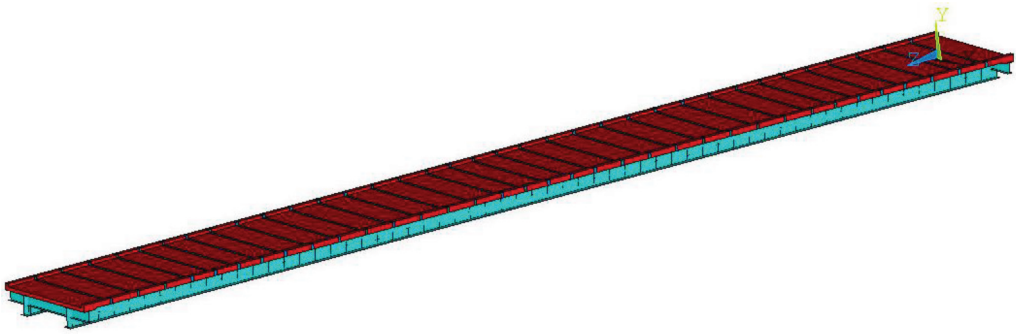

Figure 1. Finite element analysis model.

2.2 *The influence of the number of wet joint shear nails on the structure*

By reducing the number of shear studs in the wet joint area by 0% to 40%, the changes in the structural performance of the entire steel plate composite bridge under its self-weight were compared. As shown in Figure 2, under the self-weight, the structural deformation shows a linear upward trend, and when the number of wet joint shear studs is reduced by 40%, the maximum deformation of the structure increases by 0.12%, with a relatively small change.

Additionally, the impact of reducing the number of shear studs on the stress of the steel main beam is compared, as shown in Figure 3. Similarly, the reduction of shear studs in the wet joint area increases the maximum stress on the lower edge of the steel main beam while decreasing the maximum stress on the upper edge. The overall trend also shows a linear variation. Comparing the magnitude of changes, it is observed that the change in the lower edge is extremely small, less than 0.1%, which can be neglected. The variation in stress on the upper edge of the steel main beam is greater than that on the lower edge, approximately 6.4%.

Overall, the reduction in the number of shear studs in the wet joint area has minimal impact on the deformation and stress of the structure. In the cooperative force-bearing work of the steel main beam and the bridge deck, the shear studs on the bridge deck play a primary role.

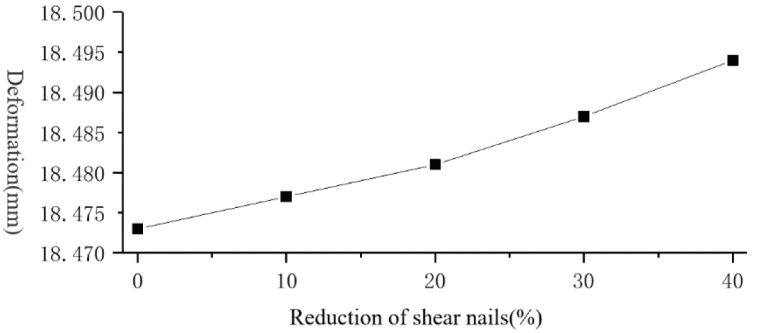

Figure 2. The reduction in shear studs has an impact on the deformation of the steel main beam.

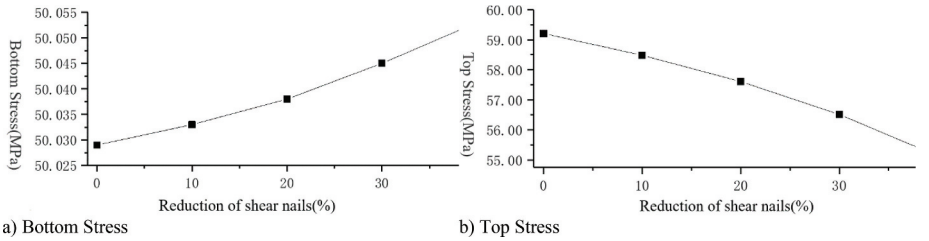

Figure 3. The reduction in shear studs has an impact on the stress of the steel main beam.

2.3 *Optimization of eliminating shear studs in wet joints*

Based on the above research, it is evident that the variation in the number of shear studs in wet joints has minimal impact on the steel main beam. Therefore, considering the elimination of shear studs in wet joint locations, the stress variation of the bridge deck under extreme mid-span and eccentric loading conditions is observed(Wei, C., et al. 2022)). The load is applied at the mid-span position and supports, as shown in Figure 4.

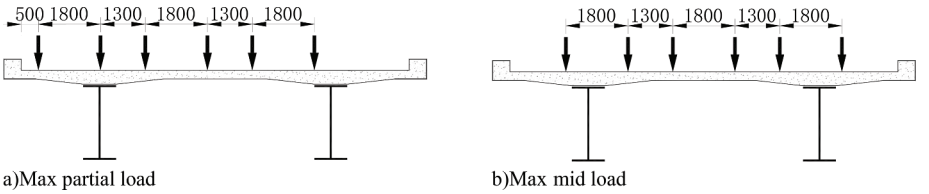

Figure 4. Location of load application.

The model calculation results, as shown in Figure 5, are clear. It is evident that after eliminating shear studs in wet joint locations, the stress on the bridge deck increases under various vehicle loading conditions. The stress increase is more significant for the end transverse beam's extreme vehicle loading condition than for the mid-span extreme vehicle loading condition. However, overall, the stress increase in the bridge deck under various conditions averages less than 4%. The maximum variation occurs in the case of eccentric loading at the support, where the maximum tensile stress in the bridge deck was 6.6 MPa with shear studs in wet joint locations. After eliminating the shear studs, the maximum tensile stress increases to 6.86 MPa, representing a numerical increase of 3.94%.

Therefore, the elimination of shear studs in wet joint locations has an impact on the stress of both the steel main beam and the bridge deck of less than 5%. Considering that the welding of shear studs in wet joint locations significantly affects construction efficiency and conflicts

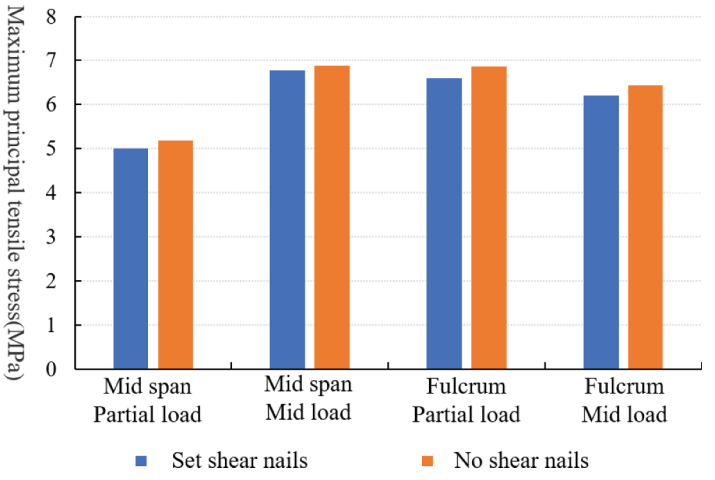

Figure 5. Before and after the cancellation of wet joint shear nails stress comparison.

with the arrangement of reinforcement in wet joints, it is advisable to consider omitting shear studs in wet joint locations during the design and construction process.

3 WET JOINT TRANSVERSE PRESTRESSING OPTIMIZATION

3.1 *Model establishment*

In practical engineering, to enhance durability, transverse prestressing can be applied to the bridge deck of a steel box girder. To study the increase in compressive stress on the bridge deck due to this prestressing, the same 12.5m double main girder steel box girder is taken as the research object, and a local segment model is established, as shown in Figure 6. The model considers the bridge deck, wet joint, steel beams, and prestressing, where the bridge deck and wet joint use Solid45 elements, the steel beams use Shell63 elements, and the prestressing uses Link8 elements.

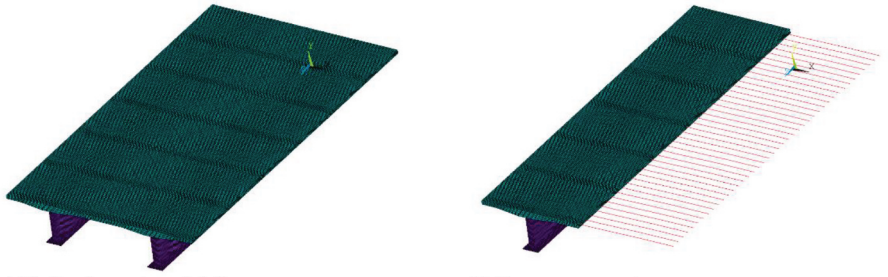

Figure 6. Finite element model of transverse prestressing.

Calculation Conditions Simulating Actual Construction Sequence

The calculation conditions simulate the actual construction sequence. Firstly, the bridge deck is activated, and prestressing is applied. Then, the wet joint is cast, and the prestressing in the wet joint is applied. In the model without prestressing, only the wet joint is activated.

Because the lateral force is the main consideration, the steel beams are supported with simple supports, accounting for the gravity of the bridge deck, considering the prestressing of the bridge deck, and considering the creep loss coefficient. The magnitude of the prestressing in the bridge deck is 1116MPa.

3.2 *Optimization of transverse prestressing in wet joints*

According to the calculation results, the extracted stress conditions of the bridge deck before and after the tensioning of the wet joint pre-stress are shown in Figure 7. It can be seen that the pre-stress tensioning of the wet joint significantly improves the compressive stress on the upper edge of the cantilever region and the lower edge of the central region, reaching a level of 1 MPa.

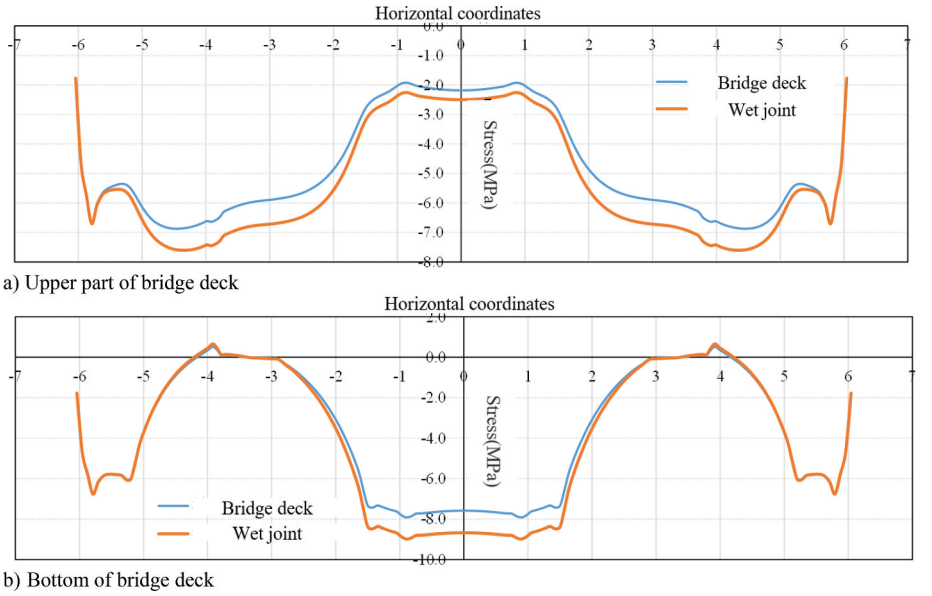

Figure 7. The Influence of wet joint tensioning and pre stressing on the stress of bridge deck.

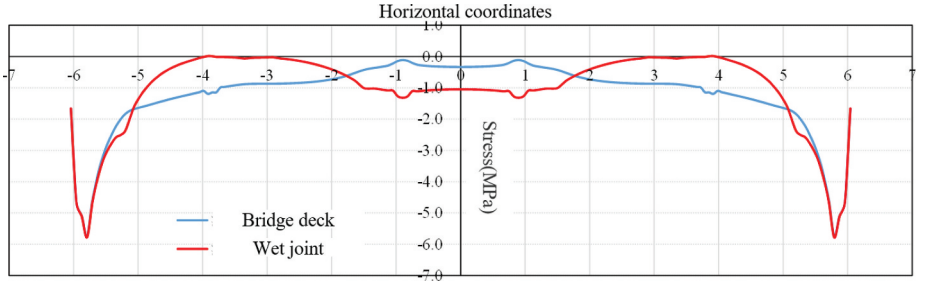
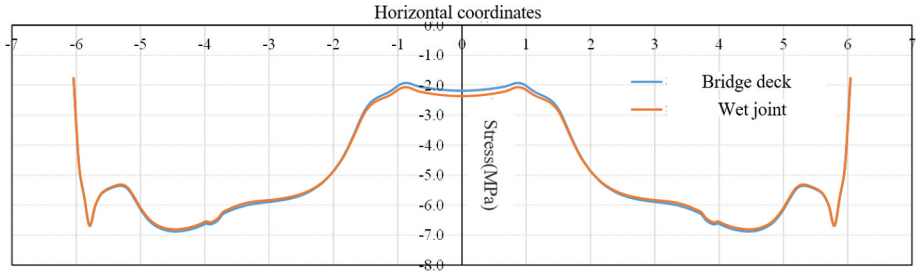
Examining the stress reserve situation after the pre-stress tensioning of the wet joint itself, as shown in Figure 8, it can be observed that the reserve compressive stress at the root of the cantilever of the wet joint is around 1 MPa, and the reserve compressive stress around the central lower edge is also around 1 MPa. This stress level is relatively low.





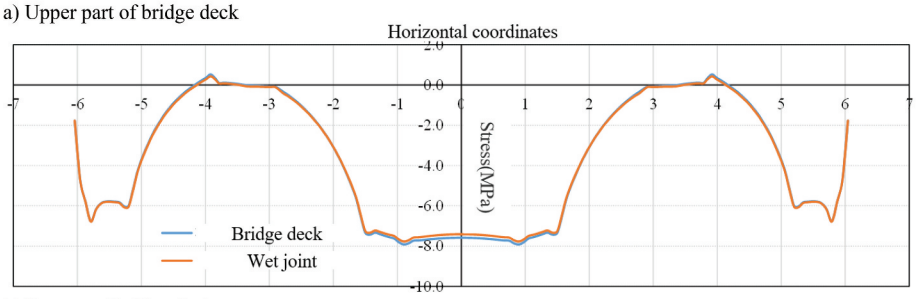


Figure 8. Stress distribution of wet joint after pre-stress tensioning.

If the wet joint is not pre-stressed, after casting the wet joint, the stress of the bridge deck remains essentially unchanged, with a pre-stress of 7MPa at the root of the cantilever, and a reserved compressive stress of 8MPa at the central lower edge. The wet joint is basically not stressed, with stress at around 0.3MPa.

a) Upper part of bridge deck

b) Bottom of bridge deck

Figure 9. The lack of pre-stressing in the wet joint has little impact on the stress of the bridge deck.

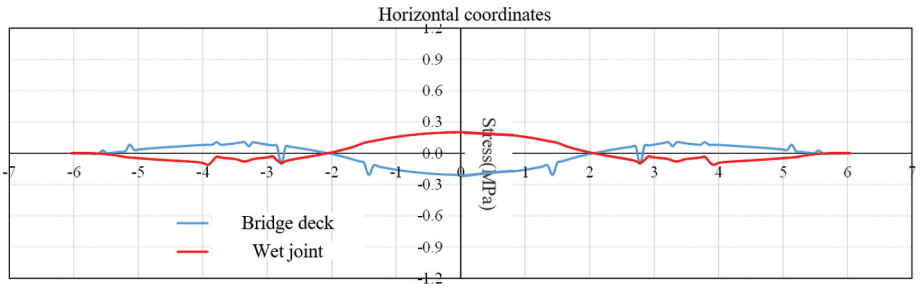

Figure 10. Illustrates the stress distribution in the wet joint after the absence of pre-stressing.

In conclusion, a comparative analysis was conducted using the solid finite element method for wet joint scenarios with and without pre-stressing. The results indicate that the pre-stressing in the wet joint is shared between the wet joint and the bridge deck, leading to an increase of approximately 1 MPa in compressive stress on the bridge deck, and an effective compressive stress of around 1 MPa in the wet joint. The introduction of pre-stressing does not effectively improve the crack resistance of the wet joint, but rather adds complexity to on-site construction, reducing construction efficiency. This approach contradicts the principles of industrialized construction. In practical engineering, it may be considered to eliminate the arrangement of transverse prestressed tendons and optimize the wet joint structure.

4 CONCLUSION

This article analyzes the performance improvement rate of internal shear nails and prestress in the wet joint of a 12.5m bridge wide double main beam steel plate composite beam, and draws the following conclusions:

An analysis of the quantity of internal shear studs in the wet joint indicates that the impact of wet joint shear studs on the deformation of the bridge structure is minimal. The elimination of the arrangement of wet joint shear studs has an impact of less than 5% on

the force distribution of both the main steel girder and the bridge deck. Therefore, it may be considered to omit the placement of shear studs in the wet joint during the design and construction process.

An analysis of the transverse prestressing in the wet joint reveals that the prestress set in the wet joint is shared between the wet joint and the bridge deck. The effective compressive stress generated by the wet joint is approximately 1 MPa. However, this prestressing does not provide effective improvement in crack resistance for the wet joint. Instead, it adds complexity to on-site construction, reducing construction efficiency. This contradicts the principles of industrialized construction. In practical engineering, it may be considered to eliminate the arrangement of transverse prestressed tendons and optimize the wet joint structure.

Analysis of the effect of hoop prestressed steel wire rope reinforcement on bridge piers and the loss of prestress

D.H. Sun
Anhui Transportation Holding Group Co., Ltd, Anhui, China

Z.Q. Liu & B. Huang
Tongji University, Shanghai, China

ABSTRACT: During the use of pier structures, vertical cracks can develop under the influence of complex factors such as stress, temperature, and corrosion. To suppress the generation and development of vertical cracks in piers and enhance structural durability, a method of reinforcing piers with a circular prestressed steel wire rope system was proposed. Studies on the stress and strain of solid and hollow pier structures under different loads, diameters, and steel wire rope spacings were carried out, verifying the reinforcement effect. Through parametric analysis, the effects of various factors on the reinforcement were explored, and the method was optimized. A study on the prestress loss of the circular prestressed steel wire rope was conducted. A complete method was proposedd. This research can provide a basis for the design of the circular prestressed system and the development of anchors and other structures, and serve as a reference for similar engineering projects.

Keywords: Annular prestress, wire rope, pier, reinforcement

1 INSTRUCTIONS

In the process of using bridge pier structures, vertical cracks can occur due to complex factors such as forces, temperature, and corrosion, severely impacting the durability of the structure. Traditional methods of bridge pier reinforcement include direct repair, increasing cross-sectional area, adhesive reinforcement, and embedded reinforcement. These methods are passive reinforcement approaches and cannot fundamentally inhibit the development of cracks and the formation of new cracks (Reggia et al. 2020; Cadenazzi et al. 2020; Czaderski et al. 2021). External prestressing reinforcement, as an active reinforcement method, can effectively address this issue with superior efficiency (Zhang et al. 2021; Zhu et al. 2015).

Traditional external prestressing reinforcement for bridges is mostly applied to bending components such as main girders. The *Specifications for Strengthening Design of Highway Bridge (JTG/TJ22-2008)* only provides relevant regulations for girder reinforcement, and external prestressing reinforcement for bridge piers is still in the research stage (JTG/T J22-2008). Guo conducted experimental research on semi-circular prestressed steel hoop reinforcement of bridge piers. The study indicated that when the effective prestress on a 5mm thick steel hoop reached 110MPa, it could significantly enhance the ultimate bearing capacity of the pier (Guo et al. 2015). Zhang investigated the axial compression performance of concrete cylinders reinforced with prestressed steel straps. The research demonstrated that with an effective prestress of 465MPa on a 0.9mm thick steel strap, the maximum bearing capacity of C20 concrete specimens increased by 224.5%, and C30 specimens increased by 208.5% (Zhang et al. 2021). Zhou explored the seismic performance of concrete circular piers reinforced with

DOI: 10.1201/9781003483755-21

prestressed CFRP strips. The study showed that prestressed CFRP strip reinforcement could effectively alter the failure mode of the specimen, greatly improve the bearing capacity, displacement ductility, and energy dissipation capacity of circular piers, but the prestress should not exceed 1113MPa (Zhou et al. 2015). However, these studies are limited by material properties and difficulties in tensioning and anchoring, resulting in relatively low effective prestress (El-Hacha and Soudki 2013; Kueres et al. 2020). Research has mainly focused on the impact on the ultimate axial compression bearing capacity and seismic performance of piers, with less emphasis on the local stress and strain that affect the durability of piers. The complex construction process and high material costs also limit the economic feasibility of large-scale use.

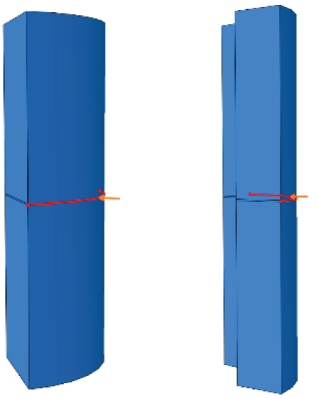
Prestressed steel wire rope, characterized by high strength, easy bending and processing, and simple tensioning and anchoring, can better exploit the external prestressing reinforcement effect (Liu et al. 2022; Wu et al. 2014). Circular prestressed steel wire ropes are widely used in the reinforcement of building structures. However, there is a lack of relevant research on larger bridge piers with greater structural dimensions and reinforcement loads. The prestress effect and prestress loss, crucial to the reinforcement effectiveness, remain unclear. In order to improve the stress and strain on the structure surface, inhibit the generation and development of vertical cracks in bridge piers, and enhance structural durability, this paper investigates the prestress effect and prestress loss in the reinforcement of bridge piers with circular prestressed steel wire ropes.

2 ANALYSIS OF RING PRESTRESSING EFFECT

The circular prestressing system can generate radial pressure on the structure. When the pressure is evenly distributed on the structure, traditional Lamé's formula can be used. However, when reinforcing bridge piers with circular prestressed steel wire ropes, the pressure is distributed at intervals on the structure, making it impractical to use traditional methods for calculation. In order to investigate the effect of prestressing on the structure, finite element analysis was conducted.

2.1 *Analysis of single-ring prestressed effects*

The pressure exerted on the concrete by tensioning the circular prestressed steel wire rope can be calculated using Equation (1).



$$p = \frac{A_y \cdot \sigma_{pe}}{r \cdot d_m} \tag{1}$$

where p is the radial pressure on the structure, A_y is the cross-sectional area of the steel wire rope, σ_{pe} is the effective prestress, d_m is the loading width of the steel wire rope on the structure, and r is the radius of the structure. The application of equivalent circular pressure on the structure can simulate the effect of prestressed steel wire rope.

When p acts on the structure, it generates circumferential compressive stress on the pier surface, directly contributing to the suppression of pier cracks. To investigate the influence of p value, whether the pier is hollow or solid, and the pier diameter on the circumferential compressive stress on the surface, a parametric finite element analysis was conducted. The set parameters are outlined in the following Table 1. Applying a single-ring prestress load to the

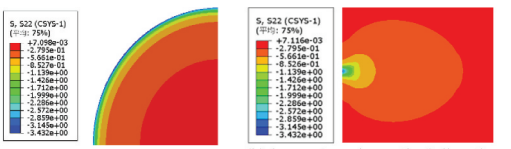


Table 1. Finite element model parameters.

Parameter	Scope	Interval	Number of values
p	6MPa~12MPa	2MPa	4
structure type	hollow or solid	/	2
diameter	1m~3m	0.5m	5

Figure 1. Single ring prestressed model.

(a) hoop stress on plane. (b) hoop stress in vertical direction.

Figure 2. Hoop stress (unit: MPa).

column, the material for the column is C50 concrete. The finite element model is as shown in Figure 1.

With a diameter of 2 meters and p=10MPa, the circumferential compressive stress on the surfaces of the solid bridge pier is depicted in Figure 2. It can be observed that the circumferential compressive stress at the edge of the planar surface is maximum, reaching -3.43 MPa and gradually decreasing inward. At a distance of 20 cm from the surface, it has decreased to -1 MPa. The max occurs at the vertically loaded area and diminishes along the vertical direction. By a distance of 10 cm from the loading position, it has decreased to 1 MPa.

The maximum circumferential compressive stress for solid and hollow bridge piers is summarized in Tables 2 and 3. It can be observed that for the same type of pier, the max gradually decreases with an increase in radius. Similarly, under the same load and radius conditions, the stress generated in the solid pier is greater than that in the hollow pier. Given that the tensile strength standard value for C50 concrete is 2.65 MPa, in order to suppress the generation of longitudinal cracks in the pier, the circumferential compressive stress on the structure surface should not be less than 2.65 MPa. Considering factors such as the weakening due to the spaced arrangement of steel wire ropes and prestress loss, the p should not be less than 10 MPa. The pre-tension can be calculated based on Equation (1).

Table 2. Maximum hoop compressive stress of solid bridge pier (unit: MPa).

	Prestressed load p			
Diameter	6MPa	8MPa	10MPa	12MPa
1m	2.34	3.07	3.82	4.61
1.5m	2.15	2.83	3.56	4.27
2m	2.1	2.73	3.43	4.11
2.5m	2.04	2.68	3.32	4.01
3m	2.02	2.62	3.29	3.93

Table 3. Maximum hoop compressive stress of hollow bridge pier (unit: MPa).

	Prestressed load p			
Diameter	6MPa	8MPa	10MPa	12MPa
1m	2.31	3.05	3.74	4.44
1.5m	2.15	2.81	3.41	4.12
2m	1.94	2.51	3.14	3.77
2.5m	1.84	2.49	3.05	3.61
3m	1.72	2.42	2.94	3.4

2.2 *Analysis of multi-ring prestressing effects*

To study the effect of multi-ring prestressing on bridge piers, solid and hollow bridge piers with a diameter of 2 meters were considered. The p was set at 10 MPa, and prestressing intervals were varied at 10 cm, 20 cm, and 30 cm. The analysis focused on the effect under axial loading, applied through displacement loading with strain control set at 0.001. Other settings remained consistent with the details mentioned earlier. The finite element analysis results are shown in Figure 3.

(a) 10cm/solid pier. (b) 20cm/solid pier. (c) 30cm/solid pier.

(e) 10cm/hollow pier. (e) 20cm/hollow pier. (e) 30cm/hollow pier.

Figure 3. Hoop strain after reinforcement.(unit:ε).

Following reinforcement and comparison with the unreinforced structure, for solid structures with reinforcement spacings of 10cm, 20cm, and 30cm, there is a reduction in the average strain ratio of 28%, 22%, and 11%, respectively. Similarly, for hollow structures, the reduction ratio is 35.6%, 27%, and 14.9%, respectively. These findings indicate that circumferential prestress can distinctly diminish the tensile strain on the surface of both solid and hollow structures induced by axial loading, effectively suppressing the initiation of vertical cracks. Moreover, the reinforcement efficiency is superior for hollow structures compared to solid structures. 30cm is deemed excessive, Considering a comprehensive evaluation involving factors such as reinforcement efficacy and economic benefits, 20cm emerges as an optimal choice.

3 PRESTRESS LOSS ANALYSIS

The principal pre-stress losses in the reinforced bridge pier with circular prestressed steel wire ropes are as follows: pre-stress loss due to frictional resistance between the steel wire ropes and the structural; loss resulting from elastic compression during staged

tensioning of concrete; loss due to deformation of the anchorages; loss caused by relaxation of the steel wire ropes; pre-stress loss resulting from the creep and shrinkage of concrete. Frictional loss, staged tensioning loss, and anchorage deformation loss are instantaneous losses, while relaxation loss and creep and shrinkage loss of concrete are long-term losses. Calculation methods for various pre-stress losses are proposed (Bonopera et al. 2020; Cao et al. 2021; Kang et al. 2021). The following conditions were employed for calculating: the reinforced structure is a C50 concrete pier with a diameter of 2 meters, a structural age of 5 years, utilizing 6×36WS+IWR steel core wire ropes with a nominal diameter of φ26mm, an elastic modulus of 1.95×105 MPa, a strength of 1870 MPa, a nominal breaking force of 450 kN, and a control stress of 1200 MPa.

3.1 *Analysis of frictional resistance and prestress loss*

The pre-stress loss resulting from the frictional resistance between the steel wire ropes and the structural during the tensioning is calculated using Equation (2).

$$\sigma_{l1} = \sigma_{con}[1 - e^{-(\mu\theta)}] \tag{2}$$

In the equation, σ_{l1} represents the pre-stress loss due to frictional resistance, σ_{con} is the tensioning control stress, μ is the friction coefficient between the steel wire ropes and the structural, and θ is the relative angle between the tensioning end and the calculation position. When employing a single-ring bidirectional tensioning method, The maximum value of θ is 180°. It can be observed that pre-stress loss increases with the roughness of the contact surface. When μ is 0.2, the maximum pre-stress is 540 MPa, constituting 45% of the control stress.

3.2 *Analysis of prestressed loss in batch tensioning*

In the incremental tensioning of circular prestressed steel wire ropes, the subsequent tensioning of the wires induces contraction in the previously tensioned concrete locations, resulting in a loss of prestress, as calculated by Equation (3).

$$\sigma_{l2} = \frac{\alpha_e \sigma_p}{2} \tag{3}$$

In the equation, σ_{l2} represents the incremental tensioning pre-stress loss, α_e is the ratio of the elastic modulus of the steel wire rope to that of the concrete, and σ_p is the radial compressive stress exerted by the subsequently tensioned steel wire rope on the previously tensioned concrete. According to the finite element analysis discussed earlier, the spacing between the steel wire ropes has a significant impact on the incremental tensioning pre-stress loss. Smaller spacing results in greater pre-stress loss. With a wire rope spacing of 20cm, considering the cumulative effect, the pre-stress loss caused by incremental tensioning is 6.72 MPa, approximately 0.6% of the control stress.

3.3 *Analysis of anchorage deformation and prestress loss*

After tensioning and anchoring, the deformation of the anchorage induces a retraction of the steel wire ropes, leading to pre-stress loss, as calculated by Equation (4):

$$\left.\begin{aligned} \varphi_0 = \frac{1}{\mu}\ln\left[1 - \sqrt{\frac{aE_s}{\sigma_{con}} \times \frac{\mu}{1000r}}\right]^{-1} \\ 0 \le \varphi \le \varphi_0 : \sigma_{l3} = \sigma_{con} e^{-\mu\varphi}[1 - e^{-2\mu(\varphi_0 - \varphi)}] \\ \varphi \ge \varphi_0 : \sigma_{l3} = 0 \end{aligned}\right\} \tag{4}$$

In the equation, σ_{l3} represents the pre-stress loss caused by the deformation of the anchorage and the retraction of the steel wire ropes. φ_0 is the angle of the reverse frictional influence zone,

a is the value of the anchorage deformation and steel wire rope retraction, which can be empirically determined or experimentally measured. E_s is the elastic modulus of the steel wire rope, r is the bending radius, and φ is the angle from the tensioning end to the calculation section. Other parameters remain consistent with the preceding text. The pre-stress loss is maximal at the tensioning end, with an empirically chosen a value of 5mm, resulting in a maximum pre-stress of 32 MPa. The loss accounts for approximately 2.7% of the control stress.

3.4 *Analysis of prestressed loss during relaxation of prestressed steel wire ropes*

The pre-stress loss caused by stress relaxation in prestressed steel wire ropes under continuous action is calculated according to Equation (5).

$$\left.\begin{array}{c} \sigma_{con} \leq 0.7 f_{ptk}: \\ \sigma_{l4} = 0.125\left(\frac{\sigma_{con}}{f_{ptk}} - 0.5\right)\sigma_{con} \end{array}\right\} \tag{5}$$

In the equation, σ_{l4} represents the pre-stress loss caused by the relaxation of the steel wire ropes, and f_{ptk} is the tensile strength of the prestressed steel wire ropes. The calculated pre-stress loss is 21.3 MPa, constituting approximately 1.8% of the control stress. Since the relaxation effect is more pronounced in the early stages, controlling the tensioning time can eliminate a significant portion of the pre-stress loss.

3.5 *Analysis of prestress loss in concrete shrinkage and creep*

The radial shrinkage of concrete components due to concrete shrinkage results in a loss of prestress, which can be calculated using Equation (6).

$$\sigma_{l5} = \frac{\varepsilon_{cs}(t, t_s) E_s}{2} \tag{6}$$

In the equation, σ_{l5} represents the pre-stress loss caused by concrete shrinkage, and $\varepsilon_{cs}(t,t_s)$ is the shrinkage strain of concrete from time t_s to t. It can be calculated according to the relevant specifications (JTG 3362—2018).

Prestress loss over the 10-year period for the reinforced concrete bridge pier at 5 years of age is 6.77 MPa. When the controlling tension stress is 1200 MPa, the proportion of prestress loss is 0.55%.

When the circular prestressing is applied to a compressed member, there is both axial and circumferential creep. The calculation of lateral expansion due to axial creep is given by Equation (7).

$$\varepsilon_1(t_1, t_2) = \frac{\sigma_z}{E_c}[\varphi(t_0, t_2) - \varphi(t_0, t_1)]\nu \tag{7}$$

In the equation, $\varepsilon_1(t_1,t_2)$ represents the lateral expansion creep due to axial pressure from t_1 to t_2, σ_z is the axial stress, E_c is the elastic modulus of concrete, $\varphi(t_0,t_n)$ is the creep coefficient from time t_0 to t_n at the loading time, which can be calculated according to the relevant specifications (JTG 3362—2018), and ν is the material Poisson's ratio. During the circumferential creep process, stress continually changes. According to the linear theory of creep, the incremental creep strain for each time period is given by Equation (8).

$$\left.\begin{array}{c} \Delta\varepsilon_2(t_n, t_{n-1}) = \sum_{j=1}^{n-1} \frac{\Delta\sigma_c(t_j)}{E_c}\left[\varphi(t_n, t_j) - \varphi(t_{n-1}, t_j)\right] \\ \Delta\sigma_c(t_j) = \frac{\Delta\varepsilon_2(t_j, t_{j-1}) \times E_s \times A_y}{2r \times d_m} \end{array}\right\} \tag{8}$$

In the equation, $\Delta\varepsilon_2(t_n,t_{n-1})$ represents the circumferential creep strain increment from t_{n-1} to t_n, $\Delta\sigma_c(t_j)$ is the stress increment at time t_j. $\varphi(t_n,t_j)$ is the creep coefficient from t_j to t_n,

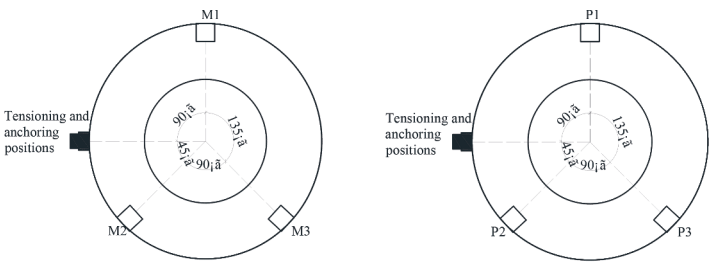
calculated using the relevant specifications. Under the conditions mentioned earlier, the recursive solution program can be developed by fitting the creep coefficient. The lateral expansion creep and lateral contraction creep are combined, and the prestress loss is calculated according to Equation (9).

$$\sigma_{l6}=\frac{(\Delta\varepsilon_1+\Delta\varepsilon_2)\times E_s}{2} \tag{9}$$

In the equation, σ_{l6} represents the prestress loss caused by concrete creep. Through program calculation, after 10 years of reinforcement, the prestress loss caused by creep is 10.3 MPa, with a loss proportion of 0.9%.

4 PRESTRESS LOSS TEST

Through the analysis of prestress loss, the most significant loss in the circular steel wire rope prestressing system is caused by the friction, accounting for over 70% of the total loss. Experimental verification of this loss is conducted.



A hollow bridge pier is designed with an outer diameter of 1.2 meters, an inner diameter of 0.63 meters, and a height of 2 meters. The pier is constructed using C50 concrete. circular prestressed steel wire ropes are tensioned on the pier in Figure 4. Magnetic flux sensors are installed on the steel wire rope, and pressure sensors are embedded in the pier, as shown in Figure 5, to measure the prestress loss along the circumference.

In the experiment, tension loading is applied to the steel wire rope. Initially, it is loaded incrementally in 10kN increments up to 50kN, then in 50kN increments up to 150kN, and finally in 10kN increments up to 200kN. After stabilizing the measured data, tension anchoring is performed, followed by an analysis of the measured data.

(a) Test structure front view. (b) Side view of test structure.

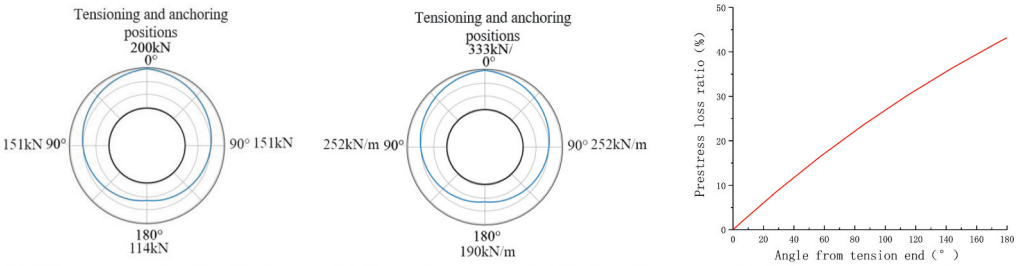


Figure 4. Test structure view.

(a) Magnetic flux sensor settings. (b) Pressure sensor settings.

Figure 5. Sensor settings.

The maximum tension load on the steel wire rope is 200kN. The tension force data of the steel wire rope at different positions is measured through magnetic flux sensors. By using Equation (2), the friction coefficient is calculated as μ=0.18. The tension of the wire rope, the pressure received by the bridge pier, and the prestress loss are shown in Figure 6.

(a) Wire rope tension distribution diagram.

(b) Concrete pressure distribution diagram.

(c) Prestress loss proportion diagram.

Figure 6. Test result.

Due to the friction, the tension in the steel wire rope is unevenly distributed along the circumference. At the tensioning end, it is maximum, reaching 200 kN, and at a position 180° away from the tensioning end, it is minimum, at 114 kN. The pressure distribution pattern on the bridge pier corresponds to the tension distribution pattern on the steel wire rope. At the tensioning end, the maximum pressure is 333 kN/m, gradually decreasing as one moves away from the tensioning end, reaching a minimum of 190 kN/m at the 180° position. As the distance from the tensioning end increases, the prestress loss gradually increases, with the maximum prestress loss percentage reaching 43% at 180° away from the tensioning end. This fully demonstrates that the prestress loss caused by frictional resistance is significant, representing the primary type of loss in the circular prestressed steel wire rope system. It also validates the calculation method proposed in the preceding text.

5 CONCLUSION

This paper conducted a study on the reinforcement of bridge piers using circular prestressed steel wire ropes through finite element analysis. It proposed types and calculation methods for prestress losses, which were then validated through relevant experiments. The main conclusions are as follows:

The maximum circumferential compressive stress generated on the surface of the structure by a single-ring prestress is crucial for reinforcing the vertical cracks in the structure. The maximum circumferential compressive stress decreases as the structure diameter increases. For C50 concrete structures, the radial pressure generated by prestressed steel wire ropes should not be less than 10MPa.

The application of multiple-ring prestress can effectively reduce the circumferential tensile strain on the surface of the structure caused by axial loads, providing inhibition to the development of vertical cracks. The effectiveness decreases with the increase in the spacing between the steel wire ropes. With a 20cm spacing, the reinforcement of solid and hollow structures reduces the maximum tensile strain by 22% and 27%, respectively. The reinforcement efficiency of hollow structures is greater than that of solid structures.

The paper proposes types of prestress losses and their corresponding calculation methods. The calculations under the specified conditions indicate that the prestress loss due to friction between the steel wire ropes and the structure is the most significant, accounting for over 70% of the total losses. Experimental validation of the frictional loss was conducted, revealing that, under μ=0.18, the frictional loss represents 43% of the control stress. Effectively reducing the frictional resistance between the steel wire ropes and the structure is crucial for enhancing the reinforcement efficiency.

Development and application of anti-differential disturbance concrete for widening bridge

D.H. Chen
Guangdong Provincial Freeway Co., Ltd., Guangzhou, China

J. Song & C.Y. Zhu
Department of Bridge Engineering, Tongji University, Shanghai, China

ABSTRACT: When the bridge splicing connection is carried out without interrupting the traffic, the differential vibration deformation will occur at the splicing position under the action of vehicle-bridge coupling vibration. It will affect the long-term performance of splicing joints. Therefore, it is necessary to develop a new type of concrete material that can satisfy the requirements of shear deflection and vibration disturbance. Combined with the vibration monitoring and simulation of the actual bridge, the vibration characteristics of the existing old bridge are analyzed to obtain the development requirements of anti-differential disturbance concrete. The vertical shaking table was applied to test the performance of proposed material. After the implementation in the widened bridge, a standardized pouring process for anti-differential disturbance concrete was formed. A series of detection methods were proposed as well. The complete set of construction technology and quality inspection technology of the anti-difference disturbance concrete are established.

1 INTRODUCTION

The traffic flow of the existing freeway is growing rapidly and needs to be reconstructed or widened (Zhou, 2020; Mahboubi, 2021; Jeong, 2018). Based on the reconstruction and widening project of freeway in Guangdong Province, China, the research on splicing of widened bridge without interruption of traffic is carried out. The hollow slab beam bridge which accounts for a large proportion on Shenhai Freeway is mainly focused (Chen, 2023). The widened bridge is mainly including three parts: the existing old bridge, the widening new bridge and the splicing joint. The typical cross-section form of widened bridge is shown in Figure 1.

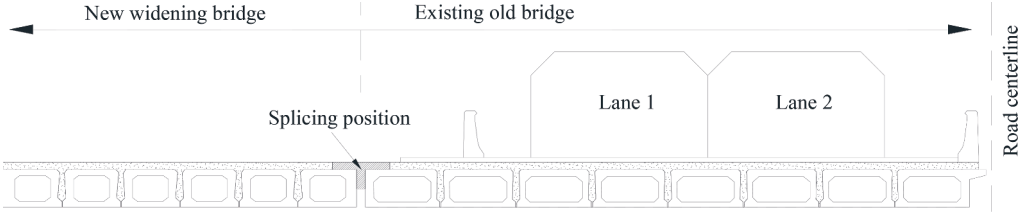

Figure 1. Typical cross-section of the widened bridge (Unit: cm).

When the existing old bridge and the widening new bridge is spliced, the differential vibration deformation will occur in the splicing joint under the action of vehicle-bridge coupling vibration (Cui, 2019). It will influence the quality of the joint concrete. However, due to the

DOI: 10.1201/9781003483755-22

lack of splicing materials to resist vibration and deflection difference, it is faced with the situation of interrupting traffic to splice, which will affect the current road traffic and the long-term performance of splicing joint. Therefore, the splicing of the widened bridge should be carried out without interrupting the traffic.

A number of studies have been carried out on the performance of concrete after disturbance (Yang, 2021; Zhang, 2019a & 2019b). Zeng (2023) proposed a new type of concrete which can resist the vibration disturbance and applied it in the splicing connection of widened bridge without interrupting traffic in freeway. The material performance was tested with the shaking table and concluded that the compressive strength can be improved by 10% to 20% after the disturbance. Liu (2021) evaluated the effect of vehicle–bridge coupled vibration on the mechanical properties of composite concrete. It can be concluded that the vibration has slightly influence on the flexural strength of specimen. Wang (2022) studied the influence of vibration on the steel fiber disturbance in UHPC material, and the mechanical performance of UHPC specimens were tested with shaking table. It can be concluded that vibration amplitude and frequency are the key parameters affecting the flexural and tensile strength of material. However, these studied are mostly based on the laboratory test, the practical application of the material and the related construction technology have not been carried out obviously.

In this article, the vibration characteristics of the existing old bridge are tested for 48 hours. The bridge-vehicle coupling vibration simulation method is adopted. The simulation results are compared with the experimental results, and the key parameters of material development were obtained. Two different types of anti-differential disturbance concrete are developed by adopting test equipment based on vertical shaking table. In addition, the standard construction process are proposed as well, which is verified by the application of anti-differential disturbance concrete in the field test section.

Based on the field test of the real widened bridge project, different types of anti-differential distribute concrete with resilient and ductile performance have been developed by combining laboratory vibration test with field application and optimization. In addition, a complete set of technology for splicing the widened bridge without interrupting traffic is proposed as well.

2 VIBRATION CHARACTERISTICS OF WIDENED BRIDGE

2.1 *Analysis of bridge vibration characteristics based on field test*

In order to obtain the key parameters for the development of anti-disturbance concrete, the vibration characteristic of widened bridges have been tested. The typical case of K3387 +424.551 Middle Bridge, Shenhai Freeway is selected as shown in Figure 2. The key parameters of vibration amplitude and frequency at the splicing of the widened bridge were obtained without interrupting traffic (Răcănel, 2021).

Figure 2. Field test of bridge vibration characteristics.

The sections of *l*/4-span, *l*/2-span and 3*l*/4-span were monitored for 48 hours. The peak value of dynamic deflection and acceleration are presented in Figure 3. For the *l*/2-span section with the most unfavorable deformation, the maximum dynamic deflection is 1.085 mm, and the maximum acceleration is 1.302m/s^2. While the average value of these two parameters are 0.564 mm and 0.487m/s^2, which is much smaller than the peak value. In addition, it can be also obtained from the field test that the first-order natural frequency of the tested bridge is 8.496 Hz.

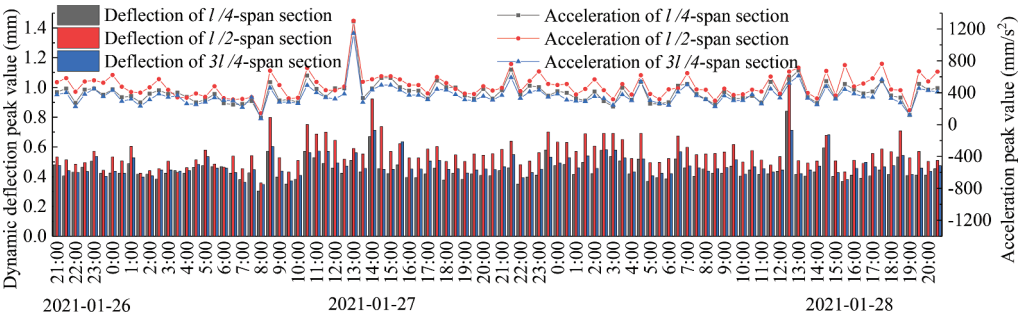

Figure 3. The peak values of bridge vibration characteristics within 48 hours.

2.2 *Vehicle-bridge coupling vibration simulation based on random traffic flow*

The cellular automaton is introduced to microscopic simulation of vehicles (Huang, 2019). By considering the traffic rules, the operation characteristics of vehicles on the bridge can be realized.

On the basis of vehicle-bridge coupling vibration theory, the mass, damping and stiffness matrices have been applied to the vehicle cell extracted from the microscopic simulation model of vehicles. The dynamic equation of vehicle-bridge coupling can be solved by the Newmark-β method. By introducing the data of random traffic flow into the dynamic analysis model, the vehicle-bridge coupling vibration simulation based on random traffic flow can be realized. The basic analysis process of bridge-bridge coupling vibration simulation is shown in Figure 4.

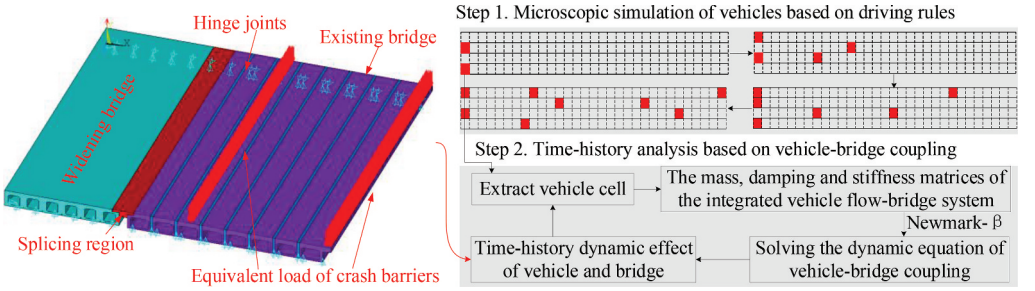

Figure 4. Basic analysis process of bridge-bridge coupling vibration.

In order to reduce the difference between the actual stiffness and the theoretical value of the widened bridge caused by factors such as materials and construction, the simulation results of vehicle-bridge coupling vibration are compared with the field test results. The reliability of the proposed random traffic flow-bridge coupling vibration simulation method can be verified. Different time periods of results are compared as shown in Figure 5. From the comparison results, it can be seen that the simulation results are in good agreement with the test data.

In the case of daytime traffic (from 8:00 to 20:00), the existing old bridge shows obvious vibration deflection characteristics. However, in the case of nighttime traffic (from 0:00 to 8:00 and from 20:00 to 24:00), the intensity of vibration deflection of the existing old bridge is reduced, and the peak vibration deflection is slightly reduced as well.

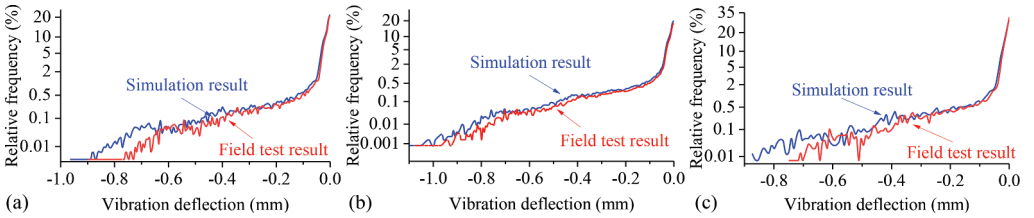

Figure 5. Simulation result of the bridge-vehicle coupling vibration: (a) 0:00 ~ 8:00, (b) 8:00 ~ 20:00, (c) 20:00 ~24:00.

3 DEVELOPMENT OF ANTI-DIFFERENTIAL DISTRIBUTE CONCRETE

According to the vibration characteristic of widened bridge, different types of anti-differential distribute concrete have been developed: the type of resilient and the type of ductile. The anti-differential disturbance resilient concrete is suitable for the case of that the bridge span is less than 20 m and the vibration amplitude is shorter than 6 mm. The anti-differential disturbance ductile concrete is suitable for the case of that the bridge span is in range of 20 m to 40 m and the vibration amplitude is less than 10 mm.

3.1 *Development of anti-differential disturbance resilient concrete*

The experimental device was designed based on the vertical shaking table as presented in Figure 6. The specimen is installed on the static side and the vibration side respectively. The shaking table is opened before the anti-differential disturbance resilient concrete pouring in the specimen mold, so that the concrete in the specimen can be divided into three segments during the condensation hardening process.

The proposed anti-differential disturbance resilient concrete is mainly composed of customized powder, fine sand, gravel, customized admixture, water and high-strength steel fiber. The customized powder is conducive to the formation of early strength of materials. The proposed concrete can be denser by increasing the sand ratio in the mix ratio. In addition, the tensile strength can be significantly improved by adding steel fiber.

The most obvious material characteristic is that the proposed anti-differential disturbance resilient concrete has the ability of reducing the time difference between initial setting and final setting to 95 min. Compared with other traditional products that directly reducing the initial setting or final setting time, the proposed concrete can reduce the time to be disturbed.

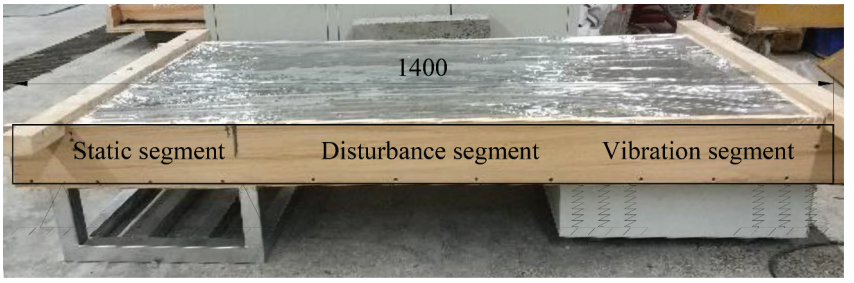

Figure 6. Test setup for the development of anti-differential disturbance resilient concrete.

3.2 *Development of anti-differential disturbance ductile concrete*

Similarly, the experimental device for the development of anti-differential disturbance ductile concrete is also designed based on the vertical shaking table as presented in Figure 7. The specimen can be divided into two precast blocks and one joint segment. The precast block is made of normal concrete of C50 in advance, and the joint segment is poured with the anti-differential disturbance ductile concrete during the test.

The proposed anti-differential disturbance ductile concrete is mainly composed of customized powder, quartz sand, coal fly ash, water reducing admixture and customized polypropylene fiber. The proposed anti-differential disturbance resilient concrete has excellent fracture resistance ability. It can improve the interfacial adhesive performance between the splicing joint and the widened bridge. The tensile properties of the splicing joint can still be maintained after vibration disturbance.

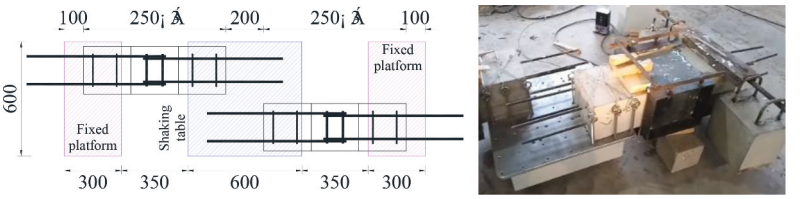

Figure 7. Test setup for the development of anti-differential disturbance ductile concrete (unit: mm).

4 PROPOSAL OF STANDARD CONSTRUCTION PROCESS

4.1 *General requirement*

Before the application of the anti-differential disturbance concrete, the technology index should be checked firstly and then determined the suitable concrete type. The checking process is listed as follows:

Firstly, the on-site monitoring of the deflection difference between the existing old bridge and the widening new bridge should be carried out. The monitoring time should not be less than 48 hours. The maximum difference of deflection and the frequency of its occurrence should be included in the collected data. And the maximum deflection difference with frequency greater than 5 % is adopted as the material selection standard.

Secondly, temporary control measures should be also proposed according to the actual needs of the splicing construction. Such as closing the lane close to the splicing joint, limiting the speed of the vehicle, limiting the weight of the vehicle, and temporarily connecting the existing old and widening new bridges. All these measures can reduce the deflection between the existing old bridge and the widening new bridge during the splicing construction process.

In addition, the anti-differential disturbance concrete selected should fit the following requirement as well. The anti-differential disturbance concrete can still maintain high material properties after the differential disturbance. The retention rate of tensile strength and splitting strength should not less than 80% of the corresponding strength under standard conditions, which should also greater than the design value.

4.2 *Construction scheme design*

Before the splicing construction, the special construction scheme for the splicing joint should be formulated in advance according to construction environment, volume of pouring concrete and so forth. The special scheme should include following contents: the construction preparation, the splicing construction method, and the construction quality inspection and evaluation method.

When making the scheme of construction preparation, the construction schedule needs to be determined according to the construction plan. The use plan of construction machinery and labor needs to be formulated. The construction machinery should be organized and provided on schedule. The assembly-line method for the splicing construction of widened bridge is recommended as follows.

- The splicing construction process should be divided into different construction stages.
- In each construction stage, the dominant construction steps should be determined. And the professional construction staff should be organized.
- The splicing construction project should also be divided into several segments.

- Calculate the flowing rhythm and ensure that it can meet the period requirements of the splicing construction and the resource constraints of the existing investment. The flowing rhythm can be obtained according to Equation 1.

$$t = p/R \cdot b \tag{1}$$

where is p is the number of labor or machinery required in a certain construction segment; R is the number of labor or machinery available; b denotes the number of teams that can participate in the construction in one day; and m represents the number of construction stages divided according to the assembly-line method.

- Calculate the flow spacing between different construction stages.

In addition, the splicing construction method includes the methods of the reinforcement connection, the concrete mixing, the concrete pouring, the concrete maintenance. In which, the concrete mixing method should be designed according to mixed design of anti-differential disturbance concrete. And the weighing scheme, mixing feeding sequence scheme, mixing time control method can be determined. In addition, the concrete pouring method should include the control of vibration time and vibration sequence.

4.3 *Construction preparation*

The existing old should be strengthened before the splicing construction operation, and the widening new bridge should also complete the construction of the main structure according to the design document.

If the design height of the existing old bridge is lower than the design document after widening, the existing old bridge should be jacked up in advance. When the splicing joint is completed, the height of the widened bridge cannot be adjusted any more.

Before the splicing construction operation, the cast-in-place work of the integral layer of the existing old bridge and the widening new bridge needs to be completed in advance. When the main girder structure is T-shape beam, it is necessary to connect the diaphragm between the existing old and widening new bridges in advance.

Each interface of the splicing joint needs to be chiseled and cleaned in advance. The interface that needs to be disposed is presented in Figure 8, it mainly including three parts: the side of the integrated layer (1), the top and side surface (2 and 3) of boundary beam connected to the splicing joint.

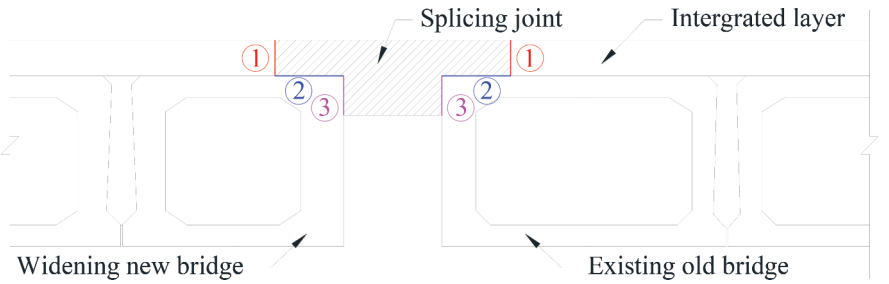

Figure 8. Interfaces need to be treated.

4.4 *Splicing construction operation*

4.4.1 *Reinforcement and formwork project*

The reinforcement should be connected before pouring the anti-differential disturbance concrete. The lap length of the reinforcements in the splicing joint should meet the relevant requirements of the design document. In particular, it is necessary to use the method of planting to connect the reinforcements lapped with the boundary beam of the existing old bridge.

The support of the bottom formwork of the splicing joint should be completed in advance according to the design document. The following requirements should be followed:

Firstly, the formwork should be located accurately.

Secondly, the formwork should have sufficient strength, stiffness and stability. To prevent the displacement of the formwork during pouring concrete, it should be able to withstand various loads generated during the construction process.

Thirdly, after the installation of the formwork is completed, its size and position should be checked according to the design document.

Finally, measures to prevent slurry leakage can be adopted at the joint position between the formwork and the concrete. There should be no slurry leakage between the girders and the formwork.

4.4.2 *Concrete project*

The construction of anti-differential disturbance concrete for widening bridges should be carried out in the following order: verification of mix ratio and operation process before construction → concrete mixing → concrete pouring → concrete vibration → concrete maintenance.

The mix ratio of anti-differential disturbance concrete should be verified before splicing construction. The anti-differential disturbance concrete that does not meet the design documents should not be adopted. However, the design mix ratio of concrete can be adjusted appropriately according to the properties of raw materials, so that the design requirements of concrete performance can be met.

When mixing anti-differential disturbance concrete, raw materials should be put in accordance with the prescribed order: fine aggregate → steel fiber → partial mixing water → coarse aggregate → powder → admixture → residual mixing water. It is advisable to mix fine aggregate and steel fiber uniformly without water, and the mixing time should not less than 60s. Then, add the coarse aggregate and mix them with part of mixing water, and the mixing time should be 30s to 60s. Finally, coarse aggregate and admixture were added and mixed with residual mixing water until uniform, and the mixing time should be about 120s.

The transportation distance and time from the anti-differential disturbance concrete mixing site to the pouring site should be controlled to prevent the surface water loss and hardening of the anti-differential disturbance concrete during transportation.

It is advisable to choose the pouring time reasonably. Combined with the hardening characteristics of anti-differential disturbance concrete, the time period from initial setting to final setting of concrete should be consistent with the period of relatively small traffic flow on the widened bridge.

During the vibration operation of anti-differential disturbance concrete, the uniformity and compactness of concrete should be controlled. There should be no obvious under-vibration and over-vibration, and the vibration operation time should be controlled within 30s at each point.

After the completion of the anti-differential disturbance concrete pouring, it should be covered in time to reduce the water loss of the joint concrete. After the final setting of anti-differential disturbance concrete, continuous wet curing should be started immediately, and the curing process should last at least 48 hours.

After 7 days of continuous wet curing, the concrete in splicing joint can fully reach the design strength state. Before removing the template, it is still necessary to measure the vertical deformation difference on both sides of the splicing joint. When the deformation difference is less than 1mm, it can be considered that the concrete in the joint can work together with the widened bridge and the new bridge.

4.5 *Construction quality inspection and performance verification*

4.5.1 *Construction quality inspection method*

The construction quality inspection scheme should be proposed according to the material performance and the vibration characteristic of the existing old bridge. The appearance quality and concrete strength of the anti-differential disturbance concrete should be checked after the maintenance of splicing joint.

In the appearance quality inspection, following items should be include: the size of the splicing joint after the construction, the surface smoothness of the splicing joint concrete, the apparent quality of the concrete, the crack distribution of the joint concrete, etc. For the top surface of the splicing joint, concrete cracking is not allowed. While for the interface between the splicing joint and the integral layer, the number of cracks per span is not allowed to exceed one, the crack width is not allowed to exceed 0.15 mm, and the crack length is not allowed to exceed 1/10 of the span.

The strength detection method of the anti-differential disturbance concrete mainly include the following three kinds: the laboratory method with standard specimens, the direct measurement of on-site concrete strength of the splicing joint, and the indirect measurement of specimens cured under the same conditions.

4.5.2 *Joint performance verification method*

The performance of anti-differential disturbance concrete in widened joints can be verified by the method of curing model specimens under the same conditions. The model specimen contains three parts: the precast blocks A and B, and the joint segment C, as shown in Figure 9. The precast blocks A and B should be prepared before splicing the joint and made of the same standard concrete as widened bridge. The reinforcement with the same standard as that in the splicing joint of widened bridge should be used in the joint segment C.

Before pouring the concrete of the joint segment C, the interface between the precast block and joint segment should be treated in the same way as that of the widened bridge. Before pouring the splicing joint of the widened bridge, the precast blocks A and B should be installed on the existing old bridge and the widening new bridge in advance. The formwork of the joint segment C should be installed before pouring the splicing joint of the widened bridge.

When pouring the concrete of the splicing joint of the widened bridge, the joint segment C should be poured synchronously. The same maintenance condition is adopted for the joint segment C, and the formwork can be removed after 7 days of maintenance. After 28 days of maintenance, the connectors between the model specimens and the widened bridge can be removed. Then, the model specimens can be tested with four-point flexural loading test to verify the material performance of anti-differential disturbance concrete and mechanical properties of the splicing joint.

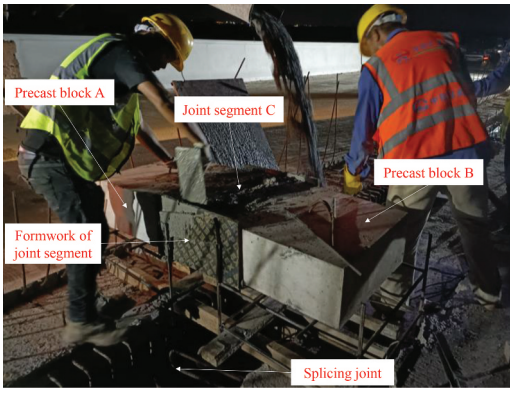

Figure 9. Model specimens cured under the same conditions of the splicing joint.

5 VERFICATION OF FIELD TEST SECTION

The typical case of K3387+424.551 Middle Bridge, Shenhai Freeway is selected as the field test section. According to the optimized on-site mix ratio of anti-differential disturbance concrete, the splicing joints are operated without interrupting the traffic. The pouring process and performance are presented in Figure 10.

The anti-differential disturbance resilient concrete was adopted in this field test section. The mix proportion of the adopted concrete is shown as follows: 400- 500 pieces of customized powder, 700-900 pieces of fine sand, 900-1200 pieces of gravel, 2.5-7.5 pieces of customized admixture, 135-180 pieces of water and 25-75 pieces of high-strength steel fiber. It is a kind of type of performance-improving concrete material, in which steel fiber was added to increase the anti-disturbance performance. The designed standard of this concrete is still the Grade of C50, with designed compressive strength of 50 MPa.

The concrete standard test block was made and cured under the same conditions on site. The compressive strength of the standard test blocks was tested, and the test results are listed in Table 1. It can be learnt from the test results that the compressive strength of adopted anti-differential disturbance resilient concrete can meet the design requirement of material performance.

Table 1. Tested compressive strength of the standard test block.

No.	Tested compressive strength	Ratio to designed compressive strength
HY-3235	57.8 MPa	116 %
HY-3282	58.7 MPa	117 %
HY-3382	67.0 MPa	134 %
HY-3590	56.0 MPa	112 %
HY-3676	60.7 MPa	121 %

After the application of anti-differential disturbance resilient concrete in the field test section, drilling core sampling and core sample CT scanning are carried out on the splicing joint (Liu, 2017). According to the scanning results, the crack depth of centerline of the splicing joint is less than 1 mm. And there is no crack appears on the interface between the splicing joint and bridge girder. There is no aggregate subsidence in the splicing joint. The distribution of steel fibers in the centerline of splicing joint is relatively uniform, and there is no obvious hole or gap in the core sample.

The material properties are verified by the application in field test section and the proposed anti-differential disturbance concrete is optimized. The complete set of construction technology and quality assurance technology of the anti-difference disturbance concrete are established.

(a) (b) (c)

Figure 10. Field test section of anti-differential disturbance concrete: (a) before pouring concrete; (b) concrete pouring and vibrating; (c) after maintenance.

6 CONCLUSION

The anti-differential disturbance concrete was developed for widening bridge, and the material application based on field test section was carried out. The main conclusions are as follows:

1. Based on the field vibration test of existing old bridges, the vibration amplitude and frequency are defined. The random vehicle-bridge coupling vibration simulation method is

introduced and verified the reliability of simulation model by comparing with the test results.
2. Two kinds of anti-differential disturbance concrete, resilient type and ductile type, are developed based on the on-site vibration test, laboratory material test. The proposed concrete can be applied to widened bridges with different span lengths and vibration amplitudes.
3. The material performance of anti-differential disturbance concrete is verified by the implementation of the test section, the standard construction process is summarized. The complete set of construction technology and quality assurance technology of the anti-difference disturbance concrete are established.

Safety performance evaluation of suspension bridge tunnel anchor structure

W. Dou
Anhui Transport Consulting and Design Institute CO., LTD., Anhui, China

Z.Q. Liu & J. Song
Tongji University, Shanghai, China

ABSTRACT: The construction of tunnel-anchored suspension bridge by using rock slope in mountainous area has significant economic benefits. However, uncertainties in lithology and geological conditions have high risks to the long-term performance of bridges. Based on Xiaochuan Bridge in Xin 'anjiang, Huangshan City, the research on tunnel anchorage structure is carried out. Using the three-dimensional fast Lagrangian analysis program, the tunnel anchor excavation and the backfill of the anchor plug body are simulated to clarify the stress characteristics and ensure the construction safety. Then, the influence of rock mass parameters on the stability of the bridge is analyzed. Finally, the feasibility of anchor measures to solve the instability risk is evaluated. This study provides an analysis method for the safety risk assessment of the tunnel anchor of the suspension bridge, which can be used as a reference for similar projects.

1 INTRODUCTION

As the bridge type with the strongest spanning capacity, the suspension bridge is often used for long-span bridges in mountainous areas. The tunnel anchorage mainly transmits the main cable force to the anchor plug body through the steel bundle, and transmits the force to the mountain body by means of the bonding between the anchor body and the surrounding rock. This structure can give full play to the connection between the anchor body and the surrounding rock and the mountain, and improve the bearing capacity of the bridge (Zhao, H.Q et al. 2014).

At present, many scholars have studied the structure and stability of tunnel anchors (He, S. et al. 2023; Han, Y.F. et al. 2023; Seo, S. et al. 2021; Xu, D.D. et al. 2021), such as: mechanical analysis of super-long-span tunnel anchors; the physical model of structural failure is obtained by analyzing the mechanical behavior of tunnel anchorage. The damage of tunnel anchorage structure of suspension bridge is evaluated by scale model. In addition, there are studies on the interaction between the anchor plug and the surrounding rock, and the reasonable action form of the structure is obtained (Xia, Q.Y.et al. 2021; Liu, S.W et al. 2020; Li, N.N. et al. 2020; Wang L.B. et al. 2019).

However, the uncertainty of mountain strata and geology has a great influence on the construction and use stage of the bridge. Therefore, it is still necessary to analyze the overall structural stability of the Xiaochuan Bridge. Firstly, this paper analyzes the structural stability and ensures the construction safety by simulating the two stages of tunnel anchor excavation and anchor plug backfill. Secondly, it analyzes the structural stability of the use process, and finally checks whether the structure meets the requirements of the specification under overload.

DOI: 10.1201/9781003483755-23

2 ENGINEERING SITUATIONS

The tunnel anchor of Xiaochuan Bridge in Xin ‘anjiang mainly includes four parts: open-cut tunnel, saddle chamber, anchor plug body and rear anchor chamber. The open-cut tunnel is 9m long, the saddle chamber is 16.77m long, the length of the anchor plug is 24m, the length of the rear anchor chamber is 2m, the axis angle of the anchor plug is 40 °, and the front and rear anchor surfaces are 6.7m × 8m and 9m × 12m (width × height) respectively. Two tunnel anchor structures are set on one side of the bridge. The distance between the two tunnel anchor axes is 13.5 m, and the distance between the nearest soil of the rear anchor chamber is 4.5 m. The structure of structure is shown in Figure 1.

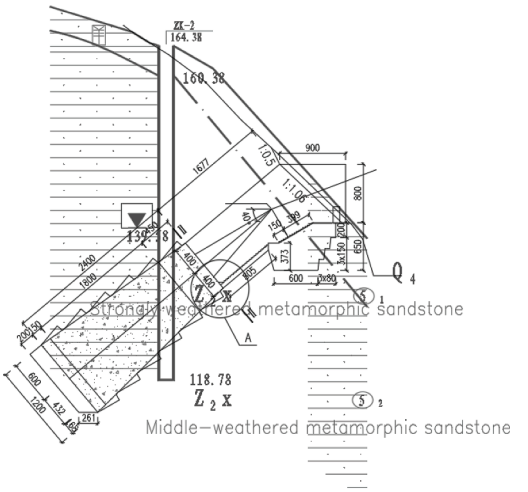

Figure 1. Anchorage structure.

3 CALCULATION METHOD AND CALCULATION MODEL

3.1 *Rationale*

FLAC3D is a three-dimensional fast Lagrangian analysis program. It is a numerical analysis method based on explicit finite difference method. It can simulate the three-dimensional structural mechanical behavior of rock and soil materials, especially the plastic rheological properties when reaching the yield limit. It is more convenient and effective in simulating nonlinear problems, large deformation problems or dynamic problems. Therefore, this simulation uses FLAC3D6.0 to analyze the stability of tunnel anchor excavation and the stress of tunnel anchor (Mahmoudi, M., & Rajabi A.M. 2023; Li, H.T et al. 2023; Xing, B. et al. 2021; Zhu, D.P. et al. 2011).

The Mohr-Coulomb criterion is essentially a shear stress strength criterion, which reflects the strength characteristics of rock more comprehensively, and can make good use of the characteristic that the tensile strength of rock is far less than the compressive strength. According to the results of field sampling and rock mechanics experiments, when the load reaches the strength limit, the rock mass is destroyed. During the post-peak plastic flow process, the residual strength of the rock mass gradually decreases with the development of deformation. Therefore, the Mohr-Coulomb yield criterion is used in the calculation to judge the failure of rock mass.

3.2 *Modeling*

The size of the model is determined to be 150m × 120m × 120m (x × y × z), and the orientation of the tunnel anchor is x-axis. Constraints are applied around the model, which is fixed in the normal direction, fixed constraints are applied at the bottom, and a contact surface is set between

the anchor plug body and the rock mass. Because the tunnel anchor is a shallow buried tunnel, its tectonic stress field is very small and can be almost ignored, so only the effect of gravity stress field is considered in the simulation analysis. The calculation model and initial stress of tunnel anchor are shown in Figure 2 and Figure 3.

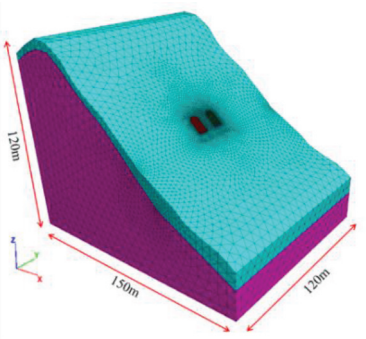

Figure 2. Simulation model.

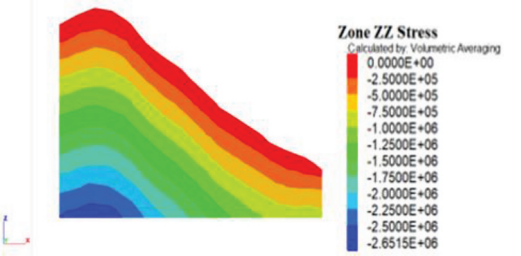

Figure 3. Initial vertical stress cloud diagram.

3.3 *Design conditions*

The location of tunnel anchor is mainly two kinds of strong and medium weathered metamorphic sandstone. Combined with the engineering geological reference materials, the soil parameters of the tunnel anchor area, the C40 and C30 concrete used in the anchor plug body, the scattered saddle foundation part and the concrete lining layer are obtained. The geological parameters are shown in Table 1.

Table 1. Calculation of physical and mechanical parameters of materials.

lithology	density / Kg/m3	deformation modulus /GPa	poisson's ratio	cohesion / KPa	internal friction angle /°	tensile strength / MPa
Strongly weathered metamorphic sandstone	2000	0.8	0.38	180	25	0.39
Middle-weathered metamorphic sandstone	2300	3.0	0.3	500	33	0.77
C30 concrete	2400	3.0	0.2	—	—	—
C40 concrete	2500	3.25	0.2	—	—	—

4 SIMULATION OF TUNNEL ANCHOR CONSTRUCTION

The excavation process of tunnel anchor is complicated. In order to ensure the stability of tunnel anchor excavation, the left and right tunnel anchors will be excavated at the same time based on the most unfavorable situation. This simulation is divided into two states: no support after excavation and timely support after excavation.

4.1 *Analysis of unsupported after excavation*

4.1.1 *Displacement analysis*

The tunnel anchor chamber is excavated without support, and the vertical displacement cloud diagram of the tunnel is shown in Figure 4. Under the condition of no support, with the

deepening of excavation, the settlement increases first and then decreases, and the maximum settlement at the top of the anchor body is 2.19 mm. The maximum uplift displacement at the bottom of the tunnel anchor is 2.98 mm, and the vertical displacement is parabolic, which expands from the excavation face to the rock mass.

The bottom of the front anchor chamber moves due to the weight of the concrete, and the maximum displacement is 0.53 mm. Due to the extrusion of the soil at the top of the rear anchor chamber, the displacement in the negative direction of the X axis is generated, and the maximum value is 0.73 mm. The displacement in the Y direction is mainly concentrated in the tunnel anchor chamber near the rock mass side, and the displacement of the middle rock mass is small, with a maximum displacement of 1.1 mm.

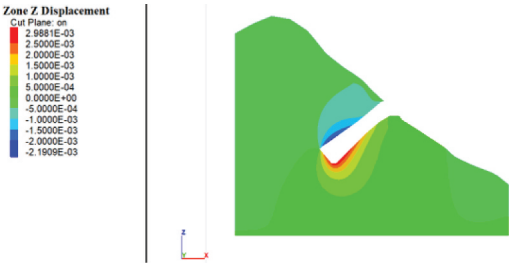

Figure 4. Displacement cloud diagram after tunnel anchor excavation.

4.1.2 *Stress analysis*

After the excavation of the tunnel, the stress of the rock mass has changed significantly. The excavation face is in a low pressure state due to the free boundary. After excavation, the rock mass is still in a state of compression, and the local stress concentration occurs at the top corner of the rear anchor chamber. The maximum principal stress is − 0.6 ~ − 0.8MPa (compressive stress), and the minimum principal stress is − 2.0 ~ − 3.0MPa (compressive stress). Because the rock mass is in a state of compression, there is obvious stress concentration in the vault section of the rear anchor chamber. The minimum principal stress value is greater than other parts, indicating that when the excavation is carried out to the bottom position, it is necessary to strengthen the support of the surrounding rock at the top.

4.2 *Analysis of timely support after excavation*

4.2.1 *Displacement analysis*

Support is carried out in time after excavation. The maximum vertical displacement settlement is 1.46 mm, which is 0.73 mm lower than that of unsupported excavation, about 33 %. In addition, the bottom of the tunnel anchor is uplifted and concentrated in the position of the anchor plug and the rear anchor chamber. The maximum uplift is 2.35 mm, which is slightly larger than the vertical settlement displacement of the top of the tunnel. Compared with the unsupported state, the uplift displacement is reduced by 0.63 mm, about 21.14 %.

4.2.2 *Stress analysis*

After excavation, the rock mass is still under compression, which is similar to the unsupported state. Local stress concentration occurs at the top corner of the rear anchor chamber. The maximum principal stress is − 0.4 ~ − 0.8MPa (compressive stress), and the minimum principal stress is − 1.6 ~ − 2.4MPa (compressive stress). Compared with the unsupported state, the stress is reduced.

The plastic zone of the intermediate rock mass is less, and the area of the plastic zone is greatly reduced compared with the unsupported state. It is mainly concentrated in the contour position of the rear anchor chamber and the anchor plug body, and it is basically in the

shear flow plastic state, indicating that the intermediate rock mass of the two tunnel anchors is not damaged.

4.3 *Anchor plug backfill simulation*

4.3.1 *Analysis of rock mass displacement after backfilling*

After the pouring of the anchor plug body is completed, it is found that there is still displacement at the top and bottom of the tunnel. The weight of the anchor plug body has an inhibitory effect on the uplift at the bottom of the tunnel. The uplift changes from 2.35 mm to 2.01 mm, and the maximum settlement of the rock mass is 1.75 mm. After the backfill of the anchor plug, the subsidence of the surrounding rock at the top increases, and the maximum increase is more than 0.2 mm. The vertical displacement is still parabolically diffused from the top and bottom of the anchor plug to the surrounding soil. Due to the weight of the anchor plug body in the X direction, there is a more obvious displacement in the negative direction of the X axis, and the displacement is small, which is 0.3mm.

4.3.2 *Analysis of rock mass stress after backfilling*

The rock mass is still in a low stress state after the backfill of the anchor plug body, and there is no big change compared with the previous stage. The maximum principal stress range of the rock mass is-0.823 MPa ~ 0.195 MPa, and the minimum principal stress range is-0.005 MPa ~ 2.6 MPa. The backfill of the anchor plug body has little effect on the stress distribution of the surrounding rock. In addition, due to the squeezing effect of backfill, the local shear stress concentration at the bottom of the rear anchor chamber is intensified.

5 STABILITY AND BEARING CAPACITY ANALYSIS

5.1 *Analysis of the impact of rock mass strength on stability*

5.1.1 *Without considering the reduction of rock mass*

Under the action of design load, the overall displacement of the longitudinal section of the surrounding rock mass is small. The maximum displacement is 0.42 mm at the foundation of the splay saddle. The displacement change is mainly gradually decreasing from the anchor plug to the surrounding rock mass. The vertical displacement along the Z axis mainly occurs at the bottom of the anchor plug, and the displacement along the X axis mainly occurs at the top of the anchor plug.

Due to the interaction between the steel strand and the anchor plug body, local compressive stress appears at the bottom of the anchor plug body, and large tensile stress is generated at the contact surface between the two sides of the anchor plug body and the rock mass. The change of the minimum principal stress cloud diagram of the whole model is small, and the whole rock is in a state of compression. The maximum principal stress range is-0.82 MPa ~ 2.35 MPa, and the minimum principal stress range is-0.006 MPa ~ -2.64 MPa.

5.1.2 *Considering the reduction of rock mass*

To simulate the loosening effect of blasting construction on surrounding rock, the strength of rock mass is reduced in the stage of main cable load application, and the parameters such as modulus and tensile strength are reduced according to the proportion of 10 %, 20 % and 30 %. The maximum displacements of rock mass from non-reduction to reduction of 10 %, 20 % and 30 % are 0.32 mm, 0.46 mm, 0.53 mm and 0.60 mm, respectively. The variation increases gradually, and the maximum displacement appears in the foundation part of the scattered cable saddle, which bears the force of the main cable perpendicular to the foundation of the scattered cable saddle. The displacement cloud diagrams under different reduction strengths are similar, and they are all parabolically diffused outward along the central axis of the anchor plug body, as shown in Figure 5.

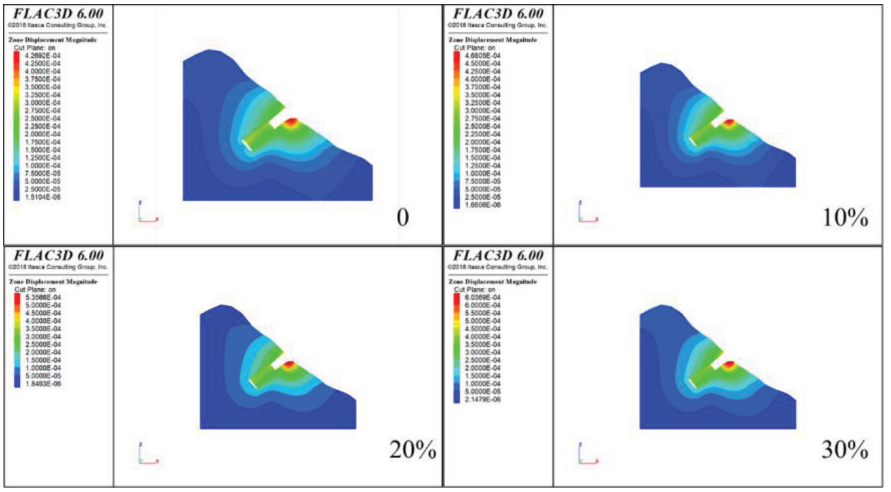

Figure 5. Displacement cloud diagram of different reduction strength (longitudinal section).

5.2 *Analysis of the impact of anchor rods on stability*

On the basis of the original concrete layer, bolt and steel arch support are added. The bolt adopts Φ25 hollow grouting bolt with a length of 3m, and the arrangement is @ 60 × 80cm. The steel arch adopts L16 I-beam with a longitudinal spacing of 60cm.

5.2.1 *Analysis of structure under design load*

Under the action of design load, the reduction of rock mass strength and rock mass strength parameters are reduced by 10 %, 20 % and 30 % respectively without considering the reduction of rock mass strength after the application of anchor rod. The displacement structure shows that the displacement changes of the two are small, both within the range of a few millimeters. In the case of strength reduction of 30 %, the maximum displacement of the two is consistent, both of which appear at the position near the top of the anchor chamber after the tunnel anchor, and the maximum value is 0.898 mm.

According to the failure of the plastic zone, it can be seen that after the replacement of the support scheme, the plastic zone has a certain reduction. Compared with the previous scheme, the plastic zone changes little, and after the strength reduction is more than 20 %, the plastic zone area is basically unchanged, and the main failure mode is shear failure.

5.2.2 *Analysis of stability in limit state*

According to the requirements of the suspension bridge design specification, the anti-slip stability of the anchor body is required to be 2.0, and the stability of the surrounding rock is required to be 4.0. Therefore, considering the application of 4.0 times the main cable force, the strength of the rock mass is not reduced, and the stability of the tunnel anchor is investigated.

Under the action of 4P limit state, the maximum total displacement of rock mass is 1.73 mm, and the maximum horizontal displacement is 1.38 mm. The vertical displacement mainly occurs at the bottom of the tunnel anchor and the foundation of the scattered cable saddle. The foundation of the scattered cable saddle sinks and the bottom of the tunnel anchor arches.

Under the action of 4P load, the plastic zone mainly appears at the bottom corner of the top of the bottom surface of the tunnel anchor chamber, and there is a slight plastic zone on both sides of the rear anchor chamber, and there is no large plastic zone damage and penetration.

5.3 *Analysis of ultimate load stability of tunnel anchor*

By applying different multiples of main cable load to the tunnel anchor, the deformation of the tunnel anchor under the action of 1P (design load), 3P (overload 3 times), 5P (overload 5

times) and 10P (overload 10 times) is compared. The deformation cloud diagram is shown in Figure 6.As the load increases, the overall deformation of the anchor plug body increases, and the maximum deformation occurs at the contact surface between the top of the anchor plug body and the surrounding rock. The distribution law of deformation in different load stages is basically the same, and it diffuses from the surrounding rock between anchors to both sides. The maximum displacement increased exponentially, and the displacements were 0.42 mm, 1.27 mm, 2.13 mm, and 4.27 mm, respectively.

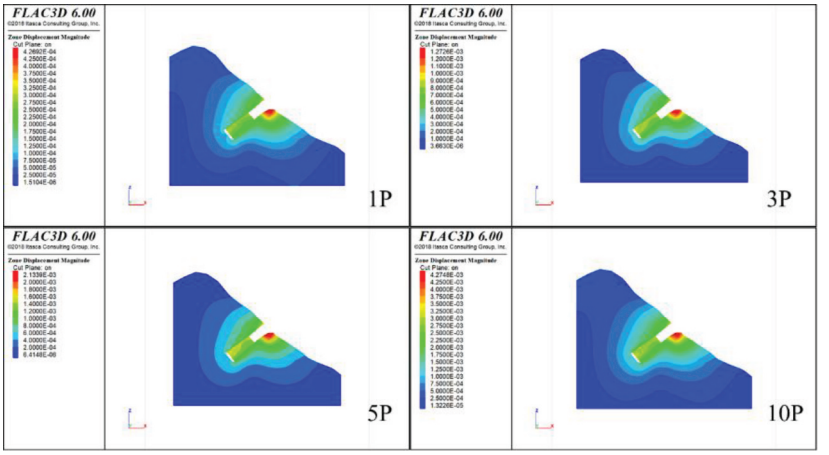

Figure 6. Displacement cloud diagram of different reduction strength (longitudinal section).

With the increase of overload, the displacement of the steel strand will also increase, and the internal compressive stress value of the anchor plug will also increase, and the steel strand at the free end will be elongated, so that it will have a large deformation difference with the anchor plug. With the increase of the depth of the steel strand, the deformation of the joint will gradually decrease. The maximum deformation of the steel strand under the load of 1P, 3P, 5P and 10P is 3.2cm, 9.0cm, 16.2cm and 32cm respectively, and the minimum deformation of the anchorage section is 1.4cm, 4.3cm, 7.3cm and 14.5cm respectively.

6 CONCLUSION

By fully utilizing natural resources to build bridges, ecological harmony can be achieved. However, the uncertainty of geological conditions can bring safety risks. Therefore, a study was conducted on an anchor suspension bridge in a certain tunnel. Through the analysis of the structural stability in the process of excavation and backfilling of tunnel anchor, the following conclusions are drawn:

Under the condition of no support, the displacement change of the top of the tunnel anchor mainly occurs at the top of the anchor plug body. With the deepening of excavation, the settlement increases first and then decreases, and the maximum settlement is 2.19 mm. The uplift at the bottom of the tunnel anchor is concentrated at the bottom of the anchor plug and the rear anchor chamber, and the maximum displacement is 2.98 mm;

Under the condition of timely support, the maximum settlement of tunnel anchor after excavation is 1.46 mm, and the maximum bottom heave is 2.35 mm. The influence range of plastic zone after excavation is small, and there is no obvious plastic penetration failure in the middle soil of the two tunnels;

The backfill pouring of the anchor plug has little effect on the deformation and stress change of the rock mass. The self-weight of the anchor plug body inhibits the uplift at the bottom of

the tunnel, from 2.35 mm to 2.01 mm, and the maximum settlement of the rock mass is 1.75 mm. The squeezing effect of the backfill of the anchor plug body leads to the intensification of the local shear stress concentration at the bottom of the rear anchor chamber;

After applying the design load of the main cable, the maximum displacement of the tunnel anchor is 0.29 mm, and the deformation of the whole rock mass extends outward in a parabolic way along the axis of the anchor plug body. Under the action of twice the design load of the main cable, there is no obvious relative deformation between the anchor plug body and the tunnel, which meets the requirement that the anti-sliding stability coefficient of the anchor plug body is greater than 2.0;

When the load is less than 4 times the design load, the structural deformation is very small. There is a small range of plastic zone inside, but there is no obvious diffusion phenomenon in the plastic zone. The displacement of the rock mass is less than 1.73 mm, which meets the requirement that the stability of the tunnel anchor cofferdam is greater than 4.0;

The overall deformation of the tunnel anchor hole area is small, and the maximum deformation does not exceed 1mm, which has good overall stability. However, the influence of bedding slope and contact between beddings is not considered in the simulation calculation. Therefore, the field investigation should be strengthened during the implementation period. If there is an interlayer or weak layer, reasonable support should be considered at the exit of the tunnel.

A review of the durability of concrete wet joints under the loading and corrosion

Yi Wang, Yin Shen & Yu Wang
College of Civil Engineering, Tongji University, Shanghai, China

ABSTRACT: Reinforced concrete bridges suffer from significant durability issues. The increased use of prefabricated assembled components with the development of accelerated bridge construction methods has led to the construction joints having an increasingly negative impact on the concrete durability. Wet joints, as a type of joints, possess a larger interface concrete porosity that promotes the transmission of harmful substances and consequently causes accelerated corrosion to reinforcement. Meanwhile, loads and environment corrosion also cause cracking and degradation of pore structures, leading to diminished concrete durability. This paper focuses on a review of durability of concrete wet joints considering the impact of loads and environment corrosion. The study includes the methods for testing the durability of concrete joints, performance related to their degradation, and the numerical models that account for joints. It also describes the potential study on impact of loads and environment corrosion on bridge construction joints.

1 INTRODUCTION

Concrete is a commonly utilized material in the bridges engineering. The presence of numerous construction joints in bridges is necessary due to the structure design and construction requirements. Concrete cannot generally be poured at once to complete for bridges. So sequentially segmental cast-in-place method or prefabricated assembled connections are used, resulting in the concrete interface. Precast concrete bridges comprise various construction joints, including wet joints, epoxy joints, and mortar bedding joints, etc. The AASHTO specification divides joints into two types: type A and type B. Type A joints include wet joints and epoxy joints, while Type B joints include dry joints.

According to Chinese *Technical Specifications for Construction of Highway Bridges and Culverts*, concrete wet joint refers to the joint that adopts sequential pouring of concrete to connect the structure as a whole, which is commonly found in segmental pouring construction, layer pouring construction, hinge joints and rigid joints of prefabricated assembled bridges, etc. It is generally placed in the part that is subjected to less shear force and bending moment and is convenient for construction. Usually, after the concrete has reached the design strength and has been roughed, cleaned, wetted and supplemented with anchoring reinforcement, the subsequent concrete is poured to form wet joints. Due to the wall effect and other effects, the cement mortar content at joints is higher, the water-cement ratio increases, and the water seepage phenomenon in the subsequent pouring concrete and the interface area gathered many pores and cracks make the wet joints are not as dense as the monolithic concrete. Therefore, wet joints are the weak part of the concrete, and become a channel for the external corrosive substances to enter the concrete.

During the mid-20th century, a significant number of concrete structures experienced premature failure due to diverse durability defects, resulting in failure to accomplish their designated service life. Structure is subject to carbonation and chloride attack, as well as other

DOI: 10.1201/9781003483755-24

erosion. These processes cause corrosion in the reinforcement and expansion, cracking and peeling on concrete. As a result, the bearing capacity of the structure is degraded. Due to corrosion problems leading to concrete structure failures, the United States spent over 100 billion dollars on operation and maintenance on bridges at the beginning of the 21st century. With China's recent rapid infrastructure development, numerous concrete bridges will likely face severe durability issues.

Previous research has not paid attention to the durability of concrete wet joints, and the bridge operation and maintenance process is mostly judged by the strength of the joints, ignoring the environmental corrosion. This paper overview the current research on the environmental corrosion resistance of concrete joints under various loads. It includes an introduction to durability testing methods for concrete joints under loads, a summary of trends in the performance of wet concrete joints under loads and environment, and a concise overview of numerical simulation methods for the corrosion effects on concrete joints.

2 TEST METHODS TO MEASURE THE COMBINED EFFECTS OF ENVIRONMENTAL CORROSION AND LOADING

2.1 *Test methods for monolithic concrete under corrosion and loads*

The progress of durability damage in concrete structures under natural circumstances is very slow and typically replicated in the laboratory through rapid durability tests, such as rapid carbonation test, chloride salt immersion test and rapid freeze-thaw cycle (FTC) test. Despite an absence of uniform standards for testing procedures under the combined impact of environmental corrosion and loading, three testing method are generally used in research. The first method is one-time alternating simulation test in which the specimen is subjected to loading, followed by a durability test or an environmental corrosion test, followed by loading. Although easier to operate, this type test may not accurately reflect the actual damage sustained by a concrete structure. The second method is multiple alternating simulation tests, in which the specimen undergoes alternating loading and durability tests several times. The third method is simultaneous testing of both mechanical loads and environmental corrosion.

Numerous experiments have studied the durability of monolithic concrete specimens under various stress conditions. Static load application methods on concrete specimens have become diverse. The compressive stress state is mainly produced by applying prestressing force (Figure 1a), usually by post-tensioning method (Tian et al., 2010, Wang et al., 2011). Tensile stress state is often achieved by applying bending moments for two primary reasons. Firstly, test equipment limits the test, such as the size of the carbonation chamber. Secondly, most concrete structures in actual bridge create tension through bending. Bending loads are commonly achieved using two or more concrete prismatic specimens anchored to each other in four-point bending (Mu et al., 2002), as shown in Figure 1b.

In addition, loading machines have also applied tensile and compressive stresses (Yao et al., 2016, Chen et al., 2022) when only a part of the concrete specimen surface undergoes environmental corrosion (Figure 1c). Chen et al. (2022) established a compression-bending state construction for freeze-thaw cycling testing. In some instances, specimens have been put in salt spray to simulate natural conditions such as coastal air (Vera et al., 2009, Wang et al., 2011).

Due to fatigue loads caused by vehicles, bridge structures may experience microcracks and increased porosity in the concrete, leading to the intrusion of external corrosive substances (Liu et al., 2023). Considering the complexity of the fatigue loading and the environment combined effect, most of the researches have been conducted through a one-time alternating approach. Li et al. (2015) set up four different test conditions, including flexural fatigue, freeze-thaw cycle, both at the same time and alternating test using an environmental test chamber (Figure 1d). Ren et al. (2015) put reinforced concrete beams in chloride salt solution to carry out flexural fatigue testing. Lu et al. (2017) determined the remaining compressive load-bearing capacity of concrete through axial compressive fatigue loading of concrete prismatic cylinders and subsequent carbonation testing.

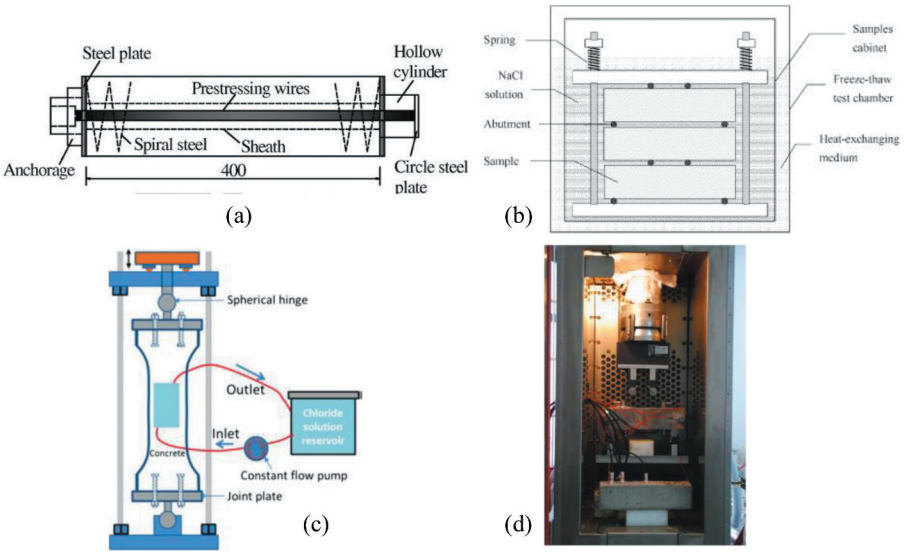

Figure 1. Monolithic concrete test methods. (a) Compressive specimen (Wang et al., 2011); (b) Four-point bending test (Mu et al., 2002); (c) Tensile specimen (Yao et al., 2017); and (d) FTC test (Li et al., 2015).

2.2 *Test method for concrete with joints under corrosion and loads*

In recent years, segmental casting and prefabricated assembling methods have become the predominant construction methods for bridges. As a result, the issue of construction joint durability has become increasingly significant and has garnered the attention of researchers. The method of applying stress state in the concrete specimens with joints is similar to that of monolithic concrete.

Due to significant differences in the construction methods of bridge joints, most previous studies have compared various joint types. Li et al. (2018) analysed the durability of direct wet joints, roughened wet joints, dry joints, and epoxied joints through exposure to chloride erosion, carbonation, and freeze-thaw cycling. Some test specimens were also subjected to compressive stress and monitored for reinforcing steel corrosion. Technical abbreviations are explained whenever necessary throughout the text. Shen et al. (2019) conducted an investigation into the durability of these joint types in concrete specimens subjected to cyclic freezing and thawing. Three compressive stress parameters of 0, 0.3 f_{ck}, and 0.5 f_{ck} were explored. Similar researches were undertaken by, Zhang et al. (2019) and Shen et al. (2023). The fabrication of specimens with joints generally involved three steps. 1) Pouring began at both ends before proceeding to the middle. 2) After disassembling the internal formwork, the joint interface was fabricated in accordance with the construction requirements. 3) Finally, the middle section was filled with concrete (Figure 2a).

Cold joints specimens are produced in a similar way to direct wet joints test samples. Cold joint is a discontinuous surface forms on the concrete surface after hardening following a delay in the working time. Yoo & Kwon (2016) assessed the resistance of cold joints to chloride erosion by applying stress to samples after they had been immersed for 28 and 91 days. Koh et al. (2019) researched the resistance of cold joints to carbonation by applying stress to specimen after a period of rapid carbonation. The specimens for compressive stress were prepared using prismatic moulds, while specimens for tensile stress were prepared using cylindrical moulds for splitting tests. To create cold joints, the concrete was placed in one half and exposed to indoor conditions for 24 hours before pouring the other half. The joints were all perpendicular to the bottom of the column.

Höffgen et al. (2023) conducted an experiment to determine the resilience of concrete joints exposed to three types of environment corrosion: carbonation, chloride attack, and FTC. The age gap between old and new concrete on both sides of the joints was 7 days. The specimens were prepared differently based on the environment exposed to, with carbonation specimens

being created from 100 mm cubes and the chloride specimens extracted by drilling cores from the cubes. The joints of the carbonation and chloride specimens were perpendicular to the bottom of the cylinders, while those for the freeze-thaw cycle specimens were parallel to the bottom of the columns. Qin et al. (2023) investigated the deterioration tendencies of cold joints exposed to wet and dry sulphate cycling. To improve joint strength, key teeth were added to the cold joints and the age of the joints varied from 0-28 days. Compressive stress was applied after wet and dry cycling (Figure 2b).

The joints aforementioned were composed of an equal quantity of concrete material on both sides, whereas certain concrete structures had varying strengths and admixtures on either side of the joints, such as the concrete requiring repair after local damage or reinforcement due to insufficient stresses in prefabricated construction. Yan et al. (2023) examined the impact of joint types (direct wet joint, roughened wet joint, and interfacial joint) and joint materials (M5 mortar, M10 mortar, and grout) on the pattern of chloride erosion. The study used typical concrete and limestone powdered concrete on both sides of the joints. Zhang et al. (2023) investigated the corrosion of steel reinforcement at UHPC interfaces under chloride attack and compared it with normal concrete and high-performance concrete interfaces.

There is a scarcity of research pertaining to the durability of joints under fatigue loading. Zhao & Li (2022) have devised an auxiliary truss unit (Figure 2c) to carry out fatigue tests. A ring of watertight glass adhesive around the edge of the penetrated specimen surface was applied to create a container for simulation of chloride infiltration in wet and dry conditions.

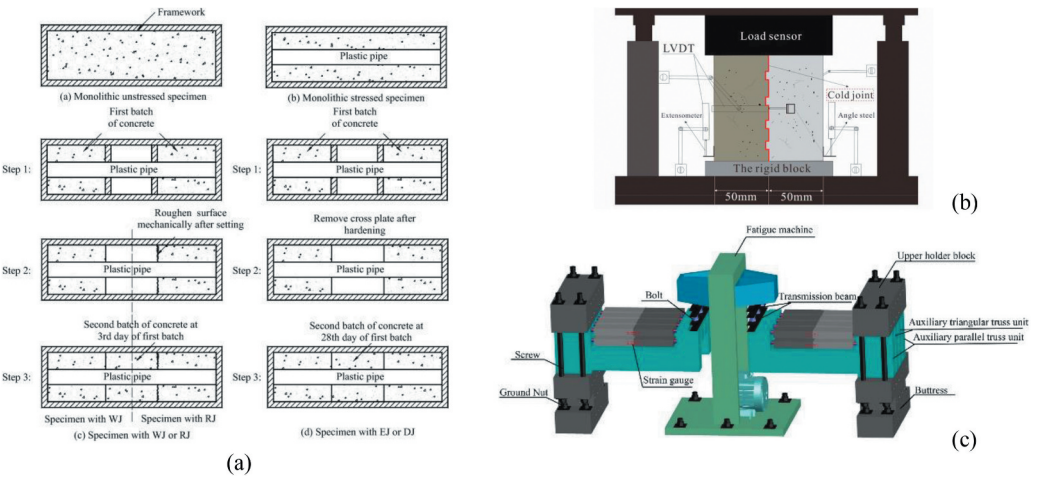

Figure 2. Concrete with joints test methods. (a) Steps for making different joints (Shen et al., 2019); (b) Specimen with teeth (Qin et al., 2023); and (c) Auxiliary truss unit for fatigue load (Zhao & Li (2022).

At present, there are initial outcomes for researching the durability of concrete joint components. In recent years, the test method has evolved from a single durability test to a coupled test with multiple corrosion effects and loads, from static loads to fatigue loads, and from monolithic concrete members to actual joint members in real engineering, gradually innovative and diverse. Mu et al. (2002) and Zhang et al. (2019) have provided a solution to the problem of multiple corrosion; Yao et al. (2016) can accurately apply the stresses and at the same time reduce the test cost. Zhao & Li (2022) through the auxiliary unit applying fatigue loads saves test time and ensures that the members are in the same environment. However, the majority of results concerning specimens with joints can only serve as reference. It is essential to closely examine the actual situation regarding component size and joints treatment adopted in real projects. To reinforce the connection, rebars must be increased on both sides of the joints, and consider the specimen to apply stress and other major factors affecting the structure of the research. These studies also lack

a developed theoretical framework to guide the planning and execution of projects and continue to utilize specifications for monolithic concrete for the purpose of design, construction, operation and maintenance currently.

3 DETERIORATION OF CONCRETE JOINT PARTS UNDER ENVIRONMENTAL CORROSION AND LOADS

3.1 *Deterioration of wet joints under corrosion*

The degradation mechanisms of concrete durability are different under environmental exposures. Carbonation and chloride ion erosion are the main reason for reinforcement deterioration. Carbonation reduces the pH value of the solution, adjacent to the rebar, destabilizing the surface passivation film and leading to corrosion. Chloride ions have strong depassivation properties that cause battery-like corrosion of the steel reinforcement. The concrete strength and stiffness diminish when subjected to the physical processes of concrete cracking and surface spalling caused by the freeze-thaw cycle. Moreover, the concrete matrix also undergoes cracking from the expansion products resulting from sulphate attack.

Concrete properties (such as water-cement ratio, concrete strength, admixtures, etc.) and environmental factors (such as temperature, humidity, dry and wet cycles, exposed environments, etc.) are significant factors that influence concrete durability. Among these, the type of loading and stress level play a important role in determining concrete durability. In recent times, stress is usually employed rather than strain to reflect the loading state of concrete (Ai et al., 2021). Compressive stress enhances the carbonation resistance and resistance to chloride erosion in concrete. It also closes internal micro-cracks and restricts the diffusion of external corrosive substances into the concrete. Conversely, tensile stress diminishes these properties, and increases porosity and cracking in concrete. Corrosive substances can undergo faster chemical reactions and reach the surface of the reinforcement on the rebar much earlier. The durability indicator of carbonization is mainly the depth of carbonization (Shen et al., 2023); the durability indicator chloride attack is measured by the diffusion coefficient of chloride ions or the time when the chloride ions start to corrode the surface of the reinforcement (Zhang et al., 2023); for freeze-thaw cycles, the number of freeze-thaw cycles and the dynamic elastic modulus are used as service period indicators (Shen et al., 2019, Zhang et al., 2019).

Mun & Kwon (2016) and Yang et al. (2018)found that the chloride ion diffusion coefficient at joints did not differ significantly from that of cracked concrete under varying tensile stress levels, indicating that joints and cracks have comparable effects. However, under compressive stress, the chloride ion diffusion coefficient of concrete joints was elevated in comparison to cracks. Koh et al. (2019) revealed that concrete carbonation occurs at a greater depth in cold joints than non-joint concrete. Additionally, the rate of concrete carbonation under tensile stress increases linearly with the level of stress.

Shen et al. (2023) proposed the joint influence factor γ_{Joint}, i.e., the ratio between the depth at the joint section and the depth of monolithic concrete. By testing a bridge in Shanghai, China, which was demolished after 30 years of service, it was found that the carbonation depth of the joints were 2.1 times that of the monolithic concrete due to the setting of a partially prestressed with a small tensile stress, and the web with the largest tensile stress, which made the carbonation depth of the joints were 2.4 times that of the monolithic concrete, suggesting that the durability of concrete bridge joints is far inferior to that of monolithic concrete. And according to the carbonization depth distribution curve derived from the test, it is considered that durability improvement measures are needed in the range of 2 times the carbonization depth of the joint on both sides of the joint.

By examining the carbonation depth and chloride ion corrosion depth, it was found that the concentration of corrosive materials and their byproducts in the wet joints followed an inverted V shape. This means the corrosion depth at the joint was highest when compared to the specimen without joints. Additionally, the impact of the joints on the distribution of corrosive materials on the specimen remained significant within a certain distance from the joint

but decreased thereafter. There is no longer a significant effect with the increase in distance from the joints (Shen et al., 2023, Yan et al., 2023).

Fatigue loading also has a significant effect on the durability of fatigue distressed concrete. For example, when the number of fatigue cycles is low, the compressive stress suppresses microcracking or microporosity in the compression zone and inhibits the carbonation process (Vicente et al., 2018). However, once the compressive fatigue damage reaches a certain level, the carbonation process also increases significantly. Residual strain (Jiang et al., 2017), dynamic modulus of elasticity, number of fatigue cycles and pore microstructure (Song et al., 2020) are the main indicators to characterize the fatigue damage of concrete.

3.2 *Comparison of the durability of different construction joints*

The comparison of the durability of various types of construction joints is a key area of research. Each type of joints exhibits different resistance to chloride ions, carbonation, freeze-thaw cycles characteristics. These properties, however, are consistently inferior to those of the monolithic concrete structure, and thus the joints can be identified as the weak points of the concrete structure (Li et al., 2012a, Li et al., 2012b). The joints can accelerate the diffusion and infiltration of external ions. Li et al. (2018) studied various compressed and unstressed joints and found that roughened wet joints generated microcracks on the surface of old concrete, resulting in damage. In terms of durability, roughened wet joints were inferior to direct wet joints. Epoxy joints did not display satisfactory durability, while dry joints had the poorest durability due to a macroscopic gap in the joints. It is believed that implementing a particular level of pre-compressive stress will have two effects. Primarily, the pore structure of the concrete within the joints will compact. Secondly, the micro-cracks caused by the roughing process will expand further. The combined effect of the two leads to the durability indexes of the roughened wet joints with the application of pre-compressive stresses have the same stochastic nature.

Zhang et al. (2019) conducted research into the carbonation resistance and freeze-thaw resistance of precast segmental girder joints and discovered that epoxy joints exhibited superior carbonation resistance. In contrast, direct wet joints showed the worst carbonation resistance, with monolithic moulded concrete joints performing better but still ranking second to epoxy joints. Yan et al. (2023) conducted a comparison between wet joints and mortar joints and discovered that direct wet joints had the highest concentration of chloride ions. Similarly, roughened joints exhibited greater chloride ion concentration than mortar joints.

The test results indicate that wet joints are significantly impacted by stress levels and that appropriate compressive stress can enhance the durability of concrete specimens by reducing pores and closing microcracks within the concrete. However, higher levels of compressive stress can have an adverse effect on concrete durability, potentially due to lateral tensile stresses arising from Poisson's effect and unstable variations in the internal pores of the concrete.

Roughened wet joints eliminate the negative effect caused by the more permeable cement mortar matrix at the joint interface. However, microcracks that emerge during chipping cause concrete damage at the joints, and such damage is usually greater than the impact of removing the cement mortar matrix. Moreover, roughened wet joints are not as resistant to chloride ions and carbonation as direct wet joints. Under FTCs, chipping had no significant effect on the freeze-thaw resistance of joints (Li et al., 2018).

The type of joints led to a negative effect on concrete durability. Epoxy joints, wet joints, and roughened wet joints had slightly different adverse effects on durability. Tensile strain directly and adversely affects the durability of concrete. Thus, when designing concrete structures under high pressure or tensile stress, a particular safety margin is mandatory to ensure the concrete durability.

4 NUMERICAL SIMULATION METHOD FOR CONSTRUCTION JOINTS

Numerical simulations concerning the durability of concrete have progressed from traditional empirical formulas and macroscopic simulations to meso-scale simulations. Empirical models

typically summarized from experiments and theory from experimentation and theory. Monteiro et al. (2012) proposed a model to predict carbonation depth based on more than 100 measurements of multiple structures with service years ranging from 4-99 years, which takes into account the age of the structure, the effect of paint, the compressive strength of the concrete, and the exposure conditions. The empirical model shows that carbonation depth is directly proportional to the square root of time, with varying carbonation rate constants and indices for different factors influencing the process. The empirical model has some limitations and it is difficult to take into account all factors affecting durability, such as aggregate distribution and concrete variability.

4.1 *Macroscopic model of concrete construction joints*

Macroscopic numerical simulations will treat concrete as an isotropic homogeneous substance. Vagelis G. Papadakis & Michael (1991) acquired a theoretical solution of his proposed system of differential equations for the carbonation process through some simplifying assumptions, which can also be solved numerically. Anna V. Saetta & Renato (1993) and Saetta et al. (1993) formulated a numerical model combining temperature, moisture, diffusion, and the kinetics of the carbonation reaction, taking into account only the carbonation reaction between CO_2 and $Ca(OH)_2$. Tian et al. (2015) developed a three-dimensional multifactor coupled concrete carbonation model, which is able to consider a series of factors such as environmental conditions, concrete material properties, and structural shape. Yan et al. (2023) examined the simulation of macroscopic concrete components featuring construction joints, for the transport of chloride ions. The study considers the decay effect of the chloride ion diffusion coefficient with time and the joints thickness of the protective layer on the durability of concrete elements in a chloride salt environment.

All of these numerical models treat concrete as a macroscopic homogeneous material and do not consider the distinct behaviour exhibited by individual concrete components in relation to the degradation of the overall properties of concrete.

4.2 *Meso-scale model of concrete construction joints*

The durability of concrete at the meso-scale has become a prominent subject recently. At the meso-scale level, the concrete's inhomogeneous distribution of aggregates in the cement paste is considered. The concept of the meso-scale of concrete is proposed by Zaitsev & Wittmann (1981), dividing the concrete into cement paste, aggregates, and the interface transitional zone (ITZ) between them. Pan et al. (2012) and Ruan & Pan (2012) formulated a numerical model for carbonation in concrete at meso-scale, accounting for the influence of aggregate distribution. In relation to the macroscopic model, the depth of concrete carbonation was reduced by the dilution effect and distortion effect of aggregates. The uneven distribution of aggregates caused the depth of carbonation to appear inhomogeneous. Qin et al. (2019)studied the interfacial fracture toughness and water infiltration behaviour of old and new concrete, and developed model at the macroscopic, meso and nano scales. Shi et al. (2022)used meso-scale numerical model to categorise concrete into uncarbonated, semi-carbonated, and fully-carbonated zones. They applied axial loads and found that both compression and tension can result in significant damage to the concrete and the creation of CO_2 diffusion paths. It is worth noting that once these paths are formed, Fick's law no longer applies.

Meso-scale numerical models consider factors such as changes in the external environment of the structure, the concrete structure's shape and internal structure, and can be applied to calculate concrete durability under complex conditions. Currently, research on meso-scale concrete joint simulation primarily centers on concrete structure repair. Concrete construction joints are considered to be a distinct component of concrete. To model construction joints and their response to combined environmental corrosion and load effects, meso-scale numerical model is a recommended approach.

5 CONCLUSION

The effects of corrosive environments and loading effects on concrete structural joints have garnered considerable interest. Current research focuses primarily on the effects of static and fatigue loading on concrete carbonation, chloride transport, FTCs and other environmental effects on monolithic concrete and concrete with construction joints. Models that take into account loading and corrosion have been developed. However, there are still some directions that need to be further explored and researched on this topic:

(1) Current durability studies focus on the properties of the concrete material while ignoring structural aspects, including the impact of construction joints. The excessive use of precast components impedes the continuity of concrete, leading to a porous structure during the initial bridge construction phase which is not as good as the concrete cast-in-place. Construction joints are present in the cement mortar matrix, which is not as dense as the monolithic concrete, becoming a weak part of the concrete, making it easier for external harmful substances to enter the concrete, accelerating the corrosion of concrete. Currently, there are limited studies on construction joints, particularly in terms of environmental corrosion and loading, which can significantly guide the design of actual bridge engineering structures.
(2) Bridge structures are often subjected to fatigue loads caused by vehicles. Previous research has primarily focused on the impact of fatigue loading on carbonation and chloride ion transportation in monolithic concrete, as well as the damage state of concrete when subjected to fatigue loading with FTCs. In addition, some chloride intrusion models considering the effect of fatigue loading have been established. However, the durability performance of the construction joints under the combined effect of fatigue loading and environmental corrosion is limited and still needs to be further studied.
(3) There is potential for enhancing test methods under the effects of fatigue loading and corrosive environments. Alternative test methods that account for these simultaneous interactions need to be explored. The typical approach in most studies employs a one-time alternating simulation test method. In reality, fatigue loading and corrosion occur simultaneously. As fatigue loading increases, concrete damage and the deterioration of microporosity and microcracks drastically accelerate salt erosion process. At the structural level, the acceleration of erosion caused by chloride salt due to fatigue damage results in corrosion deterioration of steel reinforcement embedded in concrete. Corrosion leads to decreased cross-sectional area of the reinforcing steel material, consequently reducing its fatigue resistance. The combined effect of fatigue and corrosion causes the steel reinforcement to deteriorate more rapidly, significantly reducing the service life of reinforced concrete structures. Therefore, it is crucial to establish the degradation characteristics of reinforced concrete when subjected to the joint effects of environmental corrosion and loading.
(4) Concrete structures are exposed to various environmental corrosion factors, often more than one. Studied combinations include carbonation and chloride ion erosion. Further study is needed into the performance degradation mechanism of concrete structures under the combined effect of multiple environmental factors and loads.

PC-PINNs: Physics-informed neural networks for solving the phase-field model of pitting corrosion

Nanxi Chen, Rujin Ma & Airong Chen
Department of Bridge Engineering, Tongji University, China

Chuanjie Cui
Department of Engineering Science, University of Oxford, Oxford, UK

ABSTRACT: Physics-informed neural networks (PINNs) have recently emerged as a promising tool for resolving partial differential equations. However, when confronting complex multi-physics problems, conventional PINNs suffer from substantial challenges. In this study, we present an advanced PINN framework tailored for the phase-field model of pitting corrosion (PC-PINNs) , effectively navigating the complexities of the rigidly coupled Allen-Cahn and Cahn-Hilliard equations. The main ingredients of PC-PINNs include: 1) an NTK-based adaptive weighting strategy to balance the multiple loss terms arising from coupled equations, 2) a generalized adaptive sampling scheme complemented by dual criteria to accurately track the corrosion interface, 3) a random-batch technique to accelerate the weight calculation, and 4) a cross-scale sampling technique to ensure the veracity of convergence. We evaluate the PC-PINNs against two phase-field corrosion benchmarks, using various strategy permutations to validate the effectiveness of the proposed theory. Results demonstrate that the PC-PINNs successfully overcome the limitations of the conventional PINNs, delivering simulations with high fidelity.

1 INTRODUCTION

Pitting corrosion, a form of localized corrosion, poses a significant threat to alloys in various service environments. Its occurrence can result in the development of perforations and cracks on components, ultimately leading to the deterioration and failure of engineering structures (Mai et al., 2016). Consequently, conducting comprehensive investigations into the evolution process of pitting corrosion is imperative for the purpose of reliability assessment and health monitoring of structures.

The simulation of pitting evolution using the phase field method has been intensively studied (Mai et al., 2016). The phase-field method is a computational approach widely utilized in material science to simulate the evolution of complex microstructures (Chen, 2002). It is characterized by the ability to capture dynamic processes of phase transitions by representing the material's microstructure as a continuous field variable. The problem can then be formulated as a set of coupled partial differential equations (PDEs) that govern the evolution of the phase-field variable. This eliminates the necessity of explicitly tracking interfaces and circumvents the imposition of boundary conditions on moving interfaces (Mai et al., 2016), thereby streamlining the implementation of simulations through computational programs. When solving the PDEs associated with the phase-field model, various numerical methods, including finite difference, finite element, finite volume methods, etc., have conventionally served as the principal options (Zhao et al., 2023).

However, in recent years, physics-informed neural networks (PINNs) have emerged as a promising approach for solving PDEs. By integrating the residuals of governing equations into the neural network's loss function, PINNs combine the strengths of both numerical methods and

DOI: 10.1201/9781003483755-25

machine learning. Thus, PINNs can be viewed as a self-superimposed learning strategy that does not require any labeled data, such as results of prior simulations or experiments (Cuomo et al., 2022). This novel computational framework exhibits numerous advantages. On one hand, well-established program frameworks for deep learning, such as PyTorch and TensorFlow, along with computational platforms like CUDA, enable highly parallelized computational processes. On the other hand, the governing equations are embedded into the loss function as part of a multi-objective optimization, facilitating the coupling of physical fields. Furthermore, compared to discrete conventional numerical methods, PINNs are mesh-free and continuous, thereby naturally avoiding a range of numerical challenges resulting from improper discretization (Wu et al., 2023).

In this study, we present a refined PINN framework for solving the phase field model of pitting corrosion. This phase field model is characterized by strong stiffness and sharp interface transition. Section 2 describes this PC-PINN framework in detail, including the specially designed NTK matrix-based weighting strategy for the coupled equations and the strategy for adaptive sampling, as well as a series of related techniques. Section 3 gives illustrative examples of solving typical pitting problems to validate the effectiveness of the framework.

2 PHYSICS-INFORMED NEURAL NETWORK FOR PITTING CORROSION (PC-PINN)

In this section, we first present a theoretical background for the modeling of the pitting problem using the phase field method. A PINN model is constructed based on the phase field theory. To ensure the convergence and accuracy of the PINN, several techniques, such as loss weighting and adaptive sampling, are discussed in detail.

2.1 *Phase field model of pitting corrosion*

The key idea of the phase field method for pitting corrosion is to introduce a phase field variable to describe the formation and evolution process of corrosion pits. By employing the phase field equations and boundary conditions, this approach enables the simulation of pit expansion and shape variation, thereby facilitating quantitative prediction and analysis of pitting corrosion.

Specifically, the phase field model is governed by coupled Allen-Cahn and Cahn-Hilliard equations, which are given by

$$\text{Allen-Cahn}: \frac{\partial \phi}{\partial \mathrm{t}}(x,\mathrm{t}) = -\mathrm{L}\left(\frac{\partial \mathrm{f}}{\partial \phi} - \alpha_\phi \nabla^2 \phi\right) \tag{1}$$

$$\text{Cahn-Hilliard}: \frac{\partial \mathrm{c}}{\partial \mathrm{t}}(x,\mathrm{t}) = \nabla \cdot \mathrm{M} \nabla \frac{\partial \mathrm{f}}{\partial \mathrm{c}} \tag{2}$$

In the above equations, ϕ represents the phase field variable, c represents the normalized concentration, and f represents the local free energy density. The relevant equations and parameters involved in this study can be found in Ref. (Mai et al., 2016)

2.2 *Sampling strategies*

The careful selection of a suitable dataset is a crucial and pivotal stage in the training of neural networks, as it fundamentally influences their convergence and accuracy. In the context of PINNs, the dataset consists of the sampling points within the spatiotemporal domain D. Therefore, conducting a thorough analysis of the sampling strategies becomes imperative when training PINNs.

In this study, the sampling points can be categorized into three main groups:

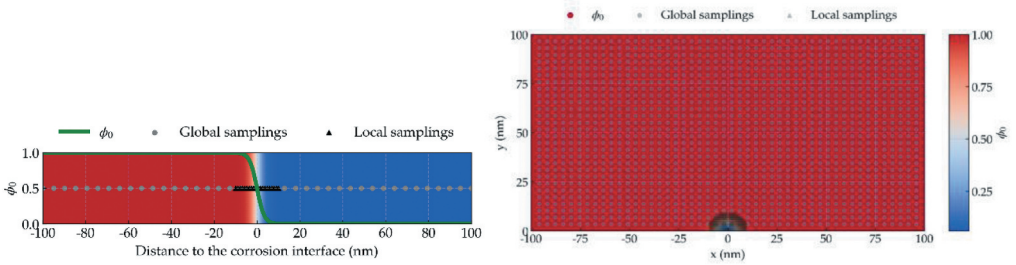
1. Common collocations $\boldsymbol{S}_c$: These points are sampled within the domain D and are representative of the overall behavior of the system.
2. Adaptively sampled collocations $\boldsymbol{S}_a$: These points are sampled and dynamically adjusted to accurately capture the sharp interface transitions that occur during the evolution of the system.
3. Initial/boundary collocations $\boldsymbol{S}_i$,$\boldsymbol{S}_b$: These points are sampled on the initial and boundary conditions of the problem.

It is worth noting that the collocations used to compute the loss term of the governing equations (namely in-domain collocations) are formed by the union of common collocations and adaptively sampled collocations, denoted as $S_f = S_c \cup S_a$. At the beginning of the training process, each category of points is sampled using specific strategies. Subsequently, the sampling points are periodically resampled and updated to ensure that they effectively capture the evolving behavior of the system. Further details regarding these sampling strategies will be discussed in the subsequent sections.

2.2.1 *Cross-scale sampling for continuous initial collocations*

When solving the phase field governing equations, conventional numerical methods typically involve meshing the domain and imposing discrete initial conditions on the mesh. Then interpolation is conducted to obtain the initial conditions at any position within the domain. In the context of pitting corrosion, it is sufficient to declare the initial position of the corrosion interface using conditional syntax, without explicitly specifying the detailed profile of the diffuse phase-field interface. For instance, in a one-dimensional problem, a common form to express the initial condition is as follows:

$$\hat{u}(x_0, 0) = \begin{cases} 1 & x_0 \geqslant 0 \\ 0 & x_0 < 0 \end{cases} \tag{3}$$



Since PINNs are meshless and continuous, the neural network will learn and fit the initial condition at any position when $t = 0$. Therefore, if the initial condition is solely defined by specifying the position of the corrosion interface at the initial moment using conditional syntax, PINNs may capture a discrete and abrupt interface. This contradicts the fundamental concept of diffuse interfaces in the phase field method. Therefore, it is necessary to incorporate a refined phase-field profile with an analytical expression.

In this regard, (Kim et al., 1999) proposed a smooth interpolation function for the equilibrium phase-field profile, which is given by:

$$\phi_0(x) = \frac{1}{2}\left[1 - \tanh\left(\frac{\sqrt{\omega}}{\sqrt{2\alpha_\phi}}x\right)\right] \tag{4}$$

$$c_0(x) = h[\phi_0(x)]c_S^e + \{1 - h[\phi_0(x)]\}c_L^e \tag{5}$$

In phase-field modeling, the interface of the phase transition between the solid and liquid phases is typically confined to an extremely narrow region (see Figure 1a). When sampling collocation points for initial conditions solely at a global scale, only a limited number of scatters are distributed over the diffuse interface. Consequently, the phase field and concentration profiles described in Equations 4 and 5 may pose challenges for PINNs to learn. Furthermore, when simulating pitting corrosion conducted in two dimensions and higher, the initial pits typically occupy a very small portion of the spatial domain (see Figure 1b). Employing single-scale sampling in such scenarios would result in a significant imbalance in the number of scattered samples representing the solid and liquid phases. This imbalance would lead to the failure of PINNs in learning the initial conditions.

(a) (b)

Figure 1. Examples for cross-scale sampling of continuous initial conditions: (a) One-dimensional case; (b) Two-dimensional case.

Consequently, a cross-scale sampling strategy is employed to address the issue. Given that the gradients of the physical fields are all zero in the region outside the phase transition, it is reasonable to cover the entire spatial domain at time $t = 0$ using global sampling with a relatively low density. However, in the vicinity of the corrosion interface at the initial moment, the local spatial domain needs to be sampled more densely.

2.2.2 *Adaptive sampling strategy*

In the simulation of pitting problems, it is common to observe extremely high gradients in the physics field near the corrosion interface. To address this issue, a residual-based adaptive sampling strategy was initially introduced in Ref. (Lu et al., 2021).The fundamental concept behind this strategy involves incorporating sampling points with the highest residual term, in relation to the governing equations, into the training of the subsequent iteration.

This study summarizes the general scheme for performing adaptive sampling in PINNs when dealing with coupled governing equations, as shown in Algorithm 1. The key concept of this algorithm is the choice of the criterion for the computation of the indicating values $\{R\}$. In particular, two kinds of effective criteria are proposed for the adaptive sampling of the phase field model.

Algorithm 1. General scheme of adaptive sampling.

Step1:	Conduct a sufficiently dense and random sampling of $N_{a,b}$ points within the spatiotemporal domain D, thereby establishing the base set of adaptively sampled points $S_{a,b}$;
Step2:	Input the complete base set into the PINN model and obtain the corresponding solution $\hat{u}$;
Step3:	Compute several groups of indicating values $\{\mathcal{R}\}$ based on a pre-defined criterion, as described in Equations 6-11
Step4:	Select the points corresponding to the highest k from each set of indicating values and subsequently merge any duplicate points from different sets to obtain the final set of adaptively sampled points S_a

Residual criterion: Points corresponding to the highest k absolute residual values of the governing equations are selected, expressed as

$$S_{a,\mathrm{AC}} = \arg_{(x_j,t_j)} \mathrm{TopK}\left|\mathcal{F}_{AC}\left[x_j, t_j, \hat{u}(x_j, t_j)\right]\right| \quad (x_j, t_j) \in S_{a,b} \tag{6}$$

$$S_{a,\mathrm{CH}} = \arg_{(x_j,t_j)} \mathrm{TopK}\left|\mathcal{F}_{AH}\left[x_j, t_j, \hat{u}(x_j, t_j)\right]\right| \quad (x_j, t_j) \in S_{a,b} \tag{7}$$

$$S_a = S_{a,\mathrm{AC}} \cup S_{a,\mathrm{CH}} \tag{8}$$

where $S_{a,\mathrm{AC}}$,$S_{a,\mathrm{CH}}$ and $\mathcal{F}_{AC}$, $\mathcal{F}_{CH}$ denote the adaptively sampled points and the residuals of the Allen-Cahn and Cahn-Hilliard equations, respectively.

Residual criterion: Points corresponding to the highest k absolute gradient values with respect to the spatial and temporal coordinates are selected, expressed as (in one-dimensional cases)

$$S_{a,x} = \arg_{(x_j,t_j)} \mathrm{TopK} \left| \frac{\partial \hat{u}(x_j,t_j)}{\partial x_j} \right| \quad (x_j,t_j) \in S_{a,b} \tag{9}$$

$$S_{a,t} = \arg_{(x_j,t_j)} \mathrm{TopK} \left| \frac{\partial \hat{u}(x_j,t_j)}{\partial t_j} \right| \quad (x_j,t_j) \in S_{a,b} \tag{10}$$

$$S_a = S_{a,x} \cup S_{a,t} \tag{11}$$

2.3 *NTK-based adaptive weighting strategy with random-batch technique*

In the context of the phase field model governed by coupled equations, the loss function consists of four terms: (1) the loss for the Allen-Cahn equation, (2) the loss for the Cahn-Hilliard equation, (3) the loss for the initial condition, and (4) the loss for the boundary condition. Consequently, the training process of PINNs can be viewed as a multi-objective optimization problem (Bischof and Kraus, 2021). To ensure the convergence and accuracy of the PINNs model, it is crucial to assign appropriate weights to the combination of these competitive loss terms.

In this study, an NTK-based weighting strategy is employed (Wang et al., 2022) to conduct the adaptive weighting of the loss terms. In addition, to improve the efficiency of the NTK-based weighting strategy, a random-batch technique is introduced to reduce the computational cost of the NTK calculation.

Let $\boldsymbol{J}_{\mathrm{AC}}(s)$,$\boldsymbol{J}_{\mathrm{CH}}(s)$,$\boldsymbol{J}_{\mathrm{IC}}(s)$,$\boldsymbol{J}_{\mathrm{BC}}(s)$ be the Jacobian matrices of the left sides of the PDE with respect to the network parameters $\boldsymbol{\theta}$ at iteration s. The NTK matrices of the four loss terms can be expressed as

$$\boldsymbol{K}_j = \boldsymbol{J}_j(s)\boldsymbol{J}_j(s)^T \tag{12}$$

where the subscript j can represent any of the four loss terms, i.e. AC, CH, IC, BC. The weight of each loss term can then be calculated as inversely proportional to the mean values of the corresponding traces, which can be expressed as

$$\omega_j(s) = \frac{N_j}{\mathrm{tr}(\boldsymbol{K}_j(s))} \left[\frac{\mathrm{tr}(\boldsymbol{K}_{\mathrm{AC}}(s))}{N_{\mathrm{AC}}} + \frac{\mathrm{tr}(\boldsymbol{K}_{\mathrm{CH}}(s))}{N_{\mathrm{CH}}} + \frac{\mathrm{tr}(\boldsymbol{K}_{\mathrm{IC}}(s))}{N_{\mathrm{IC}}} + \frac{\mathrm{tr}(\boldsymbol{K}_{\mathrm{BC}}(s))}{N_{\mathrm{BC}}} \right] \tag{13}$$

Here, j = AC,CH,IC,BC and $\omega_j(s)$ denotes the weight of each loss term at iteration s.

In order to facilitate the calculation process of NTK-based weights for large-scale samplings, a random-batch technique is proposed in this study. Instead of using all the samplings to calculate the weights, the random-batch technique reduces the requirements for computational cost by randomly sampling a small batch of points to represent the entire sampling set.

Let us consider the elements on the main diagonal of the NTK matrices as random variables, denoted as X_{AC}, X_{CH}, X_{IC} and X_{BC}, corresponding to the four loss terms. Specifically, we have:

$$X_j = \mathrm{diag}(K_j) = \left[x_{j,11}, x_{j,22}, \cdots, x_{j,N_jN_j}\right] \tag{14}$$

The ratio of the trace of the NTK matrix to the matrix dimension, $\mathrm{tr}(K_j)/N_j$, represents the mean of the population, denoted as $\mu_{X\mathrm{j}}$. Consequently, each weight ω_j in Equation 13 can be expressed as a linear combination of the means of the population of the four random variables:

$$\omega_j = \frac{1}{\mu_{X_j}} \sum \mu_{X_j} = \frac{1}{\mu_{X_j}} \left(\mu_{X_{\mathrm{AC}}} + \mu_{X_{\mathrm{CH}}} + \mu_{X_{\mathrm{IC}}} + \mu_{X_{\mathrm{BC}}}\right) \tag{15}$$

According to the central limit theorem, the mean of a sufficiently large number of random samples approaches the mean of the population (Dinov et al., 2008), i.e.

$$\lim_{b_j \to N_j} \mu_{Y_j} = \mu_{X_j} \tag{16}$$

where Y_j represents the random selected subset of X_j with a batch size of b_j. Therefore, for an appropriate batch size b_j, the mean of the random samples μ_{Yj} can be used to approximate the mean of the population μ_{Xj}. The above analysis indicates the rationality of using the random-batch technique to calculate the NTK-based weights.

3 RESULTS

To validate the effectiveness of the PC-PINN framework, we employ it to solve two illustrative phase-field pitting corrosion problems, namely one-dimensional and two-dimensional diffusion-controlled corrosion problems. The reference solution is obtained using the finite element method implemented in the Python package FeniCS (Logg and Wells, 2010).

3.1 *One-dimensional diffusion-controlled corrosion*

In this case, the spatial domain spans from –50 to 50 nm, while the temporal domain ranges from 0 to 100 s. The initial and boundary conditions are depicted in Figure 2. At the initial moment, the corrosion interface is positioned at x = 40 nm.

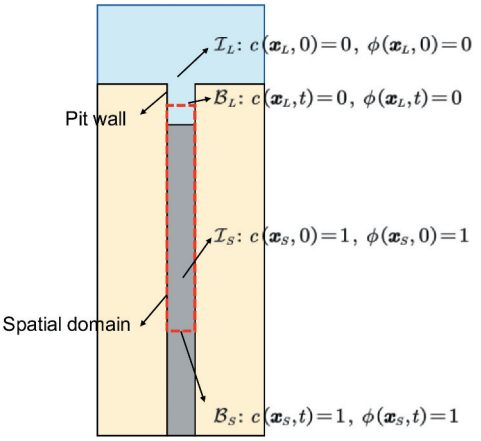


Figure 2. Schematic of the initial and boundary conditions for the one-dimensional diffusion-controlled corrosion problem.

In this model, we employ a neural network architecture consisting of 8 hidden layers, each containing 16 neurons. For the sampling process, we utilize 900 common collocations, with 30 collocations allocated on each coordinate. Both the number of initial collocations and boundary collocations are set to 128. 4,000 adaptive samplings are selected from a base set comprising a total of 30,000 points. For the weighting process, the NTK-based weighting strategy with the random-batch technique is adopted with a batch size of 512. The samplings and weights are updated once every 1,000 iterations. We train the model for 50,000 iterations with a learning rate of 50×10^{-4}.

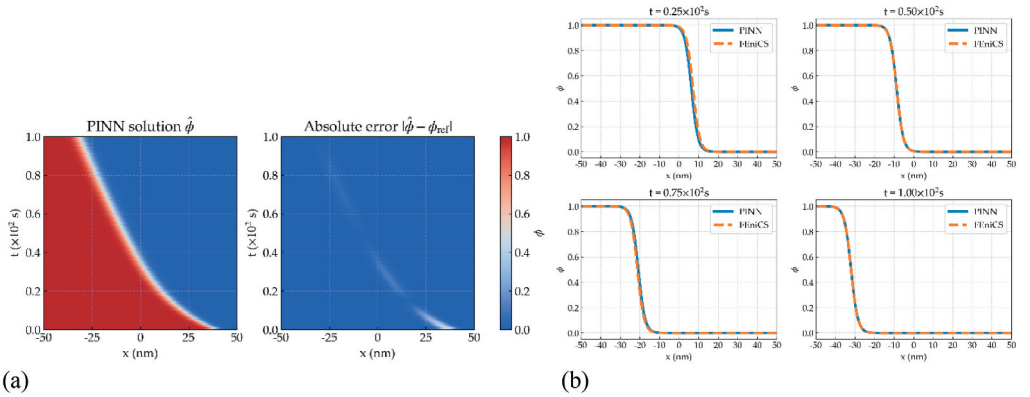

Figure 3. Evaluation of the baseline model for the one-dimensional diffusion-controlled corrosion problem: (a) The PINN solution $\hat{\phi}$ and absolute error $|\hat{\phi} - \phi_{\text{ref}}|$; (b) Time snapshots of the reference solution and the PINN solution.

The comparative solution obtained using the PINN and the reference solution is presented in Figure 3. Figure3a presents the distribution of PINN solution $\hat{\phi}$ and the absolute error $|\hat{\phi} - \phi_{\text{ref}}|$. The MSE value of the PINN solution is 8.769×10^{-4}, indicating the good performance of the PINN model on the overall accuracy across the entire spatiotemporal domain. Figure 3b demonstrates the agreement of the PINN solution and the reference solution at some specific moments.

3.2 *Two-dimensional diffusion-controlled corrosion*

In this case, the spatial domain is set to [–50, 50] × [0, 50] nm and the temporal domain ranges from 0 to 50 s. The initial and boundary conditions are depicted in Figure 2. At the initial moment, the center of the corrosion interface is positioned on a semicircle arc with a radius of 5 nm and a center of (0,0).

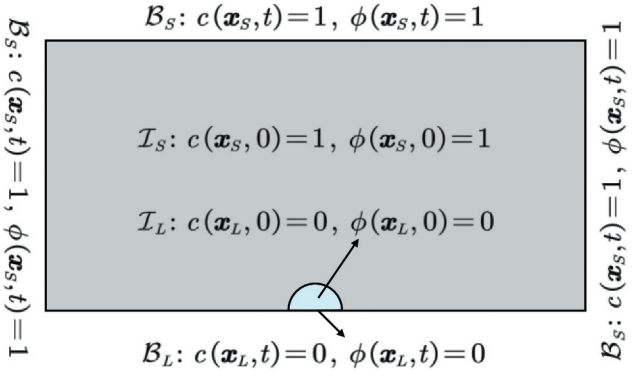

Figure 4. Schematic of the initial and boundary conditions for the two-dimensional diffusion-controlled corrosion problem.

In this model, we employ a neural network architecture consisting of 8 hidden layers, each containing 16 neurons. For the sampling process, we utilize 3375 common collocations, with 15 collocations allocated on each coordinate. The numbers of initial collocations and boundary collocations are set to 128 and 256, respectively. The residual criterion is employed to adaptively sample 8,000 points from a base set comprising a total of 60,000 points. For the weighting process, the NTK-based weighting strategy with the random-batch technique is adopted with a batch size of 512. The samplings and weights are updated once every 1,000 iterations. We train the model for 50,000 iterations with a learning rate of 1.0×10^{-3} and then continue training for another 50,000 iterations with a learning rate of 1.0×10^{-4}.

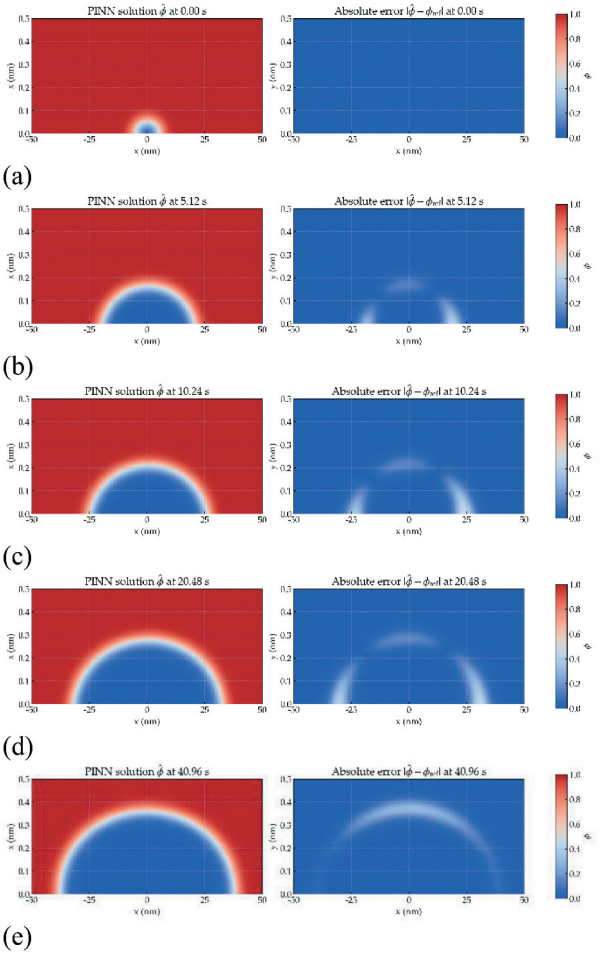

Figure 5. Time snapshots of the reference solution and the PINN solution. (a) t = 0.00 s; (b) t = 5.12 s; (c) t = 10.24 s; (d) t = 20.48 s; (e) t = 40.96 s.

Figure 5 presents the distributions of the PINN solution $\hat{\phi}$ and the absolute error $\left|\hat{\phi} - \phi_{\text{ref}}\right|$ at specific moments. The mean value of the mean squared error (MSE) at each moment is 6.658×10^{-4}, indicating the excellent performance of the PINN model in terms of overall accuracy across the entire spatiotemporal domain.

4 CONCLUSION

A new PINN framework (PC-PINN) is proposed to solve the phase-field model of pitting corrosion in real-world physical contexts. The PC-PINN model addresses the challenges posed by the high stiffness and sharp interface transition of the coupled Allen-Cahn and Cahn-Hilliard equations by incorporates adaptive strategies and techniques for weighting and sampling.

We successfully solve two representative phase-field pitting corrosion problems using the proposed framework. The obtained results clearly demonstrate the high accuracy of the PC-PINN model in predicting the evolution of the phase-field variable and the corrosion interface. This serves as a strong validation of the effectiveness of the PC-PINN framework.

Sensitivity analysis on the fatigue factors for fatigue reliability evaluation

M.Z. Mili, K. Sugiura, Y. Kitane & R. Matsumoto
Graduate School of Engineering, Kyoto University, Kyoto, Japan

ABSTRACT: This study focuses on fatigue reliability in steel bridges, a critical concern due to increasing traffic loads. Employing the *S-N* curve method, a Stochastic Sensitivity Analysis (SSA) is conducted to assess the impact of input parameters. Miner's rule and fracture mechanics are compared for fatigue assessment, considering uncertainties through stochastic sensitivity analysis. Material-related factors and the equivalent stress range are identified as pivotal contributors to fatigue reliability. The study emphasizes the importance of understanding influential parameters for improved design and predictive insights in structural behavior.

1 INTRODUCTION

Fatigue in steel bridges is a common issue caused by increasing traffic loads (Kala 2019, Kwon & Frangopol 2011, Ye et al. 2014). Repeated exposure to external loads is the root cause of this phenomenon, i.e., cyclic load, which can engender local or global failure of the structure. It is estimated that fatigue is the cause of 38% of steel bridges collapse (Kuzawa et al. 2018). In this context, there is growing interest in assessing and predicting the remaining fatigue life of components and structures.

Several studies and research focused on the evaluation and prediction of fatigue damage. Researchers employed two different approaches. The first method is Miner's linear damage rule, also known as Miner's rule or the *S-N* curve method. (e.g., Kwon & Frangopol 2011). It stipulates that fatigue damage accumulates linearly with the number of cycles experienced at a given stress level. The fatigue life of a material can be estimated by summing damage contributions from each load cycle, normalized by the material's fatigue strength at that stress level. The second one is the fracture mechanics approach. It is a crack-based method based on the Paris-Erdogan law. Here, the focus is on the crack initiation and propagation considering the stress intensity at the crack tip (e.g. Kala 2019a, b, Kwon &Frangopol 2011, Leander & Al-Emrani 2016). The *S-N* curve method is used for the fatigue design and life assessment of existing bridges. The fracture mechanics method is an effective way to evaluate fatigue life related to crack propagation, as well as for inspection and maintenance planning (Chryssantopolos & Righiniotis, 2006; Kwon & Frangopol, 2011).

Both methods involve parameters related to loads and materials, introducing significant uncertainties. Treating these parameters as deterministic entities does not account for their inherent and time-dependent variability. As a result, probabilistic approaches are adopted for fatigue evaluation (Kala 2019a, b, Leander & Al-Emrani 2016, Ye et al. 2014).

Whether conducting a fatigue assessment for structural design or predictive purposes, it is crucial to comprehend the influence of fatigue factors related to loads and materials on structural fatigue performance. Sensitivity Analyses (SA) are often conducted in engineering to assess the influence of the inputs on the outputs of a process or a system. To account for the uncertainties of inputs, researchers turn to Stochastic Sensitivity Analyses (SSA) (Kala 2019a, b, Leander & Al-Emrani 2016).

DOI: 10.1201/9781003483755-26

From a management perspective, identifying the influential parameters affecting fatigue reliability is crucial. This determination not only facilitates the enhancement of design but also enhances the predictive understanding of the structure's behavior across various scenarios (Pan et al. 2020). Leander & Al-Emrani (2016) and Kala (2019a, b) identified key factors crucial for fatigue assessment through the application of the fracture mechanics approach. In this paper, an SSA is conducted to evaluate important factors for the fatigue reliability of a steel bridge using the *S-N* curve method. The monitoring data throughout the service life is simulated and the statistical parameters of the fatigue factors are assumed based on the results and recommendations of previous research. Several SSA methods are compared in the determination of the influential fatigue factors quantitatively and qualitatively. In all cases, the material-related material factors and the equivalent stress range are found to be the most important factors.

2 FATIGUE RELIABILITY ANALYSIS

2.1 *Limit state function*

In the general case, the limit state function is given by Equation 1:

$$G(R, Q) = R - Q \tag{1}$$

where R is the resistance and Q is the load effect. This implies that if the resistance R is greater than the load Q ($G \geq 0$), the structure performs normally under the given load condition. However, if the load effect Q exceeds the structure's resistance ($G<0$), the safety of the structure is compromised. In the particular case of fatigue assessment based on the Miner's rule and the Japanese standards, the limit state function is written as follows (Kwon & Frangopol 2011, JRA 2012):

$$g(X) = \Delta - e\frac{N_{total}}{C_0}\left(SR_{eq}\right)^m \tag{2}$$

$$SR_{eq} = \left(\sum_{i=1}^{k} \frac{n_i}{N_{total}}.SR_i^m\right)^{1/m} \tag{3}$$

where Δ is the Miner's critical damage accumulation index, e is the error factor, N is the number of stress cycles, C_0 is the fatigue detail coefficient for each category, m is the slope of the *S-N* curve, SR_{eq} is the equivalent stress range given by Equation 3, n_i is the number of observations in the i^{th} predefined stress range bin SR_i, and N_{total} is the total number of recorded cycles up to the k^{th} range.

2.2 *The uncertainties of resistance factors* Δ, C_0, *and* m

Miner's rule assumes that the fraction of total fatigue life consumed by multiple stress cycles at a specific stress level is proportional to the overall number of cycles, with fatigue failure occurring when the sum of contributions from all stress ranges equals Δ (usually assumed equal to one). Experiments show that Miner's rule reasonably predicts fatigue life under random loadings, but its deterministic nature overlooks the scatter of fatigue experimental results. A more accurate description of fatigue failure considers that fatigue damage (D) exceeds the critical damage accumulation index Δ.

$$\sum_{i=1}^{k} \frac{n_i}{N_i} = D \geq \Delta \tag{4}$$

The fatigue tests employed to establish S-N curves are recognized for yielding scattered results even under identical loading conditions (Wirsching 1984, Wirsching et al. 1991). The S-N curves proposed by the design codes are lowered for the sake of safety. In other words, joints are more likely to endure more cycles than specified by the design code (Leander & Al-Emrani 2016). For

instance, studies indicate that a coefficient of variation of the fatigue detail C_0 ranges from 0.45 to 1.35, highlighting the significance of uncertainties in factors derived from S-N curves (Wirsching 1984, Wirsching et al. 1991, Kwon & Frangopol 2011). To address these uncertainties, C_0 is treated as a random variable. The slope of the *S-N* curve (m) is kept deterministic in this study as the material uncertainties in *S-N* curves are addressed through the fatigue detail coefficient C_0.

2.3 *The load factors*

Field monitoring data are crucial in the fatigue evaluation regardless of the adopted method. This data provides insight into the load condition of the structure. Using Hook's law and the rain-flow counting method, the monitored strain data provide the equivalent stress range bin histogram and the number of cycles, i.e. N, n_i, and N_{total}. In addition, this data is used to gain information on the variability of load volume and intensity over time when a long-term monitoring system is used (Kwon & Frangopol 2011).

2.4 *Error factor e*

The error factor permits accounting for modeling errors. The main source of error is the strain gauges (Kwon & Frangopol 2011, Wirsching 1984). These errors are revealed by the sensors' manufacturer or investigated by researchers. Frangopol et al. (2008) have reported that electrical strain gauges have an error margin of 1-4%. The coefficient of variation COV(e) ranges between 3-4% (Kwon & Frangopol 2011, Frangopol et al. 2008, Leander, Al-Emrani 2016).

2.5 *Fatigue reliability model FRM*

Figure 1 schematizes the fatigue reliability model used in this research. The statistical parameters of the average daily truck traffic ADTT and strain are obtained for the monitoring data. Using Hooke's law, strain is transformed into stress and the stress range bin histogram is established by rain-flow counting. The equivalent stress range is derived by Equation 3. The statistical parameters and the distribution type of the rest of the parameters are determined based on the previous studies (Wirsching 1984, Wirsching et al. 1991, Frangopol et al. 2008, Kwon & Frangopol 2011). The probability of failure P_f is the ratio between the number of times that failure occurs $S(G<0)$ and the total number of simulations (S). P_f is given by Equation 5 (Nowak & Collins 2013).

$$P_f = \frac{S(G<0)}{S_{Total}} \tag{5}$$

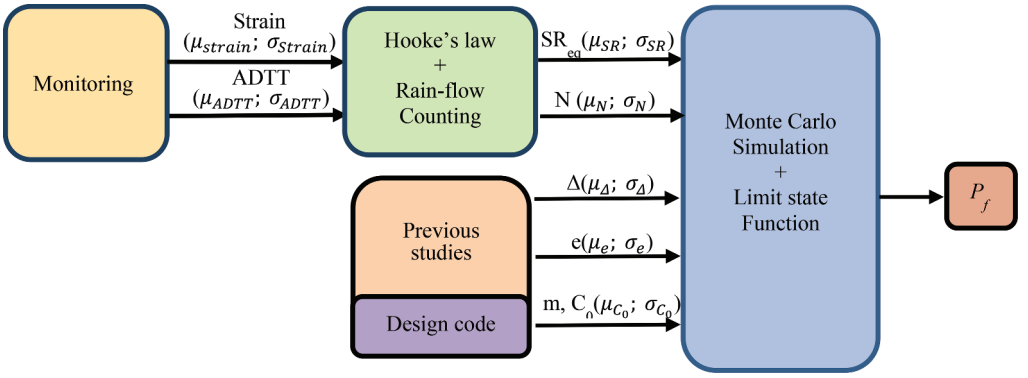

Figure 1. Scheme of the fatigue reliability analysis.

3 SENSITIVITY ANALYSIS

Many studies have looked into sensitivity methods, exploring how they work and where they can be used. Some examples include Borgonovoa & Plischke (2016), Pan et al. (2021), and Novák et al. (2017). Sensitivity methods are classified into two types: global and local sensitivity methods. A local sensitivity method assesses how sensitive a system or model is to changes in its input variables at a specific point or region. Instead of examining the overall impact across the entire system, it focuses on understanding the influence of variations in input parameters near a particular condition or scenario. A global sensitivity checks additionally how input variables interact with each other across the whole system. The Sobol indices method is a well-developed tool to analyze sensitivity. However, the calculation of the Sobol indices with the Monte Carlo method is still quite demanding in terms of computational effort (Pan et al. 2021). In addition, Pan et al. (2021) proved through examples that the local sensitivity methods, that is the local analysis of variation, present a good agreement with the results of Sobol indices method. Considering the scope of this study and the computational constraint, the following local sensitivity methods are considered.

3.1 *The local perturbation method*

The local perturbation method also called the one-at-a-time (OAT) method is a straightforward sensitivity analysis approach. It involves changing one input variable at a time while keeping others constant and observing the resulting impact on the model's output. This method provides a quick and practical way to understand the influence of individual factors on the overall system response (Pan et al. 2021, Borgonovoa & Plischke 2016).

3.2 *Local analysis of variation*

This method aims to assess the influence of the variance of a given input variable on the variance of the system. This consists on calculating the variance of the model response while setting the i^{th} variable at its mean and all the other variables free to vary. The sensitivity indicator S_i is given by Equation 6 (Pan et al. 2021).

$$S_i = 1 - \frac{CoV_i}{CoV_{original}} \tag{6}$$

Here CoV_i is the standard deviation of the response if the i^{th} input is fixed at the mean and $CoV_{original}$ is the standard deviation of the response when all the random variables are free to vary. A value of S_i close to 1 indicates that the variability of the system is generated essentially by the i^{th} variable.

3.3 *The omission sensitivity factor*

The omission sensitivity analysis was presented by Madsen (1988), and used by Lander & Al-Emrani (2016) in their fatigue sensitivity analysis based on fracture mechanics. The omission Sensitivity Factor is defined as the ratio between the output of a system or mathematical model (i.e. the probability of failure or the reliability index) when all the random variables are free to vary and the response when the i^{th} is set at its mean as denoted by Equation 7.

$$O_i = \frac{F_{original}}{F_{Xi}} \tag{7}$$

Here F_{Xi} is the response when X_i is set at its mean and $F_{original}$ is the response when all the random variables are free to vary. A value near 1 suggests that the random variable can be effectively set to its mean, indicating minimal impact on the output. Conversely, the interpretation of O_i values varies depending on the type of response. For example, the significance of

these factors changes based on whether the response relates to the reliability index or the probability of failure.

3.4 *The correlation coefficient*

The correlation coefficient (ρ), also called Pearson correlation coefficient, indicates the degree of linear dependence between two random variables (Novak & Collins 2013). In the context of sensitivity analysis, the correlation coefficient has been used to measure the relative effect of each basic random variable on the structural response (Iooss & Lemaître 2015, Novák et al. 2017). With values ranging between 1 and -1, the correlation matrix provides an intuitive insight on the relation between the response and the input random variables. This is a straightforward and uncomplicated method that demands no additional computational effort, particularly when employing Monte Carlo simulations (Novák et al. 2017).

4 SIMULATION PROCESS AND SENSITIVITY ANALYSIS

4.1 *Modeling assumption and initial values*

In this study, the monitoring data throughout the service life (i.e. strain data and ADTT) is simulated by assuming their initial statistical parameters. It is assumed that the yearly increase of traffic volume and the traffic load (GVW) are 3% and 1% respectively. The relative variability of the strain and the average daily traffic is kept constant during the service life. Young's modulus and the slope of the *S-N* curve *m* are considered as deterministic. The values of the deterministic inputs are summarized in Table 1.

Table 1. The initial values of deterministic inputs.

Deterministic inputs	Value
Service life (years)	50
e_t	3%
e_{Strain}	1%
Number of samples (MC simulation)	500 000
Young's Modulus (GPa)	210
Joint category	D
m	3

In this study, the coefficient of variation (CoV) is considered for the random variable instead of the standard deviation for two reasons. Firstly, CoV is advantageous for variables with diverse units or scales. Normalizing variability relative to the mean and providing a standardized, percentage-based measure that facilitates meaningful comparisons independently of specific units or scales. Furthermore, assessing the variation of a random variable using its Coefficient of Variation becomes more rational, especially when the variable follows a skewed distribution, such as a lognormal distribution in this context.

The statistical parameters of all random variables are derived from previous studies. It is assumed that all the input random variables are uncorrelated. The details of the input variables are summarized in Table 2.

Regarding ADTT and strain, the references mentioned in Table 2 provides the CoV. The means were considered in a subjective manner. As for C_0, it was calculated using Equation 8 in accordance with Japanese standards (JRA 2012).

$$C_0 = 2 \times 10^6 \times \Delta SR^m_{allow} \tag{8}$$

Table 2. Statistical parameters of random variables.

Random variable	Distribution	Mean	CoV	Source
ADTT (truck/day)	Normal	1000	10%	Nowak & Collins 2013
Strain	Normal	0.0012	10%	Fu et al. 2022
Δ	Lognormal	1.0	30%	Wirsching 1984, Kwon & Frangopol 2011
Error	Lognormal	1.0	3%	Wirsching 1984, Frangopol et al. 2008, Kwon & Frangopol 2011, Leander & Al-Emrani 2016
C_0 (Detail D)	Lognormal	2E+13	45%	Wirching 1984, Wirsching et al. 1991, JRA 2012

Here ΔSR_{allow} is the basic allowable stress range for each category. The mean was computed utilizing the bias factor introduced by Wirsching (1984) and Wirsching et al. (1991). These references have also identified that the Coefficient of Variation (CoV) for the fatigue coefficient C_0 ranges from 0.45 to 1.35. In this study, the minimum value within this range was assumed. The same value was adopted by Kwon & Frangopol (2011) in their corresponding study.

4.2 *Sensitivity analysis*

The initial values and the statistical parameters depicted in Table 1 and Table 2 represent the reference scenario of this study. The probability of failure is computed using the Monte Carlo simulation and Equations 2 and 5. The sensitivity analysis is performed at the end of the service life (year 50). The initial probability of failure, hereafter referred to as $P_{foriginal}$, is found equal to 0.0204. The CoV of the output variable, i.e. G, equals to 50.4%.

4.2.1 *The input perturbation sensitivity analysis*

The mean of each input random variable is first increased by 10% and then lowered by 10%. The effect of such a variation on the probability of failure P_f is calculated and compared to $P_{foriginal}$. It was observed that SR_{eq} exerts the most significant influence on the probability of failure. This observation can be mathematically explained by the fact that SR_{eq} is raised to the power of m (where m=3). The second and the third important parameters are respectively Δ and C_0. The results of the input perturbation sensitivity analysis are presented in Figure 2.

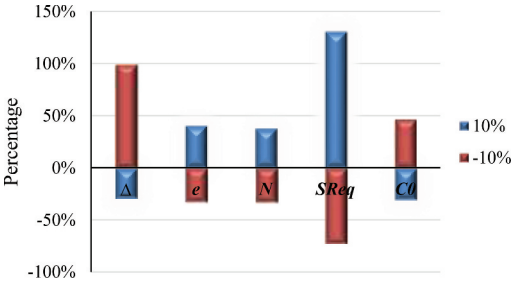

Figure 2. Results of the input perturbation SA.

4.2.2 *Local analysis of variation sensitivity analysis*

The sign of S_i signifies that when the associated random variable is set to its mean value, there is a reduction in output variability for positive values, and an increase in variability for negative values. Therefore, sensitivity is assessed based on the absolute values S_i. The outcomes of this sensitivity analysis presented in Table 3 reveal that the most influential input variables are Δ, C_0, and $SReq$.

Table 3. Local analysis of variation outcomes.

	S_i	Rank
Δ	0.462	1
e	0.001	5
N	0.004	4
$SReq$	0.108	3
C_0	-0.307	2

4.2.3 *The omission sensitivity factor*

When the response is the probability of failure, O_i values greater than 1 suggest that reducing uncertainties associated with the i^{th} variable leads to a decrease in the probability of failure. Conversely, values lower than 1 indicate that replacing the i^{th} variable with its mean value raises the probability of failure, and maintaining uncertainties in this variable contributes to improving the structural performance. According to this sensitivity indicator, SR_{eq} is identified as the parameter exerting the most significant influence on the probability of failure, followed by Δ and C_0. Similarly, consistent with previous methods, the number of cycles and the error factor exhibit an insignificant impact on the probability of failure. The results are shown in Table 4.

Table 4. Omission sensitivity factor.

	O_i	Rank
Δ	2.22	1
e	1.02	5
N	1.01	4
$SReq$	3.90	2
C_0	0.40	3

4.2.4 *The correlation coefficient matrix*

The correlation coefficients are presented in Table 5. Positive values indicate the random variable enhances the response, reducing the failure probability, while negative values imply a decrease in the response, elevating the failure probability. Notably, it is observed that ρ is positive for material-related parameters, such as Δ and C_0, and negative for the other parameters. The most important parameter here is Δ followed by SR_{eq} and C_0.

Table 5. The correlation coefficients.

	G	Δ	e	N	$SReq$	C_0
G	1	0.899	-0.021	-0.027	-0.281	0.251
Δ	0.899	1	-0.001	0.001	0.001	-0.001
e	-0.021	-0.001	1	-0.002	-0.001	0.000
N	-0.027	0.001	-0.002	1	0.001	0.001
$SReq$	-0.281	0.001	-0.001	0.001	1	-0.001
C_0	0.251	-0.001	0.000	0.001	-0.001	1

5 DISCUSSION AND CONCLUSION

A probability-based sensitivity analysis of fatigue reliability was undertaken, employing the *S-N* curve method for evaluating and predicting fatigue damage. Various sensitivity analysis methods were applied to assess the sensitivity of input parameters. Each method measured the significance of the input parameters and established a ranking, which is presented in Table 6.

Based on the results, it has been established that the material-related variables and the stress factor are of utmost importance. In simpler terms, an increase in traffic volume (N) has a lesser impact on the bridge than an increase in load spectrum (SR_{eq}). Additionally, it can be

Table 6. The sensitivity ranking of the input variables with different SA methods.

	Input perturbation	Local analysis of variation	The omission sensitivity factor	The correlation coefficient
Δ	2	1	1	1
e	4	5	5	5
N	5	4	4	4
$SReq$	1	3	2	2
C_0	3	2	3	3

deduced that the accuracy of sensors in the context of fatigue assessment does not significantly impact the evaluation of fatigue life. This aligns with the conclusions drawn by Kala (2019a, b) and Leander & Al-Emrani (2016), despite the different fatigue reliability assessment methods employed in the two studies, namely the fracture mechanics method.

It is also noted that the outcomes of sensitivity analysis are method-dependent, potentially leading to misleading estimations of the most critical parameters. Pan et al. (2021) proved, through various examples, that different sensitivity analysis methods can diverge in identifying the most influential parameter. This discrepancy is attributed to the unique characteristics inherent in each sensitivity analysis method.

However, these methods are simpler and more straightforward to implement compared to the well-developed Sobol indices method. Depending on the objectives of the sensitivity analysis, these methods can provide sufficient insights into the crucial parameters for a given model, offering a convenient initial assessment.

Structural analysis of dapped-end beams through machine learning techniques

V. Picciano, G. Santarsiero, A. Masi & A. Digrisolo
School of Engineering, University of Basilicata, Potenza, Italy

ABSTRACT: Dapped-end beams (or half-joints) are extensively used in both reinforced concrete bridge structures and roofs and flooring for prefabricated buildings. Due to their geometric configuration, they represent discontinuity regions where high stresses concentrate. Therefore, it is crucial to evaluate the load-bearing capacity of these elements which may depend on various parameters, such as the strength of materials, the quantity and the different layouts of the used reinforcements which also significantly influence their failure mode. For this purpose, a literature review led to the creation of an experimental tests database used to conduct an in-depth statistical analysis, considering the influence of various parameters on the ultimate load capacity and failure mode of dapped-end beams. The collected database has been also used to train a regression model with supervised machine learning techniques in order to predict the ultimate capacity of dapped-end beams.

1 INTRODUCTION

Dapped-end beams have some advantages related to construction speed as connections are represented by half-joints (Figure 1) which facilitate the installation operations. In bridge structures, dapped-end beams are used as part of the cantilever bridges (also called Gerber bridges) for their capability of absorbing small settlements along with a convenient stress distribution. Geometrical details of dapped-end regions make them disturbed regions in which the Bernoulli theory cannot be applied to evaluate stresses and carry out the due safety checks, requiring purposely set-up assessment methods.

In fact, the load-bearing capacity of dapped-end beams can be assessed through different analytical and numerical methods. For example, strut-and-tie models (Mattock 2012, EN 1992-2 2005), eventually accounting for deterioration (Desnerck et al. 2018), are among the lower-bound methods, capable of providing conservative assessments.

The strut-and-tie method (STM) is based on the definition of a truss model that must be consistent with the behavior of dapped-ends observed during experiments in order to idealize the force flow in the recessed part of the beam end. STM trusses that better approximate the force flow in a structural component allow the design of an efficient reinforcement layout increasing the specific failure load and minimizing the occurrence of cracks under the service loads (Mattock 2012). Eurocode 2 (EN 1992-2 2005) provides two alternative models and related reinforcement layouts (one considering only horizontal and vertical bars while the other accounts for the inclined reinforcement also) which can be combined to evaluate to overall strength of a half-joint.

A design method is also reported in the PCI Design Handbook (2010) mainly devoted to precast elements belonging to buildings. This method is based on an experimental investigation in which several potential failure modes were highlighted. In particular, the safety checks of different reinforcement devices are made concerning five specific possible failure modes which can affect both the undapped and the dapped regions of the half-joint. The PCI method has some limitations compared to STM since does not consider inclined rebars and is valid for cases where the shear

DOI: 10.1201/9781003483755-27

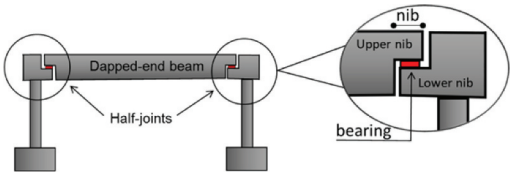

Figure 1. Typical dapped-end beam and half-joint detail.

span-to-depth ratio does not exceed 1.0. For these reasons, it is hardly helpful in the assessment of existing dapped-end elements.

Besides STM and PCI methods, kinematic methods can be used to predict the peak strength of half-joints. These methods assume that the failure mode is governed by the opening of a crack according to a selected pattern (e.g. diagonal cracking starting from the re-entrant corner) and impose that the static equilibrium is guaranteed by the steel crossing it. For example, the model proposed by Rajapakse et al. (2021) is based on the knowledge of the crack angle developing from the re-entrant corner assuming that the failure is governed by flexure stress. Moreover, the model considers the crack width as well as the amount of dapped-end reinforcement, along with the crack length and the rotation about the crack tip. This model was applied to a database of 47 experimental tests providing good prediction results compared to actual values.

A further option to assess the capacity of half-joints is represented by numerical methods consisting of refined finite element models based on nonlinear fracture mechanics (Bazant & Oh 1983). Moreover, there are modelling procedures which can explicitly account for corrosion propagation inside the member during a given period, allowing to perform durability analyses (Santarsiero et al. 2021).

In order to deepen the structural behaviour of dapped-end beams, this study describes a literature review on experimental tests of such elements, leading to the construction of a database of 210 specimens. Following a brief description of the half-joints' typical details and failure modes, a statistical analysis of the main collected parameters was conducted to observe their variability and highlight correlations, such as those between specific failure modes and certain reinforcement layouts. Finally, the database was used to train different regression models using supervised machine learning techniques to predict the ultimate strength of the specimens. These techniques helped identify the best-performing regression model that can be employed to quickly assess dapped-end beams.

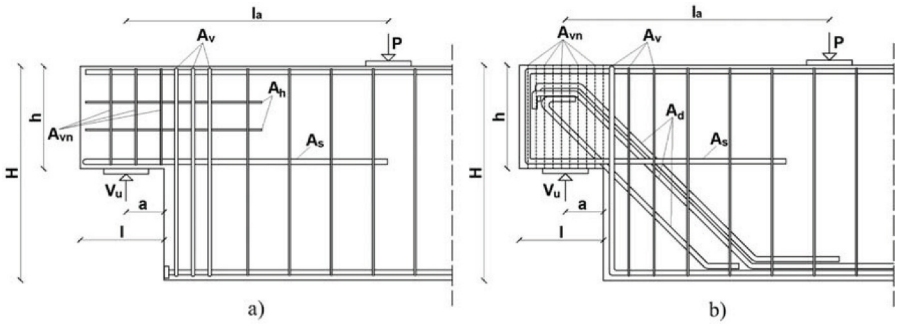

Figure 2. Different half-joint reinforcement layouts a) involving only vertical and horizontal reinforcement and b) also with inclined ones.

2 TYPICAL DETAILS AND FAILURE MODES

Due to their geometry, half-joints represent a discontinuity zone from the perspective of stress distribution, and, as previously illustrated, they require specific design and assessment methods. From a construction detailing point of view also, they represent singular elements

since the arrangement of reinforcements necessary for external load absorption can vary. In particular, considering both the upper and lower nib (Figure 1) as statically equivalent, the two most commonly used reinforcement layouts are illustrated in Figure 2.

Figure 2a illustrates a reinforcement layout mainly related to building structures, where only vertical and horizontal rebars are used. In this case, the absorption of external vertical forces occurs through the formation of an inclined concrete strut in the nib, which, for equilibrium purposes, requires the presence of a vertical tie, represented by the vertical stirrups A_v, and a horizontal tie through the presence of the A_s reinforcements, to which the contribution of horizontal secondary reinforcements A_h can be added, arranged within the nib as illustrated. The nib vertical stirrups A_{vn} have the purpose of confining the inclined concrete strut, thereby increasing its resistance and ductility. Therefore, the reinforcements form a truss mechanism, allowing for the absorption of external loads.

The alternative layout depicted in Figure 2b also involves the presence of inclined reinforcements A_d, providing an additional contribution to the truss mechanism. In particular, this second type of reinforcement layout is widely used within the Gerber saddles of existing bridges, especially in Europe. Inclined reinforcements, besides enhancing the overall half-joint's strength (Desnerck et al. 2016), also limit re-entrant corner cracking under service loads thus limiting the ingress of polluting agents such as chlorides, which can cause reinforcement corrosion (Santarsiero & Picciano 2023).

As for the dapped-end's ultimate behaviour, it is worth emphasizing that there can be different collapse modes depending on the adopted reinforcement layout. In particular, according to the PCI Design Handbook (2010), five potential failure modes are observed in half-joints under vertical loads (Figure 3). Mode 1 involves nib vertical cracking due to flexure and axial tension; mode 2 results from direct shear at the junction of the nib and the undapped region; mode 3 is caused by re-entrant corner diagonal tension; mode 4 represents nib shear failure, and mode 5 is due to diagonal tension in the undapped portion.

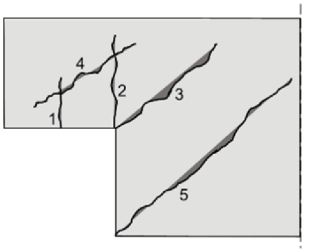

Figure 3. Possible half-joint failure modes according to the PCI Design Handbook (2010).

3 EXPERIMENTAL CAMPAIGNS AND DATABASE COLLECTION

In order to characterize the typical detailing, the failure modes and structural performances, a review of experimental research on half-joints has been conducted and partially illustrated in Santarsiero et al. (2023). This review activity allowed the collection of 147 experimental tests on dapped-end beams which have been recently updated to a total of 210, gathering information from 22 different research projects in the literature, briefly described in the following, for which several parameters were recorded. In particular, the amount and yielding stress of steel reinforcement at any position (stirrups, main vertical and horizontal, inclined) was annotated as well as the detailed geometry, concrete grade and, finally, the load test scheme along with the experimental peak load and failure type obtained during the test.

Mattock & Chan (1979) tested 8 dapped-end beam specimens all provided with the same geometry and different amounts of reinforcement in the vertical and horizontal direction along the re-entrant corner. In Kumaraguru (1992), 12 dapped-end beams were tested to find the capacity of the nibs for different locations of the support reaction and therefore with

different values of the shear span-to-depth ratio. Lu et al. (2003) conducted an experimental program to study the behaviour of high-strength concrete dapped-end beams testing 12 specimens with the same geometry and different detailing and concrete strength. The effect of different amounts of principal horizontal and vertical reinforcement, the shear span-to-depth ratio and the concrete strength on the specimens' shear capacity was analysed by Lin et al. (2003) testing 24 high-strength concrete dapped-end beams. Tests on 18 dapped-end specimens were selected from Wang et al. (2005). In this paper, the specimens' resistance was investigated as a function of dapped-end height, the reinforcement layout, in particular related to the presence of inclined rebars which is found to influence the load-bearing capacity. Taher (2005) experimentally tested 3 specimens having identical geometry but different detailing. They were used as control specimens in an experimental campaign devoted to testing various strengthening techniques. 7 specimens were selected from Herzinger (2008) that investigated the efficiency of studs with single or double heads for reinforcing the dapped-ends. This latter prevents premature failure caused by inadequate anchorage of conventional reinforcement and an experimental campaign was set up in order to make a comparison with the behaviour of conventionally reinforced dapped-end beams. Lu et al. (2012) tested 24 specimens having different geometry, concrete grades and amount of reinforcement in order to find the influence of these parameters on the load capacity and failure mode. Ahmad et al. (2013) tested 4 reinforced concrete dapped-end beams divided into two groups with different depth values. The research aimed to investigate the effectiveness of STM in predicting the failure load finding that, in the case of lower depth dapped-end beams, unconservative solutions were obtained. Moreno-Martínez & Meli (2014) conducted a research program to evaluate the performance of a dapped-end solution for a railway bridge with respect to both service and ultimate loads, to explore solutions that can enhance the component's performance. The study conducted by Mata-Falcón (2015) provides a set of 60 tests on dapped-ends (among which 8 have been selected for the database), corresponding to 30 different configurations in which parameters such as the amount and layout of reinforcement were studied. Lu et al. (2015) investigated the shear strength of 24 reinforced concrete dapped-end beams with shear span-to-depth ratios larger than unity. Aswin et al. (2015) experimentally investigated the shear response of 4 large-scale RC dapped-end specimens to find out the influence of the amount of nib reinforcements, the main flexural reinforcements, and concrete type at the dapped-end area. Atta & Taman (2016) studied the effectiveness of strengthening systems applied to dapped-end beams. Therefore, they also tested a control specimen. Desnerck et al. (2016) studied the behaviour of 4 half-joint specimens to find out the effect of local reductions in reinforcing bars and cracking in the anchorage zone on the load-bearing capacity. Desnerck et al. (2018) studied the tuning of STMs for deteriorated RC half-joints through an experimental campaign. 2 specimens out of 12 were used as control specimens and were included in this database. Hussain & Shakir (2019) tested several dapped-end specimens two of which are collected in the database. The study aimed to find the effect of repeated loads and the influence of increased shear span-to-depth ratio. Mata-Falcón et al. (2019) proposed simplified strut-and-tie models which were experimentally validated through static tests on 15 dapped-end beam specimens. The database also considered 24 dapped-end beams among the 27 specimens experimentally tested by Mohamed et al. (2020). They investigated the effect of a shear span-to-depth ratio larger than 1.0 finding that the PCI approach for the evaluation gave an underestimation with respect to experimental capacity values. The study conducted by Rajapakse et al. (2022) involved the execution of 8 large-scale dapped-end tests to investigate the influence of the amount of reinforcement in terms of the ratio of dapped-end horizontal to vertical reinforcement area. This variable was correlated with the dapped-end's resistance, crack control, and rotation capacity. Di Carlo et al. (2023a,b) investigated the impact of reinforcement corrosion on the strength and failure mode through the implementation of an experimental campaign on dapped-end beams, of which 4 control specimens have been selected for this database.

In summary, most of the experimental research programs here investigated are devoted to analysing the effect of different shear span-to-depth ratios, alternative reinforcement layouts and amounts as well as the influence of concrete grades adopted. Therefore, the database has a wide variability of governing parameters to allow an in-depth statistical analysis.

First of all, a brief overview of the collected parameters' variability is illustrated. In particular, referring to the geometric scheme depicted in Figure 2, Table 1 reports the minimum, maximum and mean values also with the standard deviation of the main specimens' geometric features, namely the dapped-end's width b, the ratio between the nib depth and the full beam depth h/H, the nib length-to-nib depth ratio l/h, the shear span-to-depth ratio a/h and the lever arm adopted during the experimental test in terms of l_a/H ratio.

Furthermore, over 60% of the specimens exhibit a full depth exceeding 500 mm, a share of 25% less than 500 mm and upper than 250 mm, and only 13% have a lower depth. As indicated by the mean value in Table 1, the majority of specimens have an a/h ratio below 1, while only 9% fall into the category where it exceeds unity. Turning to the strength characteristics of the specimens, the variability in both concrete and steel strength was analysed. Specifically, most of the specimens exhibit a mean value of cylindrical concrete compressive strength exceeding 20 MPa, and a share of 45% is classified as high-strength concrete specimens with $f_c > 40$ MPa. The steel used for tested dapped-ends has different grades for horizontal, vertical and stirrup rebars. Considering the average strength value among the different grades used for each specimen, more than 50% of them have a rather low yielding strength ($f_{ym} < 320$ MPa), 40% have $320 < f_{ym} \leq 450$ MPa and only 8% have a yielding strength upper than 450 MPa.

Regarding the failure mode, in 204 out of 210 tests included in the database, it was possible to attribute the collapse mode to one of the 5 types indicated in the PCI Design Handbook (2010) or a combination of them. Considering that only 36 tests are provided with inclined reinforcements, while 168 present only vertical and horizontal rebars, it has been observed that in the former case, the most frequent failure mode (30%) is associated with a combination of modes 3 and 4 (Figure 3), followed by mode 5 (22%) and mode 3 (13.9%), while pure mode 4 is almost absent. In the absence of inclined reinforcements, the tested dapped-ends mostly failed through modes 3 and 4 or a combination of them. Therefore, the presence of inclined reinforcements seems to prevent failure mode 4 related to shear stresses in the nib.

Table 1. Boundary range of the specimens' geometric features.

Parameter	Min	Max	Mean	St.dev
b (mm)	120	1000	208.9	99.2
h/H (-)	0.43	0.77	0.53	0.07
l/h (-)	0.46	2.50	1.20	0.47
a/h (-)	0.13	1.33	0.59	0.27
l_a/H (-)	0.64	3.79	1.32	0.64

4 DATABASE ANALYSIS AND DISCUSSION

Data from individual experimental tests were employed to train a Machine Learning algorithm aimed at predicting the load-bearing capacity of any half-joint. In fact, supervised learning techniques take a known set of input data (the training set) and known responses to the data (output), and train a model to generate reasonable predictions employing new input data. These techniques are widely used in the field of civil engineering, particularly to predict specific responses, representing a reliable alternative to analytical models based on the use of a few control parameters that may not be representative of the whole studied phenomenon (Koya et al. 2022).

In this case, supervised learning techniques were employed to train a regression algorithm based on information from 210 literature experimental tests on dapped-ends. The input data are geometric and mechanical parameters, as well as construction details in terms of reinforcement layouts and amount. The output data consisted of the ultimate strength of each test.

Figure 4 provides a detailed illustration of the input and output parameters used for model training. Specifically, 10 input parameters were considered, involving geometric parameters

such as dapped-end width b, nib depth h, full beam depth H and shear span a. Regarding mechanical parameters and construction details, concrete strength f_c was taken into account, along with the strength's contributions of each reinforcement layout. This involved the product of the reinforcement area and the average yielding strength of the corresponding steel rebars. Therefore, referring to the scheme in Figure 2, the strength associated with the main horizontal bars is calculated as $R_s = A_s \cdot f_{ym,s}$, the contribution of the main vertical stirrups is $R_v = A_v \cdot f_{ym,v}$, the inclined reinforcements contribute $R_d = A_d \cdot f_{ym,d}$, and finally, the contribution of secondary horizontal and vertical stirrups in the nib are determined as $R_h = A_h \cdot f_{ym,h}$ and $R_{vn} = A_{vn} \cdot f_{ym,vn}$, respectively.

The training of the predictive algorithm was carried out using the MATLAB software (The MathWorks Inc. 2023a), specifically through the Statistics and Machine Learning Toolbox (The MathWorks Inc. 2023b). This toolbox allows for the utilization of the Regression Learner App, which interactively trains, validates, and tunes regression models.

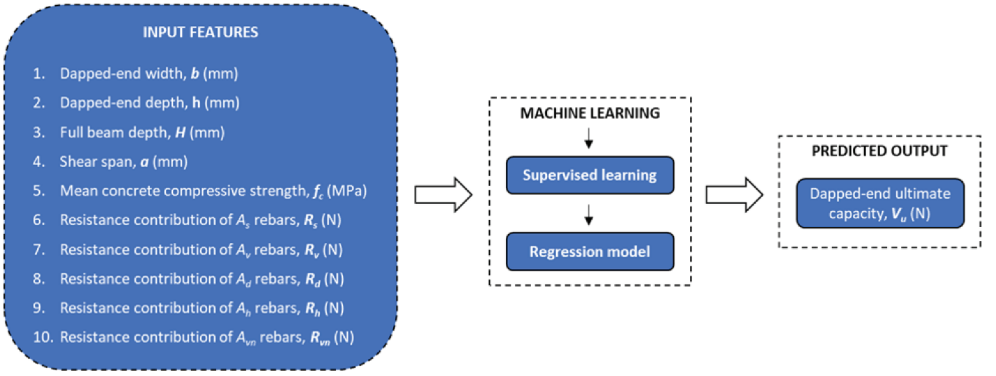

Figure 4. Adopted input and output variables for predicting the dapped-end ultimate capacity with machine learning algorithms.

The entire database of 210 observations was divided into a training set containing 80% of the samples (168 samples) and a test set comprising the remaining 20% (42 samples). This operation was performed automatically within the application to randomly partition the database based on the provided size. This latter ensures the random selection of observations used for the test dataset and avoids any bias introduced by manual selection.

The training set represents the data on which the regression model is trained, while the test set is used to check the accuracy of predictions and other statistical measures, aiming to prevent inaccurate results due to overfitting of data.

The Regression Learner App allowed for training and evaluating the predictive capability of different regression models, including Linear Regression, Nonlinear Regression, Gaussian Process Regression Model, SVM Regression, Generalized Linear Model, and Regression Tree. In order to identify the model with the best predictive capacity, the coefficient of determination R^2 was employed as a performance indicator. It can be calculated as follows:

$$R^2 = 1 - \frac{\sum_{i=1}^{N} \left[V_{upredicted} - V_{uexperimental}\right]^2}{\sum_{i=1}^{N} \left[V_{upredicted} - \overline{V_{uexperimental}}\right]^2} \quad (1)$$

Based on this performance indicator, the regression model with the best predictive capability is the Rational Quadratic Gaussian Process Regression (GPR), which exhibited an R^2 value of 0.984 for the test dataset and a value of 0.958 for the training set.

In particular, the GPR model represents a nonparametric regression method designed to accommodate more complex regression curves without specifying the relationship between the response and the predictors through a predetermined regression function (Rasmussen & Williams 2006). Figure 5 shows the results of the trained model in terms of comparison between

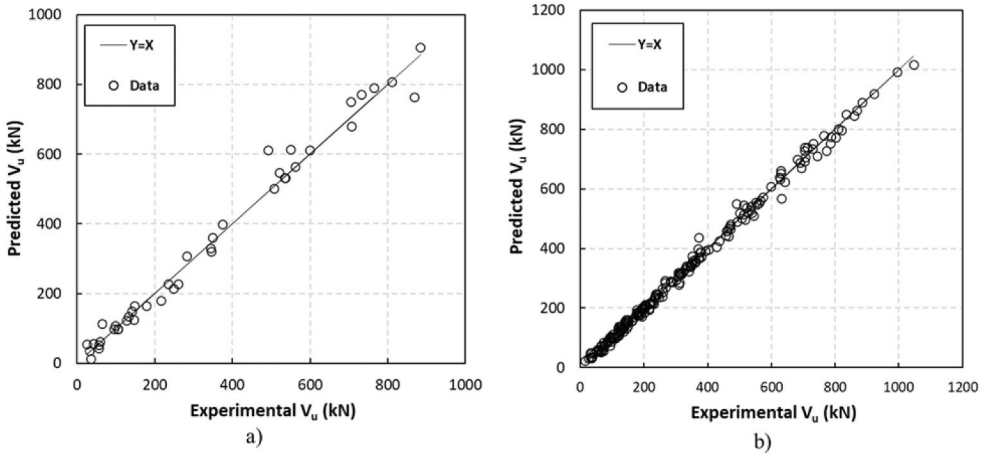

Figure 5. Comparison of the experimental and predicted dapped-end ultimate capacity a) for the test dataset only and b) considering all data.

the experimental values of dapped-end ultimate capacity and the predicted ones, considering only the test dataset (Figure 5a) as well as the prediction obtained based on the entire dataset of 210 specimens (Figure 5b). Although the trained model has shown a rather high value of the performance indicator R^2, it is worth highlighting that the accuracy of the model depends on the size of the dataset. On the other hand, this study has shown a rapid method which can be useful to obtain an accurate response for purposes such as condition assessment and preventive retrofitting measures for existing half-joints.

To make the predictive model available, a repository (https://github.com/Picciano-unibas/ML_HalfJoints) has been created, which includes the MATLAB code. This code can be used to retrain the model based on a new database, structured as illustrated in this study. Additionally, a "struct" array is included in the repository, containing the trained model, which can be employed to make predictions with new input data.

5 CONCLUSIONS

This paper is aimed at studying the half-joints' structural behaviour through the collection of a series of experimental results by various authors, allowing to building of a database including more than 200 tests. From each test, the main specimens' features were taken such as geometrical data, material properties related to concrete and reinforcing steel as well as regarding the amount and layout of reinforcement. These properties were represented by ten variables whose influence on the ultimate resistance of the half-joints was investigated through machine learning algorithms. These latter were aimed at predicting the load-bearing capacity of the half-joints considered in this study. The best performing algorithm was found to be the Rational Quadratic Gaussian Process Regression (GPR), which gave a high correlation between experimental and predicted strength values over both the test set and the entire dataset. The trained algorithm is freely available through a public repository and can be used for the preliminary assessment of reinforced concrete half-joints. In the future, ML classification algorithms will be used to predict the failure mode and ductility features of half-joints to provide a comprehensive analysis tool.

S. Ólafsson & R. Rupakhety
Earthquake Engineering Research Centre, University of Iceland, Selfoss, Iceland

ABSTRACT: Various types of models of a lead core rubber bearing are discussed in this contribution. This includes an analytical model defining the overall behavior of the isolator and a finite element model in which constitutive relations are formulated for the constituencies (rubber, lead, and steel). The models are being developed for implementation in the finite element model of a seismically protected structure. The presented ongoing study aims to simulate the dynamic response of a base-isolated bridge during a strong ground motion. On the one hand, the focus is on the LRB model, and the bridge structure is being described with relatively few details. On the other hand, both the analytical and the finite element models are to be implemented in the finite element model of the bridge. Comparison of the dynamic response of the bridge obtained with the LRB models will enable the assessment of the analytical model validity domain.

1 INTRODUCTION

Lead core Rubber Bearings (LRBs) are frequently used devices for seismic isolation. Compared to other types of seismic isolators, such as friction-pendulum systems, they reportedly possess higher energy dissipation capacity, which makes them a preferred option for structures like hospitals, nuclear power plants, and bridges.

The main goal of their implementation is to decouple the superstructure from the ground, thus reducing the damage induced during an earthquake event. Seismic isolation is expected to minimize accelerations, velocities, and displacements in the isolated structure. Also, forces developed in structural elements are expected to be smaller due to the seismic isolation; this reduces the demand and leads to a more efficient design, at least for earthquake scenarios. More generally, limiting displacement amplitudes minimizes the probability of damage to vibration-sensitive equipment.

It is widely accepted that the accurate assessment of the dynamic response of structures during a strong ground motion is a prerequisite for a safe and efficient design. If the seismic isolation of a large structure is to be assessed, it might seem mandatory to simplify the analysis procedures as much as possible. In line with this, one may choose models proven not to be extremely computationally demanding. Further in the text, such models are referred to as 'light' models. However, to assess their adequacy, a comparison with the provided output may be required. Such model validation can be performed by using either empirical data obtained via monitoring of the behavior of an instrumented bridge during a strong ground motion or by using numerical data acquired in the analysis of a structure containing a detailed model of the bearing device. Herein and further in the text, finite element models are referred to as 'detailed' models.

The contribution outlines some aspects of an ongoing study in which both 'light' and 'detailed' models of an LRB are being developed with the aim of being used in the numerical analysis of the dynamic behavior of a seismically isolated structure.

DOI: 10.1201/9781003483755-28

The LRB analytical models have been developed since the first implementation of the device in New Zealand. A number of research works have contributed to a better understanding of the global dynamic response of the LRB (see, among others, Robinson 1982, Kalpakidis & Constantinou 2009a, b, Kumar et al.2014, Eem & Hahm 2019, Liu et al. 2021). Some earlier theories still find their application (Bouc 1967, Wen 1976).

The 'detailed' models appear as an alternative. Instead of defining the global response of the LRB, constitutive relations are formulated for its compound materials (steel, lead, and rubber). The most challenging part is to model the response of the rubber, which is inherently a hyperelastic material; the Mooney-Rivlin model is employed (Ogden 1998). A bilinear model is postulated for the lead, assuming isotropic hardening after yielding. Although the same approach can be used for steel, its behavior is presumed linear, elastic, and isotropic for simplicity.

The study focuses on LRB response modeling. For this reason, the model of the seismically protected structure (a base-isolated bridge) is modeled by minimizing, as much as possible, the details considered. For this purpose, finite elements defined with fewer nodes are preferred for the model of the isolated structure. Finite elements of type structural solid are employed to generate the finite element mesh for the 'detailed' LRB model; on the other hand, finite elements of type beam and shell are used to develop the model of the bridge.

Both a model of the bridge containing a 'detailed' LRB model and a model of the bridge with implemented 'light' models are being developed.

2 MODELING THE LRB

The modeled LRB consists of 8 rubber layers, 16 mm in thickness, separated by seven 3 mm steel shims. A 100 mm in diameter cylindrical lead core is mounted in a central hole. The device contains a top and bottom steel plate with a cross-section of 460x460 mm and a thickness of 30 mm (Figure 1).

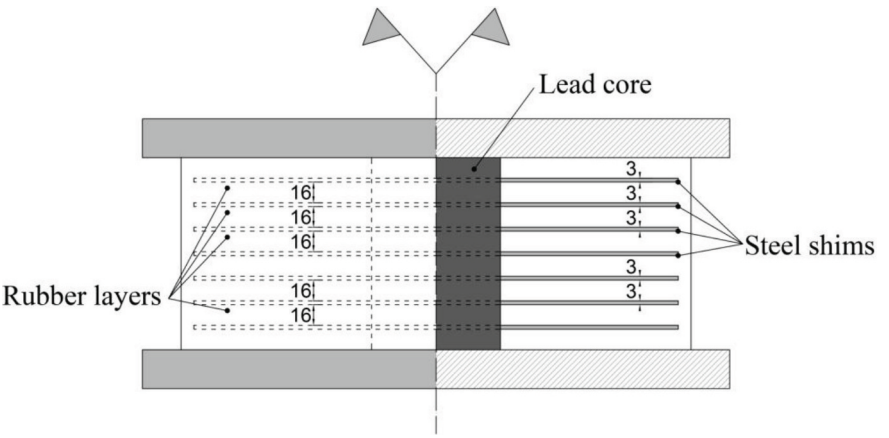

Figure 1. The LRB geometry.

Two models are being developed: a finite element (or detailed) model and an analytical (or light) model.

2.1 *The finite element model*

In the finite element model, besides the detailed geometrical representation (Figure 1), constitutive relations are defined for all the compound materials: steel, lead, and rubber. The material for the steel shims and the top and bottom steel plates is assumed to have linear elastic behavior with Young's modulus E_s=200000 MPa and Poisson's ratio v=0.3. For the lead core, a bilinear constitutive relationship is defined. The initial elasticity modulus is set to E_l=18000 MPa, and

the Poisson's ratio – to 0.43; the yield stress is assumed to be 14 MPa, and the tangent modulus is 100 MPa. A 3-parameter Mooney-Rivlin model is defined for the rubber. Additionally, a Prony model is employed to account for the viscoelastic phenomena in the rubber behavior.

Constitutive modeling is validated by simulating a characterization performed on the LRB. Nodes generated on the bottom steel plate are fixed (i.e., all nodal displacements are restrained), whereas displacements (in the function of the assumed testing protocol) are applied. The dynamic response of the LRB is obtained by performing a transient analysis. A tentative 'shear force-displacement' relationship is shown in Figure 2.

Generally, the identification of model constants involved in the constitutive relations should be based on empirical data obtained in characterization tests performed on small-scale specimens made of the corresponding materials.

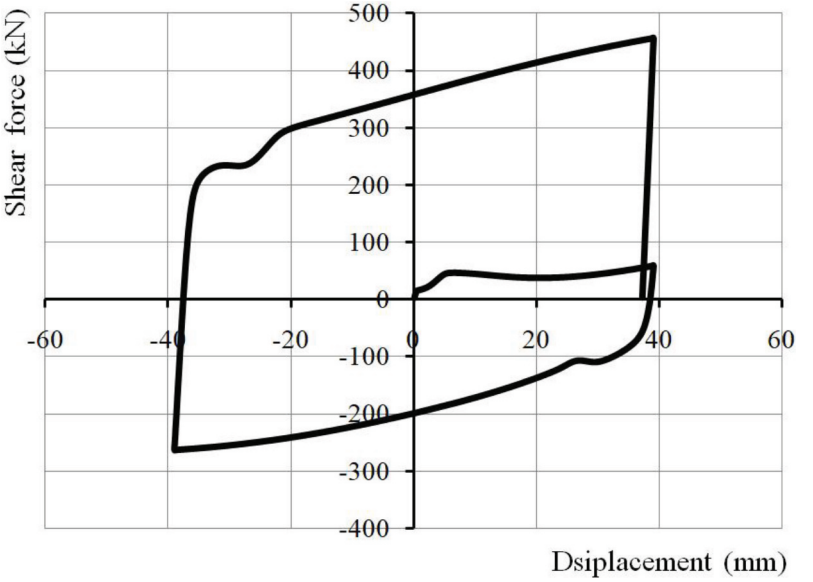

Figure 2. Characterization test on the LRB: results obtained by finite element analysis.

2.2 *The 'light' model*

Typically, the analytical models describing the LRB response consist of an equation defining a 'skeleton' curve and a second equation giving the hysteresis variable evolution. Historically, among the first analytical approaches, the smooth bilinear model (Robinson 1982) and the Ramberg-Osgood model can be cited. Approaches referred to as 'differential equation models' (Wen 1976, Ozdemir 1976) have also been proposed. The research carried out in this field led to more sophisticated models that take into consideration the temperature increase (Kalpakidis & Constantinou 2009a, b), strength degradation (Kumar et al.2014, Liu et al. 2021), and strain hardening (Eem & Hahm 2019).

The model employed herein is defined by the following two equations (Bouc 1967, Wen 1976)

$$F_r = \alpha \frac{f_y}{u_y} u(t) + (1-\alpha) f_y z(t), \tag{1}$$

$$\frac{dz}{dt} = \frac{1}{u_y}\left[A\frac{du}{dt} - \gamma\left|\frac{du}{dt}\right| z(t)|z(t)|^{n-1} - \beta\frac{du}{dt}|z(t)|^n\right]. \tag{2}$$

In Equation (1), F_r denotes the restoring force generated in the LRB, u is the current value of the applied displacement, α is the post-yielding to initial stiffness ratio (i.e., defines the tangent stiffness of the isolator after yielding), u_y is the displacement at yielding, and f_y is the

yield shear (or restoring) force. Equation (5) defines the evolution of the hysteresis variable z(t) in the function of the model constants γ, β, and *n*; the first two are expected to control the size and the shape of the hysteresis loops, and the third one – the curve smoothness upon transition between response in and out of the elastic domain.

3 MODELING A SEISMICALLY ISOLATED BRIDGE

3.1 *Geometry*

A three-span seismically isolated bridge consisting of a continuous steel deck mounted on steel girders is being studied. By assumption, the seismic isolation consists of LRBs under the steel girders placed on the caps of the reinforced concrete piers. The geometry of the structure is depicted in Figure 3 (Hedayati Dezfuli & Alam 2018).

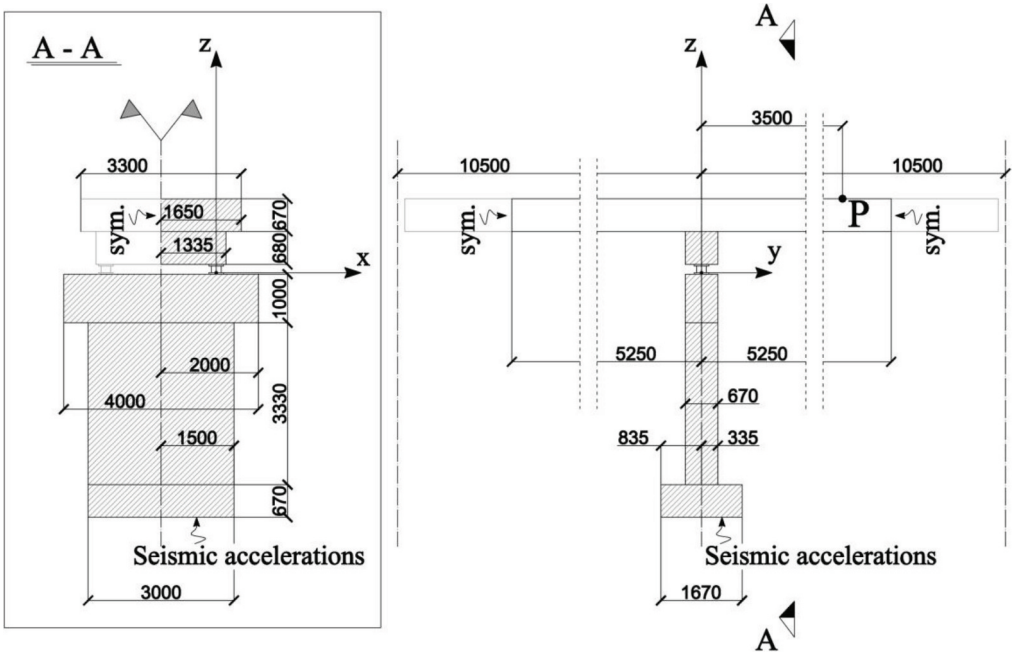

Figure 3. The bridge geometry.

3.2 *Model*

An evident strategy would be the development of a lighter model of the bearing device and its further implementation into the seismically isolated structure. However, an alternative option is employed herein. Focusing on the explicit model of the bearing device, it is inserted in the model of the seismically isolated structure.

In the developed finite element model of the bridge, the footing, the pier, the pier cap, and the girder are meshed with beam elements (BEAM188), whereas the bridge deck is modeled with shell elements (SHELL281).

For simplicity, to all structural elements, except for the LRB, linear, elastic, and isotropic materials are attributed. Young's modulus and Poisson's ratio for the bridge structural elements in steel are assumed to be identical to those of the steel shims and plates in the LRB. The elasticity modulus and Poisson's ratio for the reinforced concrete pier and the footing are 29700 MPa and 0.2, respectively. To include inertia effects, mass densities for steel and concrete are set to 7850 kg/m^3 and 2500 kg/m^3.

No soil-structure interaction is considered.

3.3 *Boundary conditions*

The response of the bridge is obtained by performing a time-history analysis. Acceleration time series recorded in an Mw5.4 earthquake is employed. Symmetries are defined in the structure and are taken into account in the simulations by modeling only a part of the bridge and postulating symmetry boundary conditions, as shown in Figure 3.

3.4 *Transient analysis*

The response of the superstructure is then obtained by performing a full transient analysis as the acceleration time series are applied to the footing. This implies the integration of a differential equation which, in its most general form, reads

$$[M]\{\ddot{u}\} + [D]\{\dot{u}\} + [K]\{u\} = \{F(t)\}. \tag{3}$$

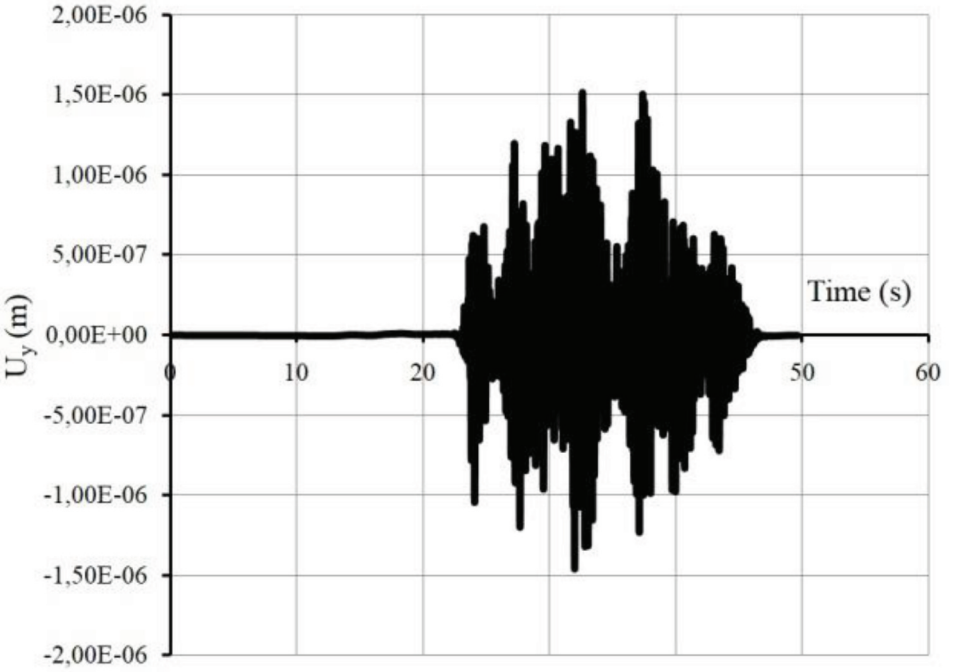
In equation (3), $\{\ddot{u}\}$, $\{\dot{u}\}$, and $\{u\}$ are the nodal acceleration vector, the nodal velocity vector, and the nodal displacement vector, respectively; [M] denotes the mass matrix, [D] is the damping matrix, and [K] is the stiffness matrix.

4 NUMERICAL RESULTS

The response of the bridge structure to seismic load is shown in Figure 4-5. More precisely, displacement- and acceleration- components obtained for a specified point on the bridge deck are plotted.

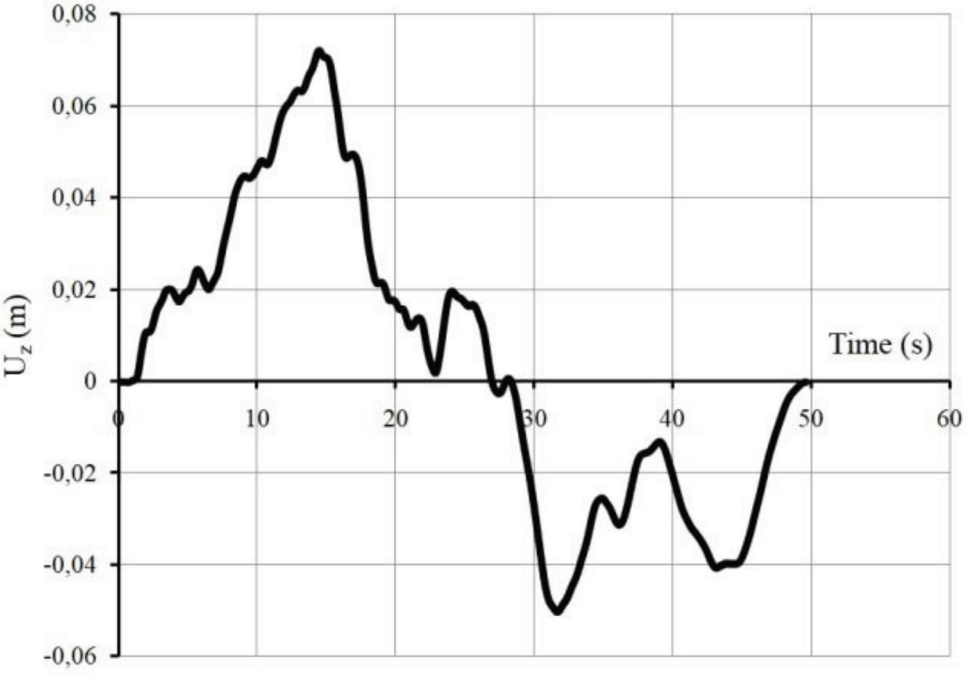
Figure 4-a), b) displays the y- and z-components of the displacement time-history at location P (Figure 3). Acceleration components are shown in Figure 5– a), b).

5 CONCLUSIONS



Elements of ongoing research work focused on the evaluation of the dynamic response of a bridge equipped with base isolation have been reported. Two approaches to model the devices for seismic isolation (LRB) have been discussed, specifically – a detailed (finite element model) and a light (analytical) model.

The detailed model is expected to capture more accurately the dynamic behavior of the seismic isolator and better reproduce the bridge dynamics. On the other hand, the detailed model is more resource-demanding. Using the light model within a finite element analysis might appear more efficient in terms of required computational time.



Clearly, the best solution to calibrate the analytical model is to have access to data acquired from an instrumented seismically isolated bridge. Given that this is not always possible, the accurate representation of all bridge structural elements, including the devices for base isolation, appears appealing.

It should also be noted that tuning the analytical model for the LRB based solely on the LRB characterization test might not be sufficient to explore the entire space containing the design variables of the device. Therefore, the detailed model implementation can fill such possible gaps.

In the context of this ongoing study, a comparison of the bridge response obtained using various LRB models, either detailed finite element models or 'light' analytical models, can shed light on the adequacy and efficiency of the latter. As an outcome, possible limitations on the 'light' models implementation can be formulated: should they be relied on in the design, or should they be used only in searching for a compromise between the accuracy and the fast design process.

Fracture toughness of structural steel in Swedish bridges

M. Ablahad & H. Pétursson
Trafikverket, Sweden

ABSTRACT: The toughness of older steel structures is of crucial interest for the remaining lifespan and safety assessment of aging structures. Many structures in operation today were constructed during times when safety requirements regarding fracture toughness were not specified. This means that very little was known about the defect tolerance of such structures under various loading conditions. It is widely recognized that the toughness of common structural steels is strongly dependent on temperature and loading rate. Since the early 1990s, the Swedish Transport Administration (Banverket and Vägverket now Trafikverket) has conducted more than 600 fracture toughness tests on several hundred old steel bridges. The testing procedures were developed by the late Kjell Eriksson, who was affiliated with Luleå Technical University. The university has also conducted the majority of the fracture mechanics testing presented in this paper. This article will provide an overview of the fracture toughness testing conducted by the Swedish Transport Administration. The research leading to and background of the method used will be described. An example how the method is used for assessment of the load bearing capacity of older steel bridges in view of the toughness properties.

1 INTRODUCTION

Many of the approx. 500 steel bridges in the Swedish national railway network were erected before 1960. The toughness of older steels in railway bridges and similar structures of the same age in public service, e.g. road bridges, has been addressed from time to time in Sweden as well as many other countries during the last decades. Often, surprisingly low notch toughness figures are reported, of the order 2-5 J, in view of the fact that Williams & Ellinger (1953) reported brittle fracture in base materials from fractured ships with up to some 15J Charpy notch toughness. Such low toughness values seem to be common knowledge of many investigators and also of those responsible for the use of older steels. This and the observations a) that the common toughness requirement, 27J Charpy notch toughness according to the Bonhommerecommendation, strictly applies to structural steels intended for welding and b) that failures due to fracture in bridges of riveted and rolled members on the whole are very rare, have risen the question "What minimum toughness is necessary to ensure present safety requirements in older nonwelded structures?"

Since the beginning of the 90:s Kjell Eriksson has worked with this question on behalf of first Swedish Rail Administration (Banverket) that became the Swedish Transport Administration. He developed the method described here. Kjell Eriksson was active in the field until his unfortunate passing in 2021.

2 PREVIOUS WORK

Kjell Eriksson did a number of publications and a few of them are mentioned here.

With the possible exception of the most brittle older steels, fracture is preceded by plastic deformation to such an extent that the conditions for small scale yielding fracture mechanics are not fulfilled Eriksson (1990).

DOI: 10.1201/9781003483755-29

It was found experimentally that Charpy testing alone of older and inhomogeneous steels might be misleading. All steels tested were tougher according to fracture toughness (Jc) tests than to Charpy (Cv) tests compared to the corresponding relationship for homogeneous steels. The steels in Eriksson (1990) investigation might be divided into two groups depending upon the relation between Jc and Cv.

In the first group the steels are twice to four times tougher according to Jc and to Cv. The steels in this group are brittle both according to Charpy-V notch toughness and to fracture toughness.

In the second group the steels are more than ten times tougher according to Jc and Cv. The steels are in fact brittle according to Cv and ductile according to Jc. This is because the toughness of these steels is (very) inhomogeneous, particularly in the second group.

It was concluded from the investigation that full thickness specimens are required to obtain the effective toughness of a structural element. The fracture toughness of a full-scale structure can be predicted from small specimens provided the constraint is similar in both cases. It was also concluded that fatigue crack growth rate does not increase with decreasing toughness.

Eriksson (1991) discusses the historical use of the Charpy test, dating back to 1905, for qualitative assessments of the brittle-to-ductile transition temperature of structural steels. Before World War II, there was no rational basis for predicting structural behavior or calibration against service performance. However, after the Liberty ship disasters in the early 1940s, it became evident that the transition temperature of a cracked body was critical for the loss of strength.

The text also highlights the inadequacy of using notch toughness alone as an indicator of defect tolerance. Notch toughness underestimates the effective toughness of a structural element, leading to conservative estimates of material quality.

Three examples were provided to illustrate these points: inhomogeneous steel with varying transition temperatures, pressure vessel steel susceptibility to embrittlement after cold forming and welding, and weld metals with poor fracture toughness despite acceptable notch toughness.

In conclusion, the text demonstrates that there is no universal correlation between notch toughness and fracture toughness. Empirical relationships may underestimate fracture toughness, especially for inhomogeneous materials, and relying solely on notch toughness for weld metal may not ensure the desired safety against fracture.

In Eriksson (1992a) the emphasis is on the safety of structures containing potentially brittle materials. The paper incorporated a blend of laboratory experiments, full-scale testing, and statistical analysis to establish appropriate toughness criteria.

Eriksson's work from 1992 also delves into a method for estimating the remaining fatigue life of structural steel members subjected to service-related damage and corrosion. This approach is rooted in the Palmgren-Miner damage accumulation rule and takes into account factors such as field-recorded stress patterns, stress concentration effects, and the influence of corrosion. Its application is vital for evaluating the structural integrity of aging infrastructure like railway bridges.

There are several key situations where an evaluation of a structure's remaining lifespan becomes necessary:

a) When the structure approaches its anticipated service life,
b) When there are alterations in loading conditions, and
c) When the structure is damaged.

Historically, inspections of older bridges have yielded favorable results, with only a minimal number of cracks being identified. However, the focus of the paper is shifted towards comprehending the consequence of common types of damage, such as scratches and impacts from road traffic, on the residual longevity of these structures.

Eriksson's 1992 work presents a straightforward model based on Palmgren-Miner's rule to quantify the potential effects of corrosion and stress concentration on the remaining lifespan of corroded areas affected by scratches or impacts. The analysis underscores that these factors can substantially diminish the fatigue life expectancy of old steel structures.

Furthermore, Eriksson (1992a) also explores the computation of damage and introduces an algorithm for calculating damage in various scenarios. He introduces fatigue strength

reduction factors tailored to different surface conditions and provides illustrative calculations for different damage types.

In Eriksson (1992b) an experimental and theoretical investigation is described. The deformation and fracture of a precracked HEB400 steel beam (St37 class D) is investigated through various methods, including full-scale testing, numerical computation of the J-integral, analytical estimations, and fracture toughness testing of small specimens. The study aims to understand how fracture properties obtained from small-scale specimens apply to full-scale structures.

Key findings and observations from the paper include: The study aimed to assess the transferability of fracture data obtained from laboratory specimens to full-scale structural elements. It found that fracture toughness data from different types of specimens correlate reasonably well. The materials used in the study were heterogeneous, with considerable scatter in mechanical properties. Some materials were taken from structures that had been in service for several decades, while others were made from steel not manufactured to current standards. The fracture toughness of the materials ranged from very low for some specimens (around 10 kN/m) to much higher for others (greater than 100 kN/m). The scatter in fracture toughness was significant but relatively consistent between laboratory and full-scale specimens.

The paper includes detailed experimental observations, including load-displacement relationships, strain measurements, temperatures, and crack mouth opening displacements for each beam. The results showed that fracture did not occur for crack lengths shorter than approximately 40 mm, even for brittle materials, indicating a threshold crack length for fracture initiation. The paper discusses the use of the J-integral and CTOD (Crack Tip Opening Displacement) to characterize fracture toughness and presents critical values for different specimens. It also presents a residual strength diagram that illustrates the borderline between "long" and "short" cracks, where "long" cracks led to fracture, and "short" cracks only resulted in plastic deformation but no crack growth.

In summary, the paper focuses on the fracture behavior of structural steel beams with preexisting cracks at low temperatures. It evaluates the transferability of fracture data obtained from laboratory specimens to full-scale structures and provides insights into the influence of crack length and material properties on fracture toughness.

Eriksson (1994) presented a method for calculating fracture toughness requirements for ordinary structural steel, particularly focusing on older and potentially inhomogeneous steels found in various structures such as bridges. The main objective was to ensure the safety and structural integrity of these older materials.

The key findings and processes outlined by Eriksson include:

There are numerous old steel structures in Sweden and around the world, some dating back to early 20th century, raising concerns about the toughness of the materials used in these structures.

Testing of older steel samples revealed two distinct groups - one group that met safety requirements and another that did not. In particular, some older steels displayed a surface layer with ductile properties and a brittle core.

Full-scale testing of structural elements and laboratory specimens was conducted to assess the transferability of results. The behavior of beams could be predicted from extracted specimens provided the constraint was similar in both cases.

The text discusses the development of a method for calculating fracture toughness requirements based on assumed crack sizes and typical loading conditions. This method aims to maintain safety standards in structures with older materials.

Two fracture toughness levels are suggested - a lower level requiring immediate replacement and an upper level that ensures satisfactory safety. The upper level is approximately equivalent to a Charpy notch toughness of 27 Jc.

The text concludes that Charpy testing alone may be insufficient for assessing older and inhomogeneous steels. Full-thickness specimens are necessary to accurately estimate structural element toughness, and fracture toughness of full-scale structures can be predicted from small specimens with similar constraint conditions.

Lorentzon & Eriksson (1995) examines the influence of quasistatic loading rate and temperature on the fracture toughness of older structural steel. The research was aimed to assess the integrity and applicability of the steel in older structures.

The results indicated that the fracture toughness of structural steel significantly decreases at common loading rates encountered in practice compared to standard fracture toughness tests. This implies that reliable fracture toughness data for structures exposed to quasi-static loading rates require testing at appropriate speeds.

The study's conclusions suggest that the impact of loading rate on fracture toughness can be predicted using data from laboratory tests with extracted small specimens. The results also emphasize that increased material toughness leads to improved safety at lower loading rates.

Lastly, the study underscores the importance of understanding the influence of loading rate on structural safety, particularly for future structures intended for high-speed train traffic.

3 TRAFIKVERKET CODES REGARDING FRACTURE TOGHNESS OF STEELS IN BRIDGES

There are two documents provided by Trafikverket explaining the procedure of testing the fracture toughness of structural steel, both are written in Swedish, (Trafikverket (2023) and Trafikverket (2014).

The fracture toughness of the steel in the main structure of a bridge is tested if the bridge is built before 1970. Before that year it was not a standard procedure to do Charpy-V tests on steels that were used in bridges.

The median is considered to be lowest fracture toughness value of three to five specimens or the second lowest fracture toughness value of six to eight specimen orthe third lowest fracture toughness value of nine or more samples.

The material testing consists of chemical analysis and fracture toughness. In order to determine each toughness value, three tests are conducted using different test specimens. The specimen can be, three-point-bend specimens with a rectangular cross section, three-point-bend specimens with broken edges (Figure 1) or CT-specimen or CT-round specimen.

A complete chemical analysis is made for the following substances, C, Si, Mn, P, S, Cr, Ni, Cu, Mo, V and N.

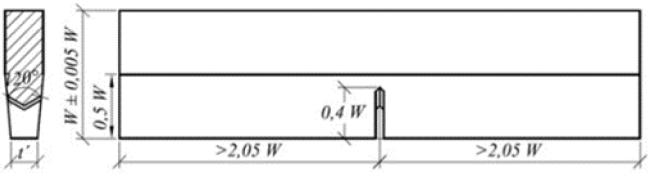

Figure 1. CT-specimen with broken edges.

The specimens are cooled to -30° C when testing and a fracture toughness is evaluated for each specimen. The loading speed of the test is chosen depending on the speed of the traffic over the bridge and the length of the influence line.

The load case during testing mimics a 50 mm deep elliptical surface crack in a comparatively substantially larger geometry. If the test shows Jc>50 kN/m, then fatigue failure will not occur for cracks shorter than 50 mm. The fracture toughness should fulfill the requirements according to level one in Table 1.

Table 1. Basic requirements.

Terms	f_v[MPa]	J_c [MPa]
Accepted	220	30
without special	260	40
measurements	290	50

If the measured toughness of the steel is lower than in Table 1, then level two is applied according to Table 2 where the maximum nominal stress in tension in serviceability limit state (σ_{nom}) is stated depending on the J_c value. If J_c is less than 20 kN/m, then a special investigation has to be made in order to verify the bridge capacity.

Table 2. Maximum allowed stress in tension with regard to steels toughness value.

Fracture toughness [kN/m]	Maximum allowed σ_{nom} [MPa]
$20 < J_c < 30$	$\sigma < 100 + 6{,}7\ (J_c - 20)$
$30 < J_c < 40$	$\sigma < 167 + 3\ (J_c - 30)$
$40 < J_c < 50$	$\sigma < 197 + 2{,}3\ (J_c - 40)$

4 CONDUCTED TESTS

The fracture toughness of structural steel has been tested on 587 different samples from different bridges. This could be seen in Figure 2 that shows the year of construction for each bridge and its Jc value. Furthermore, the results can also be seen in Table 3 from a general point of view and Table 4 from a more specific point of view where Jc < 20, 30, 40 and 50 is presented for the bridges.

In Table 3 it can be seen that one column has a max value for Jc of 50 kN/m this is due to the fact that the upper limit of this value is set to 50 kN/m and therefore Jc >50 is not of interest.

The calculation of Jc is done using equation 1 which includes the thickness (t), widtht (W) and the crack length of the specimen (a).

$$J_c = \frac{2U}{t(W-a)} \tag{1}$$

Table 3. General results of J_c for conducted tests on steel bridges.

Year of construction	Average [kN/m]	Average (max 50 kN/m)	Std deviation
Before 1910	192	40	217
After 1910	133	40	174

Table 4. Specific results of Jc for conducted tests on steel bridges.

Year of construction	Quantity	<20	<30	<40	<50
Before 1910	45	1	14	19	20
After 1910	463	57	143	203	250

The railway bridge Testeboån, was constructed in 1942 and replaced by a new bridge in 2013. From the demolished bridge structure, 7 I-beams of type Dip 32 were preserved for fracture mechanical testing. Additionally, a new HEB 320 beam was acquired for comparative testing. The fracture mechanical testing was conducted in two phases. In the first phase, the beams were tested at full scale in three-point bending. Subsequently, three three-point bending test specimens were produced per beam, using material taken from the beam flanges, totaling (7 + 1) x 3 = 24 test specimens. In the second phase, testing was carried out using the three-point bending test specimens. The testing temperature for both beam elements and test specimens was -30°C.

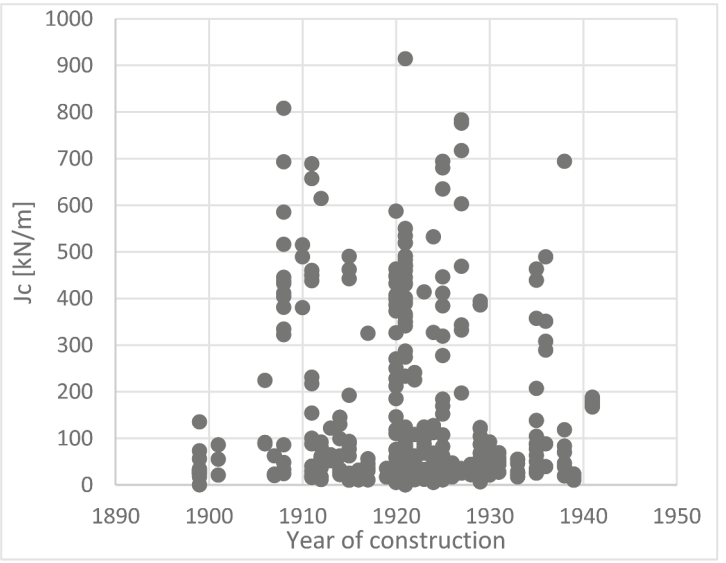

Figure 2. Results from fracture toughness evaluations in relation to age of the steel.

The fracture mechanical testing was performed following the guidelines outlined in Trafikverket (2014).

The fracture mechanical testing was conducted at two different loading rates, a low rate for three beam elements from the current bridge and a high rate for the remaining four beam elements and the newly acquired beam. The low loading rate is quasi-static and representative of structural elements with a large influence length, approximately 20 meters and larger, typical for components such as lower chord members in truss structures. The high loading rate corresponds to shorter influence lengths, on the order of 3-5 meters, as encountered in long beams and crossbeams at train speeds of 80-100 km/h. The test results are presented in Table 5.

Table 5. Test results.

Test beam	Whole beam Jc [kN/m]	Test specimen Jc [kN/m]
B1	66	19
B2	70	20
B5	23	14
B3	40	17
B4	37	12
B6	61	18
B7	41	16
New	67	37

5 EXAMPLE ASSESMENT AND TESTING OF TOUGHNESS REQUIREMENTS OF A RAILWAY BRIDGE

Fracture toughness tests have been conducted on a lot of bridges as mentioned, one bridge is "Ludvika ström" which is a simply supported bridge with three spans of 3.2m, 17.2m and 17.2m, see Figure 3 (left). The bridge is located by a stream in the town Ludvika in Sweden. It was first built in 1874. The superstructure was replaced in 1924.

The maximum load bearing capacity corresponds to line category E3 (CEN 2021) in ultimate limit state.

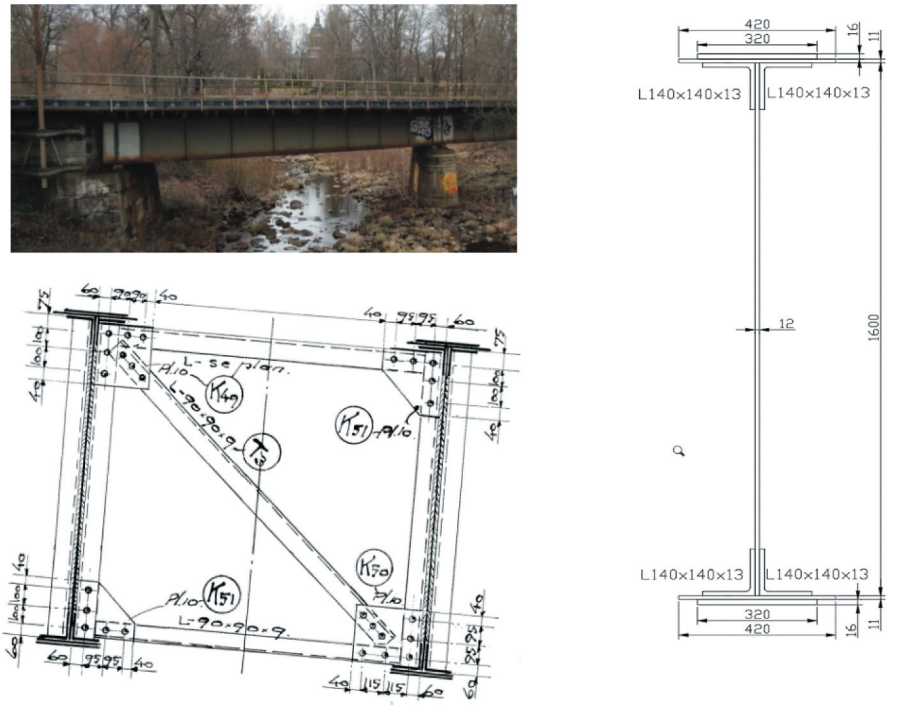

Figure 3. The bridge, Ludvika ström and bridge section (left). Beam used for samples (Right).

The fracture toughness testing of this bridge required a total of 12 specimens, six from the web and six from the flange that were taken out from the beam seen in Figure 3 (right). The test that was conducted on the specimens gave low results regarding the fracture toughness of the steel. This resulted in a need to calculate of the tension stresses in order to ensure the capacity of the bridge according to Table 1 and 2 in chapter 3.

The lowest fractur toughness turned out to be J_c = 21kN/m for the flange and the steel has fy =216 MPa, meaning that the steels require J_c>30 to be regarded to be safe without further

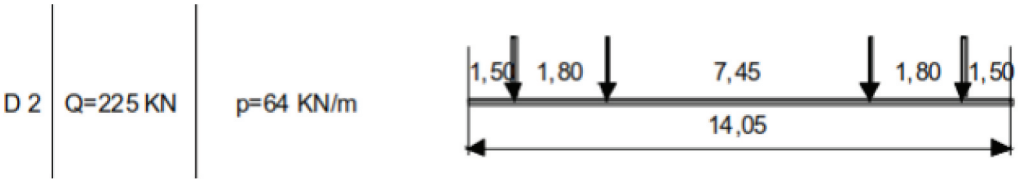

Figure 4. Train load corresponding to line category D2.

Table 6. Parameters used for calculation of tension. Loads on one (of two) bridge girders.

Parameter	quantity	unit
Steel yield strength	216	[MPa]
Dead weight	7.9	[kN/m]
Wind load (horizontal)	6	[kN/m]
Wind load (vertical)	±7.7	[kN/m]
Side support	54.6	[kN]
Dynamic factor	1.12	
Eccentricity of train load	50	[mm]

analysis. The tension stress must be less than 106.7MPa. This was not the case. The line category was lowered to D2 in order to fulfill the requirement, see Figure 4.

The parameters in Figure 3 (right) are used to calculate the bending moment in the serviceability limit state, moment of inertia and the area in order to further calculate the stress in tension was calculated to be σ D2 = 86 MPa. The requirement is now fulfilled, meaning that will a longer lifespan for the bridge is possible.

6 CONCLUSION

Kjell Eriksson's research started in the 1990s and forms the basis for the regulations used by the Swedish Transport Administration today to secure older steel bridges. This paper has described some of the research that has led to the rules, results from hundreds of tests from steels in old bridges and an example of how the regulations are use in practice. The fundaments of the regulations are the following:

a) To estimate the median fracture toughness with a 87.5% confidence level, a minimum of three test specimens are required. The estimated value of the median is the lowest of the three fracture toughness values.
b) A reasonable requirement for the fracture toughness of structural steel in load-bearing structural elements is that the standard safety is not exceeded even if a defect or crack of a certain size occurs in the most heavily loaded cross-section of the structure. As a typical case for a load-bearing railway bridge's main girder, the scenario of a wide-flange beam subjected to bending with an edge crack in the tension flange has been considered.
c) Taking into account the risk of escaping detection in inspections using common nondestructive testing methods, a crack with a depth of 50-100 mm is a reasonable starting point.
d) The variability in fracture toughness for common types of structural steel is significant, necessitating the establishment of two levels, a lower and an upper limit.
e) Steel with fracture toughness greater than the upper limit can be used without restrictions, while steel with fracture toughness lower than the lower limit is not allowed in load-bearing structural components. For steel with fracture toughness between the upper and lower limits, an individual assessment is made.
f) Limits for the fracture toughness of structural steel:
   Lower limit: Jc = 20 kN/m
   Upper limit: Jc = 50 kN/m
   At the lower limit and a crack length of 50 mm, the safety is at least equivalent to the Accident Load, and at the upper limit and a crack length of 100 mm, it is at least equivalent to Safety Class 3.
g) That full thickness specimens should be used for fracture toughness tests.
h) The fracture toughness of a full-scale structure can be predicted from small specimens provided the constraint is similar in both cases.
i) Fatigue crack growth rate does not increase with decreasing toughness.

ABSTRACT: In the Netherlands, there are about 70 prestressed T-girder bridges with cast-in-between decks, constructed post-World War II. While they have low ratings upon assessment, inspections reveal no distress. This research aims to understand the structural behavior of the full system compared to isolated T-girders. Experiments were conducted on the original structure, as well as on the structure with the deck sawn to test individual girder behavior. The main insight is that the system behavior at the ultimate limit state is driven by compressive membrane action in the deck as well as compressive arching action in the girders, and that simplified distribution factors for shear derived from linear elastic behavior do not properly reflect the distribution and load path at the ultimate. These results can be used for a better assessment of the existing pre- stressed T-girder bridges.

1 INTRODUCTION

In the decades following the Second World War, the Dutch road network underwent a large ex- pansion. This expansion also involved the construction of a large number of bridges. These bridges are now reaching the end of their originally devised service life (Lantsoght et al. 2013). Upon assessment, engineers are confronted with the fact that the live loads that are currently prescribed by NEN-EN 1991-2:2003 (CEN 2003) are heavier than prescribed by the previous national codes, and that at the same time the shear capacity calculated from the current code pro- visions in NEN-EN 1992-1-1:2005 (CEN 2005) is lower than in the previous national codes (Dutch Institute for Normalization 1962). As a result, a large number of existing bridges are ana- lytically found to be insufficient for shear.

One subset of the Dutch bridge stock consists of prestressed T-girder bridges with cast-in-between decks. About 70 of these structures are present in the Netherlands. Even though the analytical assessment for shear results in the conclusion that these bridges are not sufficient, typically no signs of distress are found upon inspection. A possible explanation for this observation is that additional load-carrying mechanisms are activated, which are traditionally not considered in assessment. In particular, for prestressed T-girder bridges with cast-in-between decks, the structural capacity could benefit from the effect of compressive membrane action in the deck, compressive arching action in the girder, the effect of the diaphragms acting as intermediate supports, and of transverse distribution from the analysed girder to the adjacent girders.

Experimental data that quantify the transverse distribution for shear in prestressed T-girder bridges with cast-in-between decks is limited. Moreover, the available experimental data were obtained through diagnostic load tests, or the distribution factors were derived based on

DOI: 10.1201/9781003483755-30

linear finite element analyses. For girder bridges, the test data are limited to slab-girder bridges, for which the deck is cast on top of the girders instead of in between the girders (Arockiasamy and Amer 1998, Jáuregui and Barr 2004, Wekezer et al. 2004, Mordak and Manko 2008, Idriss and Liang 2010). Additional difficulties for the assessment of the existing prestressed T-girder bridge with cast-in-between decks in the Netherlands are the very low shear reinforcement ratios, and the presence of diaphragms (Cai et al. 2002).

For design, the distribution factors from AASHTO §4.6.2.2 (AASHTO 2015) can be used.

Different distribution factors are determined for bending moment and shear, and for interior and exterior girders. The distribution factor (DF) for an interior girder for shear is as follows:

$$DF = 0.36 + \frac{S}{25.0} \tag{1}$$

with S the spacing of the beams in [ft]. Guidelines are available for flexure on how to use field tests to determine the distribution factors (ACI Committee 342 2016). However, it is not known if the distribution changes as the load is increased and the structural behaviour changes from linear elastic to the ultimate limit state. With this in mind, this paper will use the described test results on a prestressed concrete slab-between-girder bridge to evaluate if the distribution factors can be used to describe the system behaviour, and, if not, which mechanisms contribute to the system behaviour.

2 DESCRIPTION OF VECHT BRIDGE

2.1 *Location, structural system, and geometry*

One example of a T-girder prestressed concrete bridge with cast-in-between decks is the Vecht Bridge near the town of Muiden in the province of Noord Holland in the Netherlands. This bridge was built in 1962, and consisted of nine simply supported spans of which one span contains a movable bridge over the Vecht river. Two parallel bridges were built, one per driving direction. The bridge was situated in the A1 highway. This highway is rerouted, so that it became possible to test the bridge to failure in two spans prior to its demolition. A partial overview of the bridge structure is given in Figure 1 showing the western approach ramp. Figure 1 also marks the inves- tigated spans. On span 3 (see Figure 1) an extensive investigation into the material properties of the concrete (drilled cylinders) and the prestressing tendons has taken place.

All spans are 24 m long, and consist of 15 identical prestressed girders with diaphragms at 8 m intervals. An overview of the transverse cross-section is given in Figure 2. The center-to-center distance between the girders is 1225 mm. The thickness of the cast-in-between decks is equal to the height of the top flange of 180 mm. The girders were prefabricated on-site and pretensioned after which the ducts were grouted.

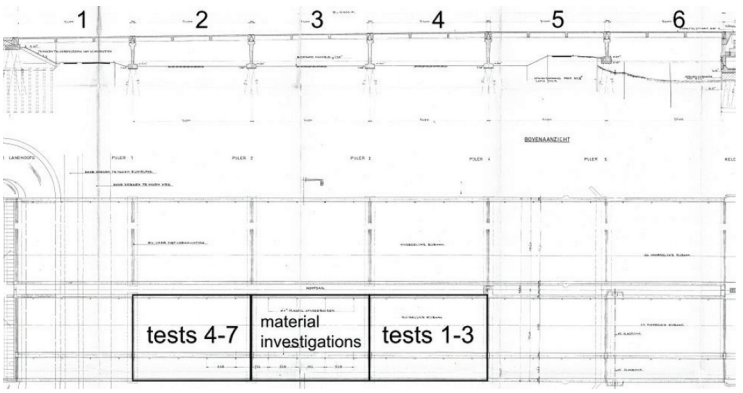

Figure 1. Partial overview of Vecht Bridge, longitudinal section (top) and top view (bottom).

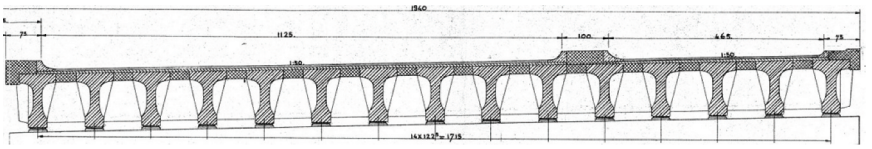

Figure 2. Cross-section of Vecht Bridge (measurements in cm).

2.2 *Material properties and reinforcement*

The longitudinal prestressing in the girders consists of seven 12ø7 mm (A_p = 462 mm^2) tendons per girder. The transverse prestressing consists of 12ø7 mm (A_p = 462 mm^2) per tendon, with a total of 59 transverse prestressing tendons per span. A detail of the curved prestressing tendons close to the support is shown in Figure 3. Prestressing steel qualities QP150 and QP170 were used during the era of construction of the Vecht Bridge. Documents from the archives suggest the use of QP170, so that f_{pk} is estimated as 1754 MPa. Extensive material research in span 3 identified the yield strength of the prestressing steel as 1505.4 MPa and the ultimate strength as 1769.5 MPa. Mild steel reinforcement is present in the deck and girders. In the bottom flange of the girders, 3ø10 mm bars are present at 1107 mm from the face of the top flange and 2ø10 mm at 980 mm. In the web, 2ø10 mm are present at 785 mm, 560 mm and 300 mm, see also Figure 4. The shear reinforcement consists of ø8 mm at 500 mm on center. The mild steel is QR24 with a character- istic yield strength f_{yk} estimated at 280 MPa and confirmed with the extensive material investigation as 287.7 MPa. With the exception of the transverse prestressing, there is no steel reinforce-ment connecting the cast in-between slab to the girder.

The average concrete cube compressive strength $f_{ck,cube}$ on the original drawings is 50 MPa. From this value the average cylinder strength f_{cm} is estimated as 64 MPa. From the extensive material research, the average cylinder strength was found as 87.7 MPa (based on 30 cores) in the T-beams and 60.3 MPa in the integrated deck slab.

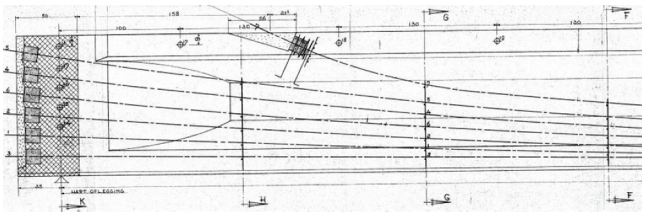

Figure 3. Detail of curved prestressing tendons in T-girder close to the support.

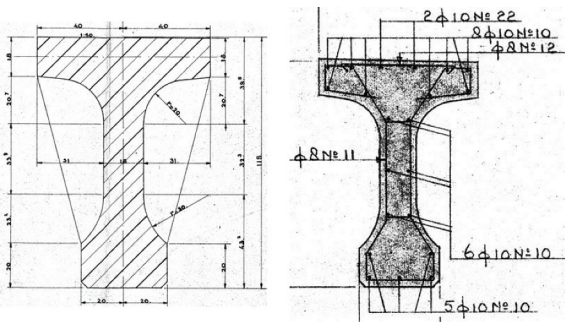

Figure 4. Cross-section of girder (left) and steel reinforcement (right) (measurements in cm).

3 TEST SETUP

3.1 *Load positions*

Three experiments were carried out on span 4, and four experiments in span 2, see also Figure 1 and Table 1. In span 4, the original structural system is unchanged. In test 1 and 2 at least four girders are present between the tested girder and the edge of the bridge. Therefore, in these tests a significant load distribution to the adjacent girders will take place. In test 3 the edge girder itself is loaded. Finally, in span 2, the deck is sawn, so that the individual behaviour of the girders could be tested. Also three of the four cross-beams, with the exception of the one on the opposite side, are sawn. The load position at 4000 mm is chosen because of the position of the cross-beams. The load position at 2250 mm is chosen as the weakest cross-section for an individual girder because of the position of the prestressing tendon anchored in the top flange (see Figure 3). By comparing the structural system to the individual girder behaviour, the system behaviour can be observed.

Table 1. Overview of tests.

Test	Span	Distance from support [mm]	Structural system	Type of test
1	4	4000	not changed	Intermediate girder
2	4	2250	not changed	Intermediate girder
3	4	2250	not changed	Edge girder
4	2	2250	sawn	Individual girder
5	2	2250	sawn	Individual girder
6	2	2250	sawn	Individual girder
7	2	4000	sawn	Individual girder

3.2 *Loading system*

The load is applied through a single concentrated load of 400 mm × 400 mm. The full loading system consist of a 25 m steel spreader beam with ballast on top. The load is then gradually applied from the steel spreader beam to the bridge by using a hydraulic jack. Additionally, a sliding system was provided to easily change the loading position, given the large number of tests planned on site. This system is shown in Figure 5. For the isolated beams in span 2, holes were drilled through the deck through which steel chains were placed and anchored in place by a steel beam, so that the beam would fall into the chains at failure instead of onto the ground.

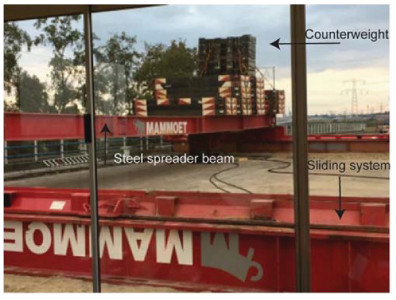

Figure 5. Load application system.

4 TEST RESULTS

4.1 *Failure loads*

Table 2 gives an overview of the results of the seven experiments. The table includes the test number and span of the experiment, with experiments in span 4 on the connected system and in

span 2 of the disconnected girders. The *a/d* distance is the ratio of the shear span *a* to the effective depth *d* of the girder. The maximum load in the experiment is indicated as F_{max} and the maximum deflection in the experiment is indicated as δ_u. The shear at failure is calculated by considering the sectional shear due to the dead weight, the prestressing, and the externally applied load.

The table also gives the Failure mode. For tests 1 and 2, Figure 6 illustrates the failure in the girder and Figure 7 illustrates the failure in the deck, which is the initial failure. Test 3 was an experiment on an edge girder. As there were safety concerns regarding the stability of the tower of counterweight upon failure of the edge girder, this experiment was limited to a maximum load of 250 tons. All experiments on the disconnected T-beams resulted in a flexural shear failure, see Figure 8. The load-deflection diagram of the connected girders is shown in Figure 9 and of the disconnected girders in Figure 10.

Table 2. Results of experiments.

Test	Span	a/d	F_{max} (kN)	V_R (kN)	δ_u (mm)	Failure mode
1	4	2.8	3004	1188	21	Punching of deck and shear failure of girder
2	4	4.8	3444	1525	14	Punching of deck and shear failure of girder
3	4	2.8	2506	998	11	Not tested to failure
4	2	2.8	1678	1301	79	Flexural shear T-girder
5	2	2.8	1703	1323	65	Flexural shear T-girder
6	2	2.8	1774	1385	74	Flexural shear T-girder
7	2	4.8	1022	774	132	Flexural shear T-girder

Figure 6. Shear failure of T-girder in test 1. The diaphragm is located on the left side and the end support on the right side.

Figure 7. Punching failure of the deck slab in test 1, showing top view and measurements in cm (left) and bottom view (right).

4.2 *Comparison of connected and disconnected girders*

It is not straightforward to compare the results of the shear at failure of the disconnected and connected girders, see Figure 11. A first reason why comparison is not simple is related to the load distribution. In the connected girders, load distribution results in a change of failure

Figure 8. Flexural shear failures in test 4 and 5.

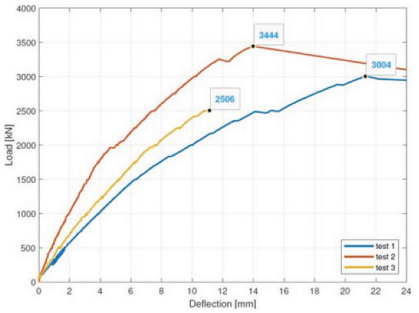

Figure 9. Load-deflection diagrams of girders in connected system.

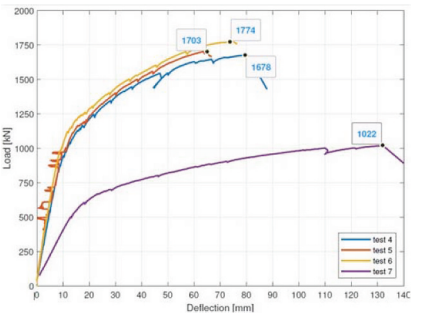

Figure 10. Load-deflection diagrams of girders in disconnected system.

mode from flexural shear for the individual girders to shear-tension for the case of the connected girders. Moreover, an important difference between the connected and disconnected girders can be at- tributed to system behavior represented by arching action in the girder and the deck. For the con- nected girders, the constraints provided by the surrounding members result in significant addi- tional compressive normal forces in the girder and in the development of compressive membrane action in the deck slab (Taylor et al. 2007, Collings and Sagaseta 2015, Amir et al. 2016). Finally, the presence of the diaphragms increases the capacity, as the diaphragm works almost as an in- ternal support.

In addition, using the shear distribution factor from Eq. (1), a factor of 0.52 is found for the interior girders of the Vecht bridge. For an *a/d* distance of 2.8, the maximum load in the connected system is 3004 kN, which would correspond to a maximum load on the tested girder of 1562 kN according to this distribution factor. This value can be compared to the average failure load of the three experiments of disconnected girders with $a/d = 2.8$ of 1718 kN. For $a/d = 4.8$ the maximum load in the connected system is 3444 kN, which would give a maximum load on the tested girder of 1791 kN. The failure load in test 7 was 1022 kN. This brief comparison shows that the AASHTO distribution factors cannot capture the complex system behavior and different shear failure mechanisms that occur in the system at the ultimate limit state.

5 DISCUSSION

This article describes the seven experiments to failure carried out on the Vecht Bridge. As can be seen from the comparison of the maximum load and the sectional shear at failure for the connected bridge system and the disconnected girders, a one-on-one comparison between the two cases is not straightforward. The reasons for the complexity of the comparison is the system behaviour of the connected system, in which compressive membrane action in the deck occurs and compressive arch action in the prestressed girder. Moreover, these two arching mechanisms need to be analysed

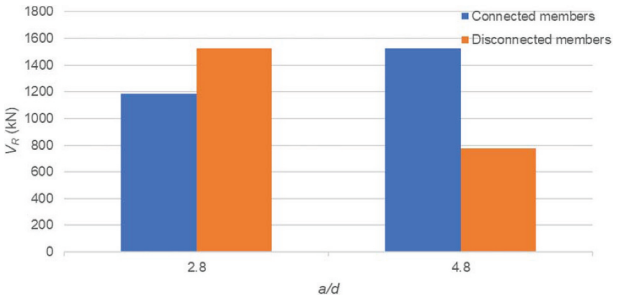

Figure 11. Comparison between sectional shear force at failure for connected and disconnected members from Table 2. Note that the average result of tests 4-6 is used in this comparison.

together. As a result, the flow of forces and the failure mode is significantly different in the connected system as compared to in the individual girders. A full analysis of system behaviour applied to this case study, as well as linear elastic finite element calculations typically used in assessment and non-linear finite element calculations used to further study the experiment can be found in (Ensink 2024).

One important aspect that can already be highlighted here with regard to the system behaviour is that in these experiments, compressive membrane action occurred, even though the load was placed right over the girder. These experiments are the first experiments that demonstrate that compressive membrane action can also be activated when the load is not in the middle of the deck, but right over the girder.

The comparison of the maximum loads also shows that the AASHTO shear distribution factors do not give good results at the ultimate limit state, as these factors are based on linear elastic analyses. The relation between the transverse distribution and the load level requires further re- search. It needs to be verified if the simplified load distribution factors gave good results for the lower load levels in the experiments on the Vecht Bridge, and it can be recommended to carry out research into transverse distribution factors that are representative of the ultimate limit state.

While collapse testing of bridges is expensive (order of magnitude of 400k€), the cost savings for the service life extension of the other slab-between-girder bridges (where replacement would cost over 10m€) is significant (approximately 45% cost savings on a 100-year time horizon when comparing annual equivalent costs). Moreover, indirect cost savings from avoid traffic delays and ecological cost savings related to material use and transportation are obtained.

A final step of this research, which is foreseen for future work, is the extension of this study to encompass all geometries encountered in the slab-between-girder bridges in the Netherlands. For these geometries, the system behaviour needs to be studied in more detail. Once this information is available, a method can be developed to improve the assessment of the existing prestressed T- girder bridges in the Netherlands.

6 SUMMARY AND CONCLUSIONS

This paper introduces seven experiments that were carried out on the Vecht Bridge, a slab-between-girder bridge in the Netherlands with diaphragms at the end and at one third of the span, and with post-tensioned girders. Three experiments were carried out on the connected system and four experiments were carried out on the bridge in which the deck and diaphragms were cut so as to study the behavior of the disconnected girder. The goal of the experiments was to compare the behavior of the connected system and individual members. Based on the described experiments, we can draw the following conclusions:

- The overall system behaves in a much stiffer way than the individual girders.
- The maximum load in the case of the overall system is significantly larger, indicating system behavior in these bridges.

– The failure mode changes from flexure-shear in the individual girders to punching of the deck with a shear-tension failure of the girder for the connected system.
– The system behavior can be attributed to compressive arch action in the girders and compressive membrane action in the deck, and cannot be represented properly by the AASHTO shear distribution factors.

Overall, these failure tests on a real bridge, with all its original details, has provided unique in- sights into the behavior and failure mode of existing slab-between-girder bridges.

ACKNOWLEDGMENT

The authors wish to express their gratitude and sincere appreciation to the Dutch Ministry of Infrastructure and the Environment (Rijkswaterstaat) for financing this research work. The contributions and help of our (former) colleagues Dick Hordijk, Rutger Koekkoek, Marco Roosen, Fred Schilperoort, Cor van der Veen, and Yuguang Yang, and of student Thomas Harrewijn of Delft University of Technology are gratefully acknowledged. The fruitful discussions with Ane de Boer, Sonja Fennis, and Herbert van der Ham from the Dutch Ministry of Infrastructure and the Environment, with Frank Linthorst and Danny den Boef of Witteveen+Bos, responsible for logistics and safety during the test, and with Otto Illing and the late Chris Huissen of Mammoet, responsible for applying the load during the collapse test, are also acknowledged.

ABSTRACT: Bridge load testing is one of the tools engineers are using for the assessment of existing bridges, which is becoming increasingly important to manage the existing bridge stock in a sustainable manner. Over the past years, various research groups have worked on theoretical and practical research regarding load testing. Moreover, various international committee work on load testing recommendations. This paper provides an overview of recent research efforts in Denmark, the Netherlands, and Sweden. The way in which recent research efforts are implemented in new committee reports and guidelines is highlighted. Overall, the efforts have focused on combining load testing with insights in structural behavior, applying improved instrumentation techniques, combining with numerical analyses, and providing a probabilistic substantiation. In conclusion: bridge load testing is a dynamic field of research that benefits from international collaboration. Further improvements to existing codes and guidelines will be forthcoming in the next years.

1 INTRODUCTION

In Europe, the decades after the end of the Second World War marked a time of economic expansion and growth, which is reflected, among other aspects, by the expansion of the transportation network. As a result, many of the existing bridges in Europe are from the 1950s to 1970s (Lantsoght *et al.* 2013). These bridges are reaching the end of their originally devised service life. Replacing bridges at the end of their service life is however not a wise decision: the economic cost and CO_2 emissions are high, the impact on traffic flows creates a high indirect economic cost, and natural resources are dwindling. In short, to manage the existing bridge stock sustainably, it is important to assess existing bridges and decide how and in which way the service life of the existing bridges can be extended (Yang *et al.* 2019).

Load testing of bridges can be a valuable method for assessment when uncertainties regarding the overall behavior of the bridge are large (Alampalli *et al.* 2021). Often these uncertainties are dedicated to the contributions from certain mechanisms (such as the effect of support boundary conditions, transverse distribution when strong bands of reinforcement are used for the sidewalks, or to quantify the contribution of the non-structural elements), which are difficult to quantify analytically. Typically, two types of load tests can be distinguished: diagnostic load tests and proof load tests. In a diagnostic load test, a known live load is applied and the resulting structural responses are compared to analytically determined responses to better

DOI: 10.1201/9781003483755-31

understand the overall bridge behavior. Ultimately, a field-validated model can be developed and used for assessment. In a proof load test, a load representative of the factored live load is applied directly to the bridge to demonstrate in the field that the bridge fulfills the code requirements. As high loads are involved, the load needs to be applied incrementally, and at each load level, the structural responses need to be compared to pre-determined thresholds, the so-called stop criteria (Lantsoght *et al.* 2019; Christensen *et al.* 2022). When a stop criterion is reached, further increasing of the load is not permitted. A final type of field test is a collapse test, in which a bridge is loaded to failure, which can give a full insight into the structural behavior of the bridge and all its load-carrying mechanisms.

2 PROOF LOADING ASSESMENT

2.1 *General*

Proof loading methods used as a means to capacity-upgrade existing concrete structures are, at present state, highly country dependent. However, proof load testing assessments seem to be limited by procedure uncertainty, lack of consistent methodologies, guidelines and codes. Often reluctance towards proof loading is present since safety measures and traffic disturbances occur during testing. Short testing time and environmental conditions could influence the result acquisition. This challenge, combined with a possibility of structural collapse, provides an important bridge owner caution that has to be addressed to ensure confidence in proof loading methods.

2.2 *Denmark*

A comprehensive concrete bridge-proof loading research project in Denmark has been ongoing for approximately half a decade. The project collaborators are the Danish Road Directorate, the Technical University of Denmark (DTU), Aalborg University (AAU), and COWI A/S.

The proof loading concept has its basis in the Danish classification system, where specified axle loads are given for each classification vehicle (Vejdirektoratet - The Danish Road Directorate 2017; Schmidt *et al.* 2020). The heavy vehicles' positioning is described, where a classification vehicle A is placed in the desired position on the bridge. Adjacent to the vehicle A, a stable vehicle B load is applied. A bridge has sufficient resistance if the bridge class is higher than the class of the passing vehicle. The research includes a multidisciplinary approach that combines experimental testing, theoretical response evaluations, and probabilistic assessments. Bridges on a road stretch between Herning and Holstebro in Denmark were initially tested in the Danish bridge testing project. Some of the weakest bridges were seen to have significantly larger resistance than predicted theoretically (Schmidt *et al.* 2018). Several pilot-proof loadings were performed during the research project to verify the developed methods and to get unique experience with the in-situ response- and handling of sensitive equipment. It was experienced that in-situ proof load can be very challenging compared to laboratory testing due to the environmental and practical conditions which may affect result acquisition. This aspect is combined with a short testing time demand to reduce related costs and traffic disturbances. Advanced testing equipment should thus be efficiently optimized and reduced to an extent that meets these challenges and generates the desired output. The outcome aims to accommodate a satisfactory evaluation of deformations, stop criteria, target loads, etc., to ensure a sufficient proof load decision basis.

Experiences and findings from the Danish proof loading research project have generated input for a Danish bridge proof loading guideline, which is expected to be published soon. The guideline describes how to perform proof loading on one-span bridges with a background in the Danish classification system. A pilot project was initiated to verify whether the guideline procedure was possible. Four class 80 bridges were identified on a chosen road stretch, which was aimed to be upgraded to class 100 using the developed proof loading method. The bridges

were tested successfully in three days, (including a manageable traffic disturbance (Christensen *et al.* 2023)). Consequently, the road stretch was upgraded to class 100, and the results could be integrated into the Danish strategic road network.

2.3 *The Netherlands*

In the Netherlands, research related to assessment of existing concrete bridges originally focused mostly on reinforced concrete slab bridges, as a large number of these bridges form the 1960s and 1970s were found to be insufficient for shear upon assessment according to the newly introduced Eurocodes (Lantsoght *et al.* 2013; Lantsoght *et al.* 2017a). These efforts were in line with the development of the Dutch Guidelines for the Assessment of Existing Bridges (RBK) (Rijkswaterstaat 2013).

Assessment of existing bridges in the Netherlands is carried out at four different Levels of Approximation (LoA). The first LoA is usually a spreadsheet-based hand calculation, which compares the factored load effect in a simplified way with the factored capacity from the code. If the Unity Check, i.e. the ratio of demand to capacity, is more than one, the assessment is taken to the next level. If not, it is found with a simplified approach that the critical cross-section, and by extent, the bridge, fulfills the requirements. At the next LoA, a linear finite element analysis is used for finding the factored load effect, and the factored capacity is again determined using the code expressions. Then, if a next level is necessary, a nonlinear finite element analysis may be considered, following the Dutch Guidelines for Nonlinear finite element analysis of concrete structures (Rijkswaterstaat 2012). Finally, if none of the analytical approaches can demonstrate that the bridge fulfills the code requirements, and it is expected that additional sources of capacity can be activated, a proof load test may be considered.

Proof load testing in the Netherlands is not a common method of assessment. At this moment, a series of pilot proof load tests have been carried out (Lantsoght *et al.* 2017b). These pilot proof load tests showed the feasibility of proof load testing for the assessment of existing reinforced concrete bridges in the Netherlands, both for flexure and shear. However, it was decided to first carry out fundamental research to determine stop criteria for shear and to develop a probabilistic substantiation of proof load testing in line with the current code requirements before proof load testing can be carried out by market parties.

2.4 *Sweden*

Sweden owns approximately 30,000 bridges, of which about 4,000 are railway bridges and the remaining are road bridges BaTMan (Trafikverket 2023). Some 70% of these bridges are owned by the Swedish Transport Administration (Trafikverket), while the rest, exclusively road bridges, are owned by regional counties. Very few railway bridges are also owned by private companies. The bridge population is relatively young, with many built after the Second World War, and their design lifetimes vary. As codes have evolved and the quality of materials and workmanship has improved, many bridges have been designed with longer lifetime expectations. It is also acknowledged that the quality of the bridges is high. To the authors' best knowledge, failures or service impairments have been seldom encountered. Currently, capacity assessment is conducted using a national code issued by the Swedish Transport Administration (TRVINFRA-00331 2023), based on the European Norms (Eurocodes), incorporating adjustments from the previous Swedish national codes.

The assessment of the bridges is largely undertaken by consulting companies, supervised by 10 bridge specialists from Trafikverket. The initial assessment step involves automated worksheets or simple linear elastic calculations based on design values, complemented by verification through inspection reports in BaTMan. If the capacity conditions are met, no further steps are taken. If not, Trafikverket may contract more detailed analysis, which can include non-linear finite element simulations, in-depth inspections, and structural health monitoring. Sweden has a relatively short history of proof load testing of bridges.

According to (Elfgren *et al.* 2018), thirteen full-scale bridges have undergone testing in the past three decades, with five tested to the point of failure. The objectives of these proof load tests varied, including monitoring the bridge under controlled loads, validating advanced calculations, verifying strengthening methods, or checking for settlements. The tests conducted to the point of failure aimed to collect data for verifying and comparing capacities in shear of concrete and prestressed concrete bridges under concentrated loads, using methods like finite element modeling (FEM). The results consistently showed discrepancies between code estimates, test results, and numerical simulations, thus prompting further developments.

3 RECENT RESEARCH

3.1 *Denmark*

The bridge proof loading project's first version (V1) succeeded with significant in-situ test experience and descriptions of a test setup and related design. The optimized multidisciplinary approach seemed to work well where advanced monitoring could be optimized and reduced to an extent that enabled several pilot-proof loading tests. In addition, testing and theoretical evaluations also revealed sufficient interaction between OT elements under in situ and laboratory conditions. Thus, desirable slab behavior was obtained, enabling more optimized calculation methods and capacity upgrading of several bridges, see Figure 1.

Findings and results from the V1 project provided a good basis for continuing the Danish proof loading project based on the classification system. A good foundation for classification-based proof loading, which is economically competitive, seemed to be provided. The V1 project dealt with one-span bridges and seems to provide an excellent background for an extension to the second version 2 (V2), which will research methods to proof-load multi-span bridges. In addition, further evaluation and optimization of stop criteria is ongoing in the V2 project. This evaluation will be one of the main scopes since an open question remains concerning stop criteria related to the potentially brittle behavior of non-shear reinforced (shear-critical) slabs and prestressed concrete bridges. The extension to V2 was deemed to work in excellent synergy with upcoming international activities, ensuring an even more significant gain. One of the main aims is to extend the Danish guideline with the findings of the V2 project.

3.2 *The Netherlands*

Recent and current research in the Netherlands on proof load testing has mostly focused on fundamental research to support the proof load testing practice. This research has focused on

developing stop criteria for shear for use during proof load testing of reinforced concrete members without shear reinforcement, and on deriving a probabilistic substantiation of proof load testing.

The research on stop criteria encompasses two series of experiments. A first series consists of 25 experiments in flexure and shear on 6 reinforced concrete slabs of 5m × 2.5 m × 0.3 m subjected by a proof load testing protocol first, and then tested stepwise to failure. A second series, ongoing at the time of writing this paper, consists of 8 skewed reinforced concrete slab specimens, see Figure 2. To develop these stop criteria, first shear stop criteria for slab strips have been developed, and then these stop criteria are extended to reinforced concrete slabs. The shear stop criteria for beams can be found in (Zarate Garnica *et al.* 2024), whereas the shear stop criteria for slabs are under development. The second series of experiments has the following goals: 1) validate the developed shear stop criteria for straight slabs for the situation of skewed slabs, and 2) validate current assessment procedures for skewed slab bridges, and in particular the way in which the load effect is determined in the obtuse corner.

Figure 2. Skewed slab testing at TU delft.

The research on the probabilistic substantiation of proof load testing is addressing the following aspects: 1) time-dependent probabilities of failure (de Vries *et al.* 2022), 2) state of information and the effect of the type of prior selected (de Vries *et al.* 2023), 3) using stop criteria and measurements during proof load testing for the probabilistic analysis (de Vries *et al.* 2024), and 4) spatial variability.

3.3 *Sweden*

During the last 30 years about fifteen tests on bridges have been conducted in Sweden, primary led by Luleå University of Technology (LTU) (Elfgren *et al.* 2018). The most recent work on proof loading of bridges in Sweden aims at contributing to the sustainability challenge by identifying the True Capacity of the existing bridges. This is done by developing tools

Figure 3. Concept used at Luleå University of Technology (LTU) for life extension of existing structures.

and methods for life cycle assessment in areas of SHM, prediction simulations and tests, see Figure 3.

A 65-year-old prestressed box-girder concrete bridge in Kalix, northern Sweden, was demolished in 2022. Prior to this, an experimental campaign was conducted to enhance our understanding of the behavior of such bridges. The work focused on three aspects: (1) condition assessment of the bridge using non-destructive testing (NDT), (2) development of a proof loading method for assessing service limit conditions with standard convoys and Structural Health Monitoring (SHM) sensors, (3) formulation of controlled demolition methods for prestressed concrete bridges. The results have shown that NDT tools are promising for identifying defects, though they require further field validation and a comprehensive understanding of the bridge's design and construction principles. The proof loading method incorporated tests with new technologies, including Fiber Optic Sensors (FOS), acoustic emission testing, and various techniques for measuring prestressing forces. The developed demolition process was successfully executed, ensuring safety and environmental cleanliness.

Figure 4. View of the midspan of the Kalix bridge under proof loading.

New research related to railway bridges began in 2021 with an investigation into potentially increasing axle loads from 30 tons to 32.5 and 35 tons on one of the most heavily utilized railway lines, the Iron Ore Line in Northern Sweden. Approximately 50% of the bridges on this line are trough-type, comprising two side beams and a slab that form a U-shaped structure filled with ballast. The study (1) verifies the existing standard load distribution model by monitoring pressure distribution between the ballast and the concrete deck and beams, and (2) assesses the impact of increased axle loads on the lifespan of these bridges. Of high interest is the development of criteria for the fatigue assessment. Experiments are conducted on a full-scale model bridge (7 m × 4 m) in the LTU laboratory, Figure 5. A suite of sensors, including standard strain gauges, Linear Variable Differential Transformers (LVDTs), Fiber Optic Sensors (FOS) on the internal reinforcement and concrete surface, and photogrammetry for crack detection and mapping, has been deployed. The data collected will be utilized for benchmarking numerical analyses and subsequent parametric stochastic validation.

Figure 5. View of the full-scale trough bridge tested at the LTU lab.

Research into developing proof loading methods for railway bridges has included analysis, condition assessment based on autonomous crack detection, and instrumentation of four bridges of various designs: trough, composite steel girder - concrete slab, concrete arch, and portal frame bridges. Sensors have been strategically placed in areas deemed critical for assessing bridge performance. Controlled train loads have been applied in both dynamic and static tests under varying seasonal conditions. These tests aim to understand how temperature fluctuations and humidity levels over a year affect the interaction between the bridges and their support structures.

3.4 *State of collaboration*

Current research in Denmark, the Netherlands, and Sweden focuses in broad lines on the following common themes: modeling of existing concrete structures, automated condition assessment, improved instrumentation methods for field measurements, and probabilistic aspects, see Figure 6. Moreover, field testing occurs under constraints of time and budget. As such, sharing experiences is to the benefit of all. In particular, a synergy of activities can be found between the three countries for the following topics: solving practical challenges related to application of loading and sensors when multiple spans need to be tested, determination of the required number of positions and proof load for the test, extrapolation of results from one span to another span for an assessment, evaluation of the choice of testing a lower number of positions under a higher load, versus a higher number of positions under a lower load, and the practical repercussions of such a choice, and developing considerations for different types of bridges, and those that are multiply statically determinate versus statically indeterminate bridges.

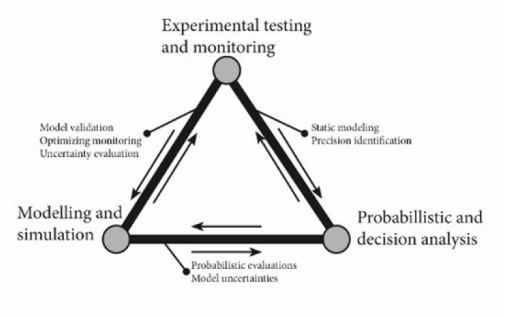

Figure 6. Synergy between research topics.

4 RECENT GUIDELINE AND ADVANCED IN INTERNATIONAL COLLABORATION

Recent research efforts related to proof load testing as illustrated above, as well as carried out by colleagues internationally, have resulted in the publication of a number of technical documents, codes and guidelines that may be of relevance to the reader. The first relevant document is a recent *fib* Bulletin of TG 3.2 (fib TG 3.2 2024), which includes a section related to proof load testing of existing structures, and in particular existing concrete bridges. For existing reinforced concrete buildings, the new ACI 437.2M-22 (ACI Committee 437 2022) code is a major development as compared to ACI 437.2M-13 (ACI Committee 437 2013), as the current version of the code includes the option to proof load test buildings for shear. For bridges, the upcoming version of the AASHTO Manual for Bridge Evaluation includes a new Chapter 8 on Load Testing, which is aligned with the contents of the TRB e-circular 257 (Alampalli *et al.* 2019).

Besides the recently published documents mentioned in the previous section, various international committees have included or are including load testing recommendations in their reports and guidelines. In particular, within IABMAS, the IABMAS Bridge Load Testing

committee is working together with *fib* COM 3 on the development of a guidance document related to proof load testing of existing concrete bridges. Moreover, the members of the IABMAS Bridge Load Testing committee meet twice a year virtually, as well as in hybrid mode at the IABMAS symposia. Interested readers can find the minutes of the activities of the technical committee on the IABMAS website (IABMAS 2021), as well as find the mission, goals and membership of the committee reported.

5 CONCLUSION

This paper shows how assessment of existing concrete bridges is carried out in Denmark, the Netherlands, and Sweden, and how proof load testing is used in these countries as part of the assessment. The paper also gives a summary of recent research insights from the three countries. A summary of the research efforts show that these efforts have been focused on combining load testing with better insights in structural behavior, applying improved instrumentation techniques in the field, combining measurements with numerical analyses, and providing a probabilistic substantiation of the practice. Synergy in the research efforts is identified by looking at the broad categories of practices applied in the three countries, even though assessment and proof load testing practices are driven by national differences. In conclusion: bridge load testing is a dynamic field of research that benefits from international collaboration. It is expected that further improvements to existing codes and guidelines will be forthcoming in the next years.

ABSTRACT: Structural assessment of existing bridges is one of the most challenging aspects for the correct and sustainable management of civil infrastructures that emerged in the last few years. Specifically, Italy has a substantial number of bridges over 50 years old, mainly represented by simply supported prestressed concrete I-girder-type with a cast-in-situ deck. Proof load testing represents an empirical alternative to the standard calculation methods commonly adopted for safety assessment of existing structures. This article investigates the reliability of a bridge in different configurations including damaged and undamaged scenario through site-specific traffic data collected by Weigh-In-Motion (WIM) systems in the Netherlands. Assuming a target load corresponding to characteristic load combination according to Eurocode provisions, the proof load test resulted into slightly reduced reliability indexes during the test while achieving higher values under successful completion. Preliminary results contribute to demonstrate proof load test can represent a valuable method for assessment of existing bridges.

1 INTRODUCTION

1.1 *Motivation for proof load testing*

Looking at the high number of ageing structures, management and safety assessment of existing bridges have emerged as increasingly crucial global concerns. Taking into account mainly the European and North American panorama (Calvi, et al., 2019), a pervasive imperative has arisen to understand the condition of our infrastructure to create prioritisation for good asset management and ensure ongoing safety and efficiency. Many bridges are reaching their nominal design life in the short term. For example, in Italy, the majority of the modern road network (total 840,000 km) was built during the two decades from 1955 to 1975 (Pinto & Franchin, 2010). Moreover, the intricate topography of Italy is a cause of a dense distribution of bridges (Calvi, et al., 2019), with an approximate frequency of one every two kilometres of highways (Miluccio, Losanno, Parisi, & Cosenza, 2021). Additionally, in (ANSFISA, 2022) it is possible to see that the Italian road network is mainly owned by Municipalities (~80%). Similar considerations for ageing bridges can be made in the Netherlands and the United States (Lantsoght, 2023).

DOI: 10.1201/9781003483755-32

In such a challenging framework, different safety assessment methods should be evaluated for the existing bridges (Lantsoght, 2023). This paper focuses on Proof Load Testing (PLT), i.e. a complementary method to the numerical desk-study assessment for evaluating bridges' structural safety against traffic loads. Basically, through a prescribed static loading protocol, the aim is to check actual bridge conditions by monitoring its structural response and at the same time obtaining a minor of its capacity. PLT assumes particular relevance when standard calculation methods encounter limitations, such as in case of lacking original plans (Shenton, J.Chajes, & J.Huang, 2007) (Anay, Cortez, Jáuregui, ElBatanouny, & Ziehl, 2015) or when numerical models are limited by a number of assumptions regarding structural analysis. Moreover, sometimes analytical safety checks are too demanding and time-consuming for several local authorities, when the level of knowledge is low and the number of bridges is very high with a limited budget for an in-depth safety assessment. In this case, exceptional vehicles that passed over the bridge during the past would represent a proof load and could be taken into account for reliability assessment in absence of deterioration phenomena.

1.2 *Codes and state-of-art overview*

As regards international code provisions, mainly two approaches can be acknowledged all over the world. The former approach is typical in the USA and is highlighted by the Manual for Bridge Evaluation (MBE) (AASHTO, 2011), which prescribes the so-called "Proof Load Test" to demonstrate the ability of the bridge to carry some "magnified" live load that is correlated to a specific load rating vehicle. The second approach is more typical in Europe, where an "acceptance" load test after bridge completion or extraordinary maintenance operations is conceived and it is based on an equivalent sectional effect between the load applied during the test and the design unfactored live load. Unfortunately, a fragmented outline persists in the European scenario regarding codes and guidelines for PLT (Lantsoght, 2023). For example, the Italian Building Code (Italian Ministry of Infrastructures and Transportation, 2018) only prescribes the so-called "acceptance" test. Recently, in 2020, the Italian High Council of Public Works (HCPW) issued new guidelines for classification and risk management, safety assessment, and structural health monitoring of existing bridges (Italian High Council of Public Works, 2020) introducing a "temporary operational" condition to be proved by load testing. Nevertheless, this PLT has to be followed by a conventional, i.e. analytical-based, safety assessment (to be completed within 60 days from the test). In (AASHTO, 2011) the calibration of proof load factors is based on literature review, (Lichtenstein, 1993) and (Transportation Research Board, 1998). In the European framework (Casas & Gómez, 2013), a methodology to calibrate proof loads to be applied to existing highway bridges was proposed, based on available WIM data for traffic modelling. Several modifications have been recently proposed by (de Vries, Lantsoght, & Steenbergen, 2023) to improve the PLT practice.

1.3 *Research objective*

After reviewing the current literature on PLT, this study aims to highlight the potential of an empirical alternative to the standard calculation methods commonly adopted for the safety assessment of existing I-girder PC bridges, linking proof load testing and structural reliability. Based on restricted but realistic hypotheses, theoretical benefits in terms of increasing reliability have been proved for different traffic load combinations and damage scenarios.

2 PROOF LOADING RELIABILITY

According to (Melchers & Beck, 2018), structural reliability is related to the probability of a limit state being exceeded for an engineered structural system at any stage during its life. The main concern of PLT is the calibration of the load to be applied in order to achieve target reliability, assuming that a trade-off between collapse risk during the test and posterior benefit regarding proved capacity has to be found. Indeed, the use of relatively high target loads entails an increased risk during the test itself, but once the test has been successfully completed

the reliability of the structure would be higher. For this reason, a reliability-based approach is required for a research-oriented analysis and calibration of proof load targets, stop criteria and methodology (Spaethe, 1994). In a probabilistic framework, all types of uncertainties and randomness affecting initial assumptions can be accounted for. The nominal probability of failure P_f (Melchers & Beck, 2018) and the relative Reliability Index β at a structural element level can be considered exhaustive safety measures. Considering all the variables as mutually independent, an example of general limit state function equation Z before any proof load test, adopted in (de Vries, Lantsoght, & Steenbergen, 2023) and (de Vries R., Lantsoght, Steenbergen, & Fennis, 2023), is represented by Equation 1:

$$Z = [\theta_R R - \theta_E G] - \theta_E C_{0T} T = R' - \theta_E C_{0T} T \quad (1)$$

where R represents a capacity measure, G is the permanent load (i.e. the self-weight plus the load due to non-structural elements) and T is the traffic live load. Both for resistance and loads, model uncertainties (θ_R; θ_E) may be considered in the analysis to account for approximation when calculating resistance and load effects, respectively. Finally, the random variable C_{0T} may account for time-independent uncertainties of traffic trend effects. During the PLT, Z_{PL} of Equation (2) may be considered as a limit state function, assuming that in the meantime of the test, the bridge is closed to traffic:

$$Z_{PL} = [\theta_R R - \theta_E G] - \theta_{E,PL} Q_{PL} = R' - \theta_{E,PL} Q_{PL} \quad (2)$$

where R, G, T, θ_R and θ_E are the same as Equation (1) and Q_{PL} represents the effect due to the proof load PL and $\theta_{E,\ PL}$ is the model uncertainty for the controlled proof load effect. Both Q_{PL} and $\theta_{E,\ PL}$ can be modelled as random or deterministic variables. Looking at the posterior analysis, at the state-of-the-art, different ways exist to consider the actual benefit due to a PLT in a reliability framework. The most consolidated and spread approach is to consider the effect generated by a specific load as a lower bound of the actual capacity of the bridge through a truncation of its probability distribution (Christensen, et al., 2023), (Transportation Research Board, 2019), (Casas & Gómez, 2013) and (Faber, Val, & Stewart, 1999). For instance, Equation (1) may still be considered valid with a truncate distribution of R'. Other methods to consider the additional knowledge about the bridge behaviour, such as a bayesian updating, can be found in (K. Nishijima, 2006), (Schmidt, et al., 2020), (Kapoor, Christensen, Schmidt, Sørensen, & Thons, 2021) and (de Vries R., Lantsoght, Steenbergen, & Fennis, 2023).

3 CASE STUDY BRIDGE

3.1 *General description*

The I-girder prestressed concrete (PC) deck archetype represents a significant number of Italian roadway bridges built during past decades. Most of the bridge stock is represented by simply supported decks of 30 to 40 m span with PC girders designed according to an allowable stress method in force at the time (Pinto & Franchin, 2010; Borzi, et al., 2015). In (Miluccio, Losanno, Parisi, & Cosenza, 2021) and (Miluccio, Losanno, Parisi, & Cosenza, 2022), the authors investigated the traffic-load fragility of a portfolio of I-girder PC bridges assumed to be representative of many existing bridges. At the Ultimate Limit State (ULS), the case-study bridges showed higher vulnerability (i.e. higher values of conditional failure probability) to flexural mechanisms rather than shear under traffic load model 1 (TLM 1) (Comité Européen de Normalisation, 2003). Grounding on these preliminary results, the authors of this paper assumed a case study bridge built during the '60s along an important highway in the South of Italy. With a span length of 42m and a total length of around 1km, the bridge is simply supported and it is composed of 3 m high PC I-girders, a cast in situ concrete slab (variable thickness between 0.20 and 0.30m) and four diaphragms (Figure 1).

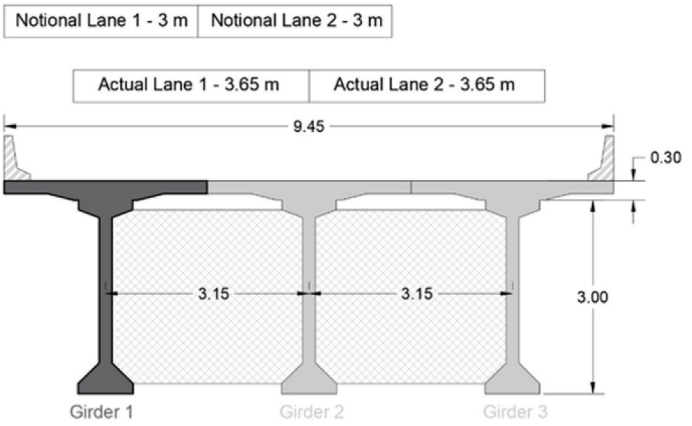

Figure 1. Deck cross-section including traffic load configurations.

Due to the deteriorating state of the viaduct, retrofit interventions were designed in the last few years in order to restore the full bearing capacity of the bridge. Original design and retrofit plans were made available. Additionally, an acceptance load test (i.e. imposed traffic load) after restoration was recently performed to reproduce the TLM1 bending moment. This effect was achieved with four steps of loading, each with two 42t heavy trucks. In the final loading configuration, the eight trucks were arranged according to the notional configuration of traffic (Figure 1). The structural response during the PLT was monitored through displacement transducers, demonstrating linear behaviour and no damage upon unloading.

3.2 *Capacity modelling*

At ULS, the flexural capacity model M_R (Equation 3) has been adopted by considering contributions from both prestressing steel area A_{sp} and reinforcing steel area A_s to be lumped in their centroid with internal lever arm $d \approx 0.9h_{section}$, being $f_{p,\,01}$ the conventional yield strength of prestressing steel and f_y the yield strength of mild steel:

$$M_R = d \cdot \left(A_{sp}f_{p,01} + A_s f_y\right) \tag{3}$$

During on-site visual inspections, different corrosion scenarios were detected in a number of girders prior to retrofitting. In the following analyses, both undamaged and damaged configurations have been assumed; in the latter case the most severe corrosion was considered in terms of 10% loss of total prestressing steel area (i.e. 8 out of 80 strands in total) and total loss of reinforcing steel area at the bottom of the beam (Table 1). Based on original plans, mechanical properties f_y and $f_{p,\,01}$ were assumed as lognormal random variables defined in the next section.

Table 1. Deterministic geometric variables.

Undamaged	Reinforcing steel area Prestressing steel area	A_s A_{sp}	6ϕ10 + 7ϕ20 80 strands*	2670 mm^2 7440 mm^2
Damaged	Reinforcing steel area Prestressing steel area	$A_{s,\,dam}$ $A_{sp,dam}$	- 72 strands*	0 mm^2 6696 mm^2

*1 strand = 7 wires 1/2''.

Safety checks in terms of internal bending moment accounting for partial safety factors at ULS yielded capacity-to-demand ratios (CDR) equal to 1.36 and 1.26 in undamaged and damaged configuration, respectively. The PLT was performed on the retrofitted bridge whose intervention aimed at restoring the original undamaged safety level (i.e., CDR =1.36).

3.3 *Load distribution factors*

Load distribution due to traffic load is paramount in assessing existing structures. In a few circumstances, simplification may be assumed. Because of the presence of a discrete number of diaphragms, the Engesser-Courbon method (Raithel, 1978) was adopted to calculate load distribution factors for the case study bridge. Basically, the deck deflection profile of the deck is assumed to be rigid in the transverse direction and defined in terms of downward displacement plus rotation only. The primary torsional stiffness of the single girder is neglected therefore deck torsional stiffness is associated with flexural stiffness of the girders. Additionally, the vertical displacements obtained during the load tests validated this assumption with a maximum error of less than 5%. Due to equal girders and traffic load eccentricity, the maximum bending moment M was expected at midspan in the edge right girder (i.e. girder 1) located beneath the slow lane where trucks primarily drive (Figure 1). Two different lane configurations were considered, one having notional lanes (3m width) and one with actual lanes (3.65m width) (Figure 1). In both cases, two load lanes are assumed to obtain maximum effects from the analysis. The effects of each lane in terms of distribution load factors of the edge girder are summarised in Table 2.

Table 2. Load distribution factors.

Lane configuration	Factor lane 1	Factor lane 2
Notional	0.83	0.35
Actual	0.64	0.03

3.4 *Traffic effect modelling*

Acknowledging the present absence of robust Italian Weigh-In-Motion (WIM) data and the methodological purpose of this article, for the present case study a statistical characterisation of traffic load is derived from WIM measurements, utilising an extensive dataset from the Netherlands. Preliminary WIM data from Italian highways is going to be made available in the near future also due to new guidelines promoting traffic monitoring of existing bridges, (Iervolino, et al., 2023) and (Cosenza & Losanno, 2021). WIM recording stations considered in this study are strategically positioned in the Netherlands along high-intensity highway locations and are assumed representative of the traffic load on the case study bridge. Considering that Netherlands traffic is some of the heaviest in Europe (O'Brien, O'Connor, & Arrigan, 2012), the former hypothesis could be considered conservative in terms of intensity and loads. Data from four specific locations (highways A16L, A27L, A50L, A67L) featuring 2-3 traffic lanes were selected due to their high quality. The weekly block maxima of the load effect were obtained to determine the distribution of the load effect in terms of maximum bending moment at midspan. Subsequently, the Gumbel extreme value distribution was fitted to the data using the maximum likelihood estimation (MLE) method. A threshold value (probability of exceedance S = 0.25) was selected to capture the linearly descending right tail of the distribution on the log scale. Lastly, the distribution of weekly maxima was converted to the distribution of annual maxima (de Vries, Lantsoght e Steenbergen 2023). Considering the load distribution factors of Table 2, the simulation was conducted for both notional and actual lane configurations, yielding two sets of parameters for the Gumbel distributions (Table 3), represented in Table 4 as T_{Not} and T_{Act}, respectively. The mean value of the traffic load in the

Table 3. Load effects due to Gumbel distributions for notional and actual traffic lane configurations.

Lane configuration	Annual mean [MNm]	COV [-]
Notional	9.13	0.039
Actual	6.63	0.019

notional lane configuration significantly exceeds that in the actual configuration due to higher eccentricity. Furthermore, contributions from the second lane amplify the coefficient of variation. The realism of the notional lane configuration is a subject of inquiry, especially when considering the layout of the bridge, including the presence of guardrails. Such a configuration would be code-compliant that rarely happens.

3.5 *Permanent load effect modelling*

Permanent load G (Table 4) is considered to model deck self-weight plus non-structural components. The mean value of the associated bending moment (11.70 MNm) is assumed to be equal to the value computed deterministically considering original plans, with a CoV supposed to be equal to 0.10.

3.6 *Proof load effect modelling*

The effect due to a proof load PL, α is modelled both deterministically and probabilistically. The Deterministic Proof Load (DPL) initial assumption considers $Q_{PL,\ \alpha}$ as a deterministic variable equal to α times the value M_{LM1}, which represents the unfactored TLM1 effect (Comité Européen de Normalisation, 2003). According to Italian code provisions for acceptance test (Italian Ministry of Infrastructures and Transportation, 2018), M_{LM1} was computed considering the notional configuration (Figure 1) with tandem (Q1K, Q2K) and distributed loads (q1k, q2k) for the first and the second lane, respectively. A remaining area uniformly distributed load qrk has been considered for the unfavourable parts of the influence lane. $\theta_{E,\ PL}$ is modelled as a deterministic variable equal to 1. For the posterior analysis, DPL truncates the lower tail of the random variable $R' = \theta_R R + \theta_G G$ at the value $\alpha * M_{LM1}$ and uses this distribution when computing Z. Two different values of α (1 and 1.5) are taken into account to investigate the influence of a PLT with a target effect equal to 100% and 150% LM1, respectively. The Probabilistic Proof Load (PPL) initial assumption considers $Q_{PL,\alpha}$ as a normal random variable with a mean equal to α times the value M_{LM1} computed as in the case of DPL. A CoV equal to 0.05 is considered to account for geometric uncertainty when positioning the trucks. $\theta_{E,\ PL}$ is modelled as a normal variable with mean and CoV respectively equal to 1 and 0.10. In the posterior evaluation of reliability, PPL considers only samples for which there is no failure during the PLT.

3.7 *Probabilistic models*

All the random variables used in the analysis are defined in Table 4. Bending moment probability distribution functions are displayed in Figure 2 without model uncertainties.

Table 4. Random variables.

Variable	Symbol	Unit	Mean	CoV	Distribution
Yield strength mild steel	f_y	*MPa*	440	0.075	Lognormal

3.8 *Methodology and results*

Before and during the PLT, P_f has been estimated as the probability of the limit state functions Z and Z_{PL} being not positive. After the PLT, the nominal probability of failure P_f (Melchers & Beck, 2018) has been estimated through the Monte Carlo Simulation (MCS) method for a time-invariant analysis, counting the number of successes over the total number of simulations. Considering the two Proof Load Effect Modelling (PPL and DPL), P_f at ULS has been estimated for each traffic load configuration, before, during and after the PLT, in both undamaged and damaged scenarios. Once P_f was estimated, reliability indexes β were calculated and are summarised in Tables 6 and 7. Percentage variations of β are computed according to Equation 4 and reported in Tables 6 and 7.

$$\Delta\beta_i\ [\%] = \left(\beta_i - \beta_{before}\right)/\beta_{before} \tag{4}$$

where β_{before} is the reliability indexes before the PLT and β_i is the reliability index during or after the PLT.

Table 6. Reliability indexes for undamaged scenario.

			During PLT				After PLT			
Traffic	Before PLT	α	PPL	[%]	DPL	[%]	PPL	[%]	DPL	[%]
Notional	4.25	1	3.67	-14	4.80	+13	4.58	+8	4.28	+1
Notional	4.25	1.5	1.95	-54	2.83	-33	5.88	+38	4.96	+17
Actual	5.26	1	3.67	-30	4.80	-9	> 6.0	> +14	5.61	+7
Actual	5.26	1.5	1.95	-63	2.83	-46	> 6.0	> +14	> 5.5*	> +5

*e10 trials without failure samples

Table 7. Reliability indexes for damaged scenario.

			During PLT				After PLT			
Traffic	Before PLT	α	PPL	[%]	DPL	[%]	PPL	[%]	DPL	[%]
Notional	2.79	1	2.13	-24	2.80	0	3.56	+28	2.99	+7
Notional	2.79	1.5	0.41	-85	0.55	-80	5.60	+101	4.93	+77
Actual	3.77	1	2.13	-44	2.80	-26	5.92	+57	4.67	+24
Actual	3.77	1.5	0.41	-89	0.55	-85	> 6.0	> +59	> 5.5*	> +46

*e10 trials without failure samples

It can be seen that the higher the value of the PLT, the higher the posterior value of β compared to its initial value. Assuming a PLT with $Q_{PL,\ 1}$ in the PPL hypothesis, in the case of undamaged configuration, the variation of β with the notional and actual lane is equal to +8% and more than +14%, respectively. Limited effectiveness in the case of a notional lane can be explained in terms of CDR larger than unit (1.36). In the case of lower CDRs as per damaged configuration, this benefit increased up to +28% and +57% for notional and actual lanes, respectively. As regards the differences between PPL and DPL, data indicates slight differences with higher values in case of PPL. Considering variability during the proof load test PPL results in lower reliability than neglecting proof load model uncertainty in DPL. As a matter of fact, for the notional configuration and according to DPL the reliability index doesn't reduce during the PLT. The lower risk during the PLT is reflected in a lower benefit after that, i.e. there is always a positive difference between β_{after} computed probabilistically and deterministically compared to β_{before}. This outcome suggests that the model uncertainty may have important effects on reliability and more investigation is needed.

4 CONCLUSIONS

Proof load testing is a powerful empirical method for the assessment of existing bridges, especially when the level of knowledge of the structure is limited. Specific considerations have to be drawn in terms of damage prevention during the test, target PLT and reliability levels during and after the test as well as in terms of feasibility. The paper presented a preliminary study on the positive impact of a PLT on an existing I-girder PC bridge deck, considering different traffic load combinations and both undamaged and damaged girder conditions. The higher the imposed proof load, the lower the reliability index during the test but the higher the benefit once it is passed successfully. In contrast to CDRs showing a relative difference of less than 10% between undamaged and damaged configurations, the impact of the PLT in terms of posterior reliability would be significantly higher. The methodology could be particularly effective for those bridges interested by exceptional traffic loads during the past which did not report any damage. Even if the preliminary results address the positive impact of PLT on existing bridges, a number of limitations have to be acknowledged from the present study. Further refinement of capacity modelling is recommended considering different failure mechanisms and limit states, such as shear mechanism and cracking. Experimental tests, including laboratory testing on prototype girders, could represent a benchmark for calibrating the PLT and reducing model uncertainties. Dynamic amplification factors should be taken into account when calculating the live load effects. WIM data represent a major breakthrough in traffic modelling to be developed in the near future for the reliability assessment of existing bridges.

ABSTRACT: A Danish concrete bridge proof loading project (V1) was initiated in 2016 and followed by a project extension (V2) initiated primo 2023. A main scope of the project V1 was to provide a classification-based proof loading procedure in accordance with the Danish classification system. In addition, significant CO2 and societal economical savings was deemed possible. A multidisciplinary approach was used for the evaluations involving multi-scale testing, theoretical capacity evaluations and probabilistic assessments. The project resulted in various novel testing and theoretical developments as well as significant experience gain. Several bridges were classified to a higher capacity through pilot projects, using the developed proof load test procedure. A Danish national guideline is expected to be published soon based on the findings, just as an excellent basis for the V2 project was established. Several main results from the V1 project leading to the background for initiating the V2 proof loading project, will be presented.

1 INTRODUCTION

The Danish bridge testing project (V1) was commenced to investigate the load-carrying capacity of existing concrete bridge structures through advanced evaluation, load testing, and probabilistic analysis (Schmidt et al., 2020) as it potentially could provide significant economic, CO2 and societal savings through enhanced understanding.

As an integrated project scope, the project aimed to establish a proof-loading test method tailored for one-span bridges in accordance with the Danish classification system (Vejdirektorat (The Danish Road Directorate), 2017). The Danish road bridges are classified through this unique system based on the weight and axle configurations from specified heavy classification vehicles. Figure 1a illustrates three examples of the vehicles outlined in the system. A heavy classification vehicle can cross a bridge if the bridge class is higher than the vehicle class. Failure to meet this criterion necessitates either a detour or a rearrangement of goods on the vehicle. A comprehensive literature study revealed a consistent trend of capacities being higher in practice than what was theoretically estimated during the design. Some of the reasons for this were deemed to be; 1) more desirable material parameters due to time dependency, 2) boundary conditions, 3) interaction between structural elements, and 4) redistribution of stresses, etc. (Bakht & Jaeger, 1990; Goodpasture & Burdette, 1973; Saraf & Nowak, 1998; Schmidt et al., 2018).

Nevertheless, the existing literature showcased a wide array of unique test approaches, predominantly tailored to specific bridge types, rendering them unsuitable as a universal foundation for the Danish project (Bagge et al., 2018). Furthermore, no prior testing had been

DOI: 10.1201/9781003483755-33

conducted in accordance with the Danish classification system. The project objective, however, was not only to evaluate the behavior of a specific bridge type but to develop a more standardized methodology for performing load-carrying capacity tests. Based on this knowledge, the following main research objectives were generated at the initiation of the V1 project:

- Carrying out several in-situ load-carrying capacity tests that will form the basis of an upgrading of the bridge class on which the tests were carried out.
- Perform capacity tests which can be used to identify- and evaluate the critical failure mechanisms in a bridge classification test perspective.
- Generate a link between applied theoretical- and monitoring methods and thus form a basis for a future strategy for non-destructive load testing of existing bridges.
- Develop calculation models that conform and verify the monitoring results from the full-scale testing.
- Provide optimized test set-ups that can reduce advanced methodologies into representative more simplified methods for evaluating the bridge class of one-span bridges.

Throughout this paper, the main findings and milestones related to these objectives will be discussed and an initial insight into the research perspectives of a newly initiated project extension, version 2 (V2), initiated primo 2023 will be revealed.

2 SAFETY MARGIN AND STOP CRITERIA

When performing in-situ bridge load testing, uncertainty regarding a sufficient safety margin seems to be a main concern (Christensen et al., 2023; Lantsoght et al., 2017). In previous studies, the authors suggested that a multidisciplinary approach may be required. Such an approach may involve; 1) representative testing combined with advanced monitoring, 2) initial calculation estimates sometimes followed by advanced modelling and simulation, and 3) probabilistic and decision analysis, see Figure 1b. These research field interfaces represent a transfer of information, that can help improve the evaluation approach within each field. Often the research fields 1,2 and 3 are not equally represented in research projects, since their substance often depends on the available information and scope of the project. The probabilistic research area 3, is often reduced and more focus dedicated to 1, and 2, if research projects contain well defined material- and structural information. However, 1 and 3 may be more in focus if little information concerning the material and structure is available and theoretical model uncertainties are relatively high. The latter often providing the basis for proof loading assessment. Consequently, the multidisciplinary research field synergy may help to improve initial considerations regarding proof loading and safety margin.

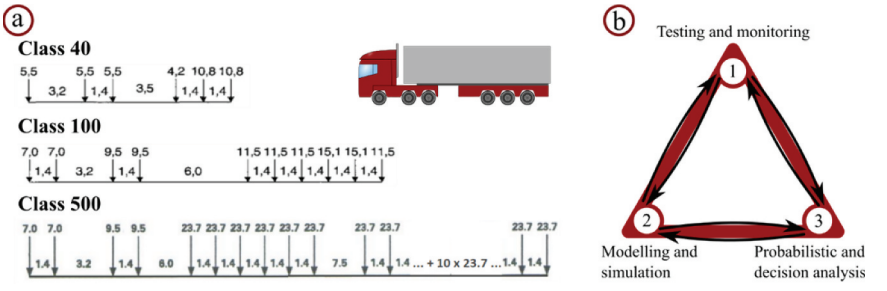

Figure 1. A) An example of the vehicles described in the Danish classification system. Axel loads in tons b) Schematic multidisciplinary research synergy overview (Schmidt et al., 2020).

The true in-situ behavior of a bridge structure may however only be revealed through load testing. Following a proof-load test, the multidisciplinary interactions between research fields may be updated in accordance with the obtained proof loading output. However, to do so, the response uncertainty and bridge collapse concerns must be considered beforehand, and measures must be

taken to avoid these. Monitoring-based stop criteria may be used to achieve this. Such thresholds may provide indications of irreversible damage during proof loading. Note that an effective stop criterion should provide a sufficient margin of safety but also not be overly conservative (Lantsoght et al., 2019). It is essential to use sufficient monitoring and loading schemes to ensure that the bridge response regimes are well depicted in the data acquisition. Only few countries have provisions that describe stop criterion thresholds but recent work in this field has aimed to combine the information given in the guidelines to provide a flexure stop criterion threshold (Lantsoght et al., 2019). Work is still ongoing regarding suitable stop criteria in general, but especially those relating to shear failure mechanisms and pre-stressed concrete structures are still up for discussion. Typical stop criterion values relate to strain, crack width, stiffness reduction, etc. which are quantitative values where a qualitative outcome can be deformation profiles, load-deflection curves, crack detection, and overall structural behavior (Schmidt et al., 2022). Digital image correlation (DIC) measurements have been a superior measurement tool in the Danish bridge testing project combined with conventional monitoring (LVDTs, Strain gauges, distance lasers). Especially a wide-angle 2D system was investigated to provide high-resolution monitoring and facilitate a short installation time. However, due to out-of-plane movement, the 2D DIC system measures too large strain values and must be corrected (Halding et al., 2019). It should be noted that a large distance from the camera to the surface reduces the error and that for pure out-of-plane movement, the error is always on the safe side when monitoring towards stop criteria. A common stop criterion is monitoring of crack widths. The following are some examples of stop criteria provided in literature for crack width in flexure:

- The German guideline where the crack width has to be within, $w_{max} \leq 0.5$ mm for new cracks and $w_{max} \leq 0.3$ mm for existing cracks (DAfStb, 2000).
- A more theoretically based criterion is presented in (Lantsoght et al., 2019) where crack widths are proposed to be within $w_{max} \leq 0.11$ mm and $w_{max} \leq 0.19$ mm, based on the considered bridges. It is also stated that crack widths less than 0.05 mm should not be considered as a crack.
- Using EN 1992-1-1 (EC2) maximum crack widths in the serviceability limit state are $w_{max} \leq 0.2$ mm for pre-stressed members with bonded tendons and $w_{max} \leq 0.3$ mm for non-prestressed structures.

Quantifying the stop criteria thresholds still requires further research where failure mode, monitoring precision, loading approach, etc. must be evaluated in a theoretical and/or probabilistic perspective. An additional constraint that can have a significant effect on an in-situ proof load testing project is engineering judgment and related experience. A link that provides a desired connection between laboratory- and in-situ testing seems extremely important but is challenging due to the different environmental and test conditions, related equipment, and crew capabilities (Christensen, Halding, et al., 2022). Nevertheless, such projects are often tied up in delivering robust advanced methods that provide consistency and sufficient precision which can generate a proof loading decision basis. In addition to monitoring-based stop criteria related to damage states, the definition of a relevant target load may also be considered a stop criterion. The magnitude of the target load must be determined so that the test gives grounds to conclude that the bridge has sufficient reliability, ensuring it can withstand actual load effects anticipated on the bridge. Multiple approaches exist for determining the target load (Casas & Gómez, 2013), but most require input from resistance models. However, bridges with poor information on the resistance are the ones most relevant for proof-load testing. As part of the Danish bridge testing project, an alternative approach to target load has been presented (Christensen et al., 2023), where the target load is determined based on representative standard vehicles from the Danish classification system (Vejdirektoratet (The Danish Road Directorate), 2017) and associated probabilistic design guideline.

3 V1 IN-SITU TESTING

Throughout the V1 project, several in-situ tests have been performed and different approaches have been applied for load application and monitoring setup. The tests comprise full-scale high magnitude load tests, subcomponent tests, and proof-load testing.

3.1 *High magnitude load testing*

Several bridges were tested on a road stretch in Denmark in 2016 (Schmidt et al., 2018). The most critical of these bridges were OT (upside down T-beam)-slab bridges and they were originally evaluated to class 40. To test these bridges, a novel high-magnitude load testing rig was needed. The classification vehicle for class 40 has a maximum axle load of 10.8 tons. The test setup was designed as a cradle system with cross-beams, hydraulic pistons, and wheel pressures reflecting the Danish classification system and with a significant capacity reserve compared to the original bridge class. However, when testing these bridges, the axle load capacity for the test setup of 100 tons was reached. At this time, no visible cracks were seen. The axle load level was approximately 4 times higher than the highest axle loads in the Danish classification system, belonging to the class 500 vehicle. The results indicated that significant capacity reserve may be present when dealing with concrete OT-slab bridges. In addition, the tests provided significant experience with high-magnitude load testing. In addition to the full-scale in-situ tests, several subcomponent tests were performed. Slab strips were cut from the bridge deck and tested in-situ with the same test rig setup, and beams were cut to be tested in the laboratory. These tests provided some of the same indications of available capacity reserve but also provided more information for the identification of stop criteria. The link between in-situ testing and laboratory testing was, however, identified as one of the major challenges, because in-situ testing often involves: 1) A short testing time window, where preparations should be made to limit the effect on traffic, and 2) Challenging environmental conditions that differ significantly from the laboratory. The valuable information gained in all these initial tests provided the background for later pilot tests of four single-span bridges which were upgraded from class 80 to class 100 through the developed in-situ test approach. In addition, it provided an important basis for the later approaches developed in the project.

3.2 *Proof-load testing*

Based on the initial findings and application of the multidisciplinary approach used in the project, (Figure 1b), a national guideline, expected to be published soon, on proof load testing was developed (Vejdirektoratet (The Danish Road Directorate), 2021). To verify the concepts of the guideline, an in-situ pilot proof load project was arranged. For this project, a more time-effective test method was developed. This method involved the use of special vehicles reflecting the Danish classification system with individually hydraulically controlled axle loads. Such vehicles are shown in Figure 2a along with a concept drawing and the classification vehicles.

The pilot project scope was to show that the developed method could be used as a basis for upgrading the bridges on a class 80 road stretch into a class 100. If the project succeeded, the road way could be included in the existing traffic roadway system where Class 100 heavy vehicles can drive freely without applying for a Danish permit.

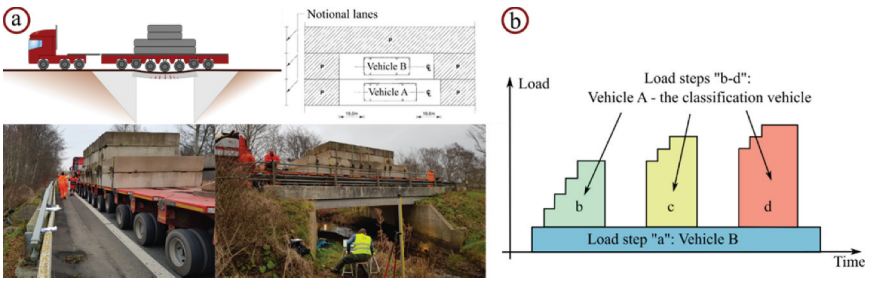

Figure 2. A) Example of testing using special heavy vehicles with hydraulic axle control. b) Example of a loading scheme for proof load testing.

The target load was defined according to a reliability-based method (Christensen et al., 2023) and was applied in load steps with increments as seen in Figure 2b. Monitoring was applied according to the provisions of the Danish proof loading guideline with output from a land surveyor, hydraulic output of the test vehicles and real-time DIC (Christensen et al., 2021;

Christensen, Zhang, et al., 2022). All four bridges were successfully tested to the designated target load. An example of a response curve can be seen in Figure 3a. The maximum deflections of the bridges were 0.45 mm, 2.0 mm, 0.63 mm, and 0.65 mm, respectively, and no visible signs of distress were observed. This was supported by the real-time DIC, where no signs of crack initiations or critical deformations were measured. Consequently, the road stretch was upgraded from a class 80 to a class 100 road stretch. The pilot project thus indicated the applicability of the Danish guideline which applies for one-span bridges with a span from 2m to up to 12m.

4 LABORATORY TESTING AS A REFERENCE

In order to perform the proof load testing and provide the basis for the national guideline, significant background knowledge was required. A part of this knowledge, was gained through several advanced laboratory tests, with a large array of monitoring equipment (Christensen, Halding, et al., 2022) applied. The laboratory tests reflected the experiences and gains from the in-situ testing throughout the V1 project and provided additionally directions for important areas of improvement. For instance, in-situ conditions were implemented in the laboratory for the DIC system with no artificial lighting and camera distances similar to the in-situ bridges. Additionally, supporting the tested slabs along three edges was used to mimic a continuous slab and to test the shear transfer capabilities of the construction joints between the OT-elements. The primary components of the laboratory test setup are depicted in Figure 3b. The setup components included (1) multiple load-carrying columns with three stiffeners, (2) horizontal I-profiles along three edges for support along with pinned bearings between the profiles and the slab surface, (3) the primary actuator used for load application, and (4) the OT-slab. The described setup provided a transverse span of approximately 1.6 m and a longitudinal span of approximately 7.5 m.

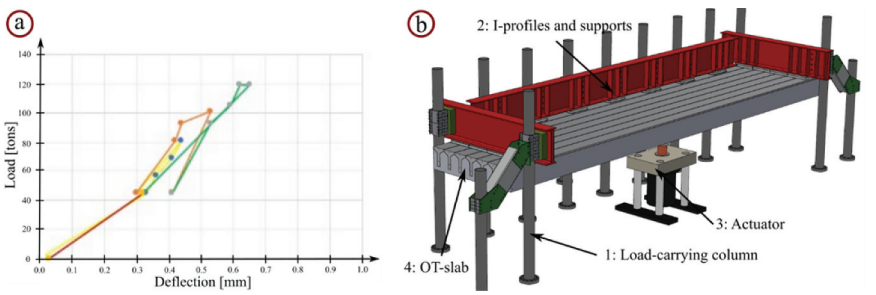

Figure 3. A) Response curve from a proof load test. b) Laboratory test setup for testing of OT-slabs.

A large monitoring setup of approximately 60 sensors of at least 8 different types was applied (LVDTs, strain gauges, wire potentiometers, load cells, inclinometers, distance lasers, DIC, and AE (Acoustic emission). The evaluation included a comparison of sensor output and establishing the relevance of the different sensors. The 2D DIC camera was placed at a distance of 3.8 m to provide a correlation with the in-situ tests. The surface was covered in a black speckle contrast pattern and no additional light except for the laboratory overhead lighting was applied (Christensen et al., 2021). It should be noted that the application of a surface pattern generates an extra working procedure compared to direct measurements on the concrete surface. However, the used application method and optimized pattern seemed applicable for in-situ testing as well, and was deemed to provide a more optimized measurement consistency; this was later verified in the proof load testing. The AE sensors were placed based on the test results from the first slab test in the critical zone. AE analysis was performed in collaboration with colleagues from TU Delft (Christensen, Zhang, et al., 2022). Since AE measures inside the structural component and DIC on the surface, they are independent, and the combination of the two methods may be a desirable monitoring method for future

application. Figure 4a shows the load/deflection curve from two laboratory OT-slab tests. Markers are placed for crack detection and fully developed yield lines. The crack patterns of these two stages are additionally depicted in Figure 4a.

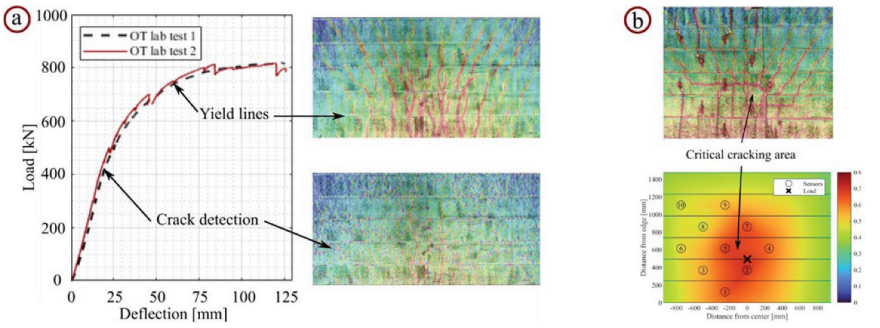

Figure 4. A) Results from OT-slab tests. I) Response curve, ii) Crack pattern at crack detection, iii) crack pattern with developed yield lines. B) Comparison of DIC crack pattern and AE activity contour (calm ratio). AE sensors are numbered 1-10.

The tests supported previous indications of sufficient interaction between the OT-beam elements to provide slab behavior. In terms of 2D DIC, it was seen that crack detection occurs in the linear elastic regime before any stiffness change. Directly measured values (without correction for out-of-plane movement) from a distance of 3.8 m, resulted in a crack detection between 0.2 mm and 0.3 mm. However, after correcting for out-of-plane movements, the crack widths ranged from 0.080 to 0.132mm which is below the EC2 SLS threshold. When combining the DIC crack pattern and acoustic emission (AE) a good correlation was found. High AE activity was seen in the areas with extensive cracking and much less activity in the lesser- and un-cracked areas (Christensen, Zhang, et al., 2022), Figure 4b. The results indicated that the DIC seemed efficient as an independent monitoring technique, whereas AE may be more advantageous to use in conjunction with other monitoring techniques. However, to ensure optimal proof loading, it seems beneficial to apply several independent monitoring methods in conjunction with a sufficient loading scheme, as described in the, soon published, Danish proof loading guideline (Vejdirektoratet (The Danish Road Directorate), 2021) and in associated research paper (Christensen et al., 2023).

5 UPCOMING ACTIVITIES

The upcoming activities of the V2 project reflect the achievements and conclusions of V1 but also involve the shortcomings. So far, the proof-loading guideline facilitates proof-load testing of specific bridge types. However, further refinement for stop criteria assessment is required and the guideline must be expanded, to facilitate testing of more bridge types. For the V2 project, the Danish Road Directorate has opened opportunities to perform in-situ tests on a series of bridges. The primary bridges are multi-span bridges set for demolition due to a highway expansion from two to three lanes. However, other bridge tests on both single-span and multi-span bridges may also present themselves in the project duration. A special focus will be dedicated to four wing bridges which are almost identical and highly relevant for the Danish bridge testing project. Example drawings of the concrete wing bridges are depicted in Figure 5 with a plan view (Figure 5a), a side view (Figure 5b), and a section view (Figure 5c). The concrete bridges are constructed with prestressed in-situ cast main girders and slabs which terminate sideways with cantilever wings. The full three span bridges are evaluated to a sufficient classification capacity and are relevant for testing in several localized areas for different test purposes. Ideally, the middle span could be used for in-situ testing, however, due to passing traffic in the middle span during demolition, the focus is initially dedicated to the side

spans, see Figures 5a and b. Figure 5c governs additionally initial thoughts on how testing may be performed. Work in regards to a suitable monitoring setup is presently ongoing. However, it should be noted that the descriptions are very early test considerations and may be adjusted before the final test approaches are settled upon. It is the aim to cut the slabs between the main girders of the full bridge in a way that enables in-situ slab testing of representative slab subcomponents. Such a cut-out is shown in Figure 5c.

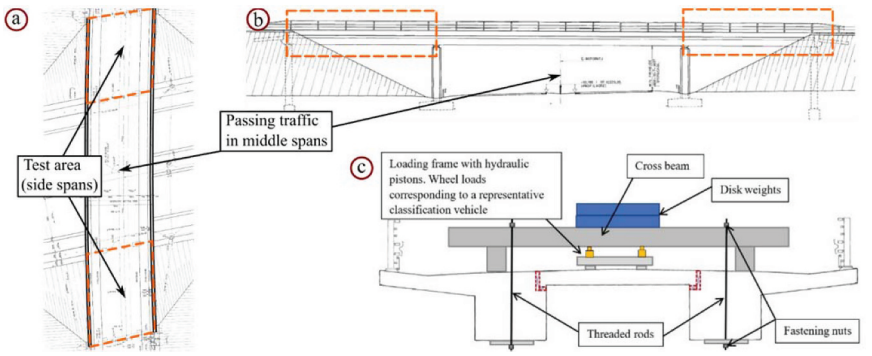

Figure 5. A) Plan view with marked test areas, b) side view with marked test locations, and c) Section view with initial thoughts on a load rig.

The slab length is aimed to be approximately 10m. A vertical and horizontal cut may separate these from the longitudinal main girders. This ensures more relevant support boundary conditions toward single-span non-shear-reinforced slab bridges. The slabs may be tested using the loading frame setup also illustrated in Figure 5c. Drilled holes through the longitudinal main girders enable mounting of the threaded rods to the loading frame and underneath the main girders. Underneath the cross beams, the loading frame may be placed for the representation of loads of the Danish classification system. The load will be applied using hydraulic pistons between the cross-beams and the loading frame and potentially counteracting disk weights. In addition, material and subcomponent testing will be performed which may include beams and slabs that are cut from the middle span during the demolition process. As part of the investigations, the authors aim to evaluate structural failure modes of the tested specimens and evaluate potential brittle or ductile behavior further. Identification of sufficient stop criteria related to obtained failure modes and multi span bridges will additionally be a primary investigation. Based in the V2 project findings it is the aim to update the Danish proof-loading guideline.

6 CONCLUSIONS AND PROJECT OUTLOOK

It can be concluded that the significant experience with the multidisciplinary approach was gained. The V1 project succeeded in performing representative testing in accordance with the Danish classification system. The project identified capacities which was significantly higher than predicted theoretically in the in-situ test and desirable interaction between the OT slab-elements, to provide slab behavior, was identified. Consequently, plate behavior with yield lines occurred in the laboratory tests and provided comparable DIC and EA results when evaluating the crack pattern. Based on in-situ -and laboratory testing an optimized monitoring method was developed including real time evaluations during testing. The findings and experiences from the V1 project provided a good basis for the upcoming Danish guideline on proof load testing of concrete bridges. The guideline was thus used as basis for upgrading a road stretch with four bridges, from class 80 to class 100, in a pilot project. The research additionally provided knowledge which revealed areas where more knowledge is needed which is included in the V2 research scope. Investigations of stop criteria thresholds related to relevant failure mechanisms of non-shear reinforced slabs for both single and multi-span bridges, will be investigated. It is the aim to update the Danish proof-loading guideline, accordingly.

ACKNOWLEDGEMENT

Special thanks to the Danish Road Directorate for their pivotal role in the Danish concrete bridge testing project. We are grateful for your support and are looking forward to our continued collaboration on load testing practices in Denmark. Additional thanks are addressed to all collegues and partners, who has taken part in the Danish bridge testing project - technicians, workers and scientists, thank you. Your knowledge and competence have been instrumental for our shared success.

ABSTRACT: Proof load testing is increasingly used to assess existing road bridges. The load configuration of a proof load test is however an open research question and approaches vary in the literature. To the author's knowledge, a comprehensive comparison of different load configuration approaches is not available in the literature. As part of a Danish bridge testing project a literature study has been carried out regarding proof load configurations. This paper presents part of this study with an emphasis on comparison between the Danish approach and approaches using the Eurocodes LM1. A brief state-of-the-art is presented. Following this, proof load configurations calculated from Danish codes and guidelines are compared with LM1 approaches. The results indicate numerous benefits of a bridge classification system like the Danish. The research may inspire a common European bridge classification system, ultimately paving the way for better utilization of bridges through proof loading.

1 INTRODUCTION

For the assessment of existing bridges where traditional assessment methods fail to show sufficient load-bearing capacity or for which there is little to no documentation, proof load tests may be carried out to prove the desired capacity. Many of the European bridges in use today were erected in the 60s and 70s. In many cases theoretically determined load bearing capacities prove insufficient for allowance of the heavier vehicles of today, especially regarding special transports. These are transports exceeding legal weight limits, which therefore need to apply for permits for travelling on roads and crossing bridges. Practices for issuance of these permits vary greatly within Europe (European Commission, 2008) and the practice is highly related to the traffic load models adopted. Commonly, the first approach to assessing bridges along the desired route of the special heavy transport is to compare the load effects, bending and shear, of the special transport to the load effects of the traffic load model, for which the bridges were designed or later classified (Bundesministerium für Verkehr und digitale Infrastruktur, 2016; Correia & Branco, 2006; Statens Vegvesen, 2023; Trafikverket, 2011; Vigh & Kollár, 2007). If this proves insufficient, a following approach is commonly to carry out direct assessment of the bridge for the special transport applied for. It is of course desirable to reduce the number of direct assessments or proof load tests. Therefore, the load applied in a proof load test should be chosen, such that an appropriate number of future permits can be granted through the first approach.

A common approach to proof load testing, is to calculate proof load factor to be multiplied by a chosen load model, such that the posterior reliability of the bridge, after a successful test, is proven equal to or higher than the target reliability. Throughout the years, different methods

DOI: 10.1201/9781003483755-34

to determine proof load factors have been reported, some without consideration of a code traffic load model (Faber et al., 2000) and some with the consideration of predetermined traffic load models but with uncertainty modelled based on probabilistic guidelines (Christensen et al., 2023; Lantsoght et al., 2017; Saraf & Nowak, 1998) or traffic measurements (Casas & Gómez, 2013). Some of these studies consider a resistance model, while others omit them.

In this paper, comparisons are made between Danish approaches to proof load configurations and approaches using the Eurocode Load Model 1 (LM1). Danish proof load factors are calculated both with and without inclusion of a resistance model to investigate the research questions:

- What are the advantages and disadvantages of applying proof loads based on Danish codes and guidelines compared to using LM1?
- What is the gain from including knowledge on a resistance model when calculating proof load factors?

2 STATE-OF-THE-ART ON PROOF LOAD CONFIGURATIONS

2.1 *Theoretical background for proof loading*

The goal of a proof load test is typically to prove that the reliability of the structure is at least equal to the target reliability. Prior to a proof load test, when there is knowledge on the resistance, the probability of failure, P_f, is calculated as the probability of the load effect, S, being higher than the resistance, R, (Thoft-Christensen & Baker, 1982), $P_f=P(R<S)$, see Figure 1a. If the target reliability is not reached through this evaluation, a proof load test can be carried out, where the structure is loaded to a desired load effect S_p. With the knowledge that the resistance is at least equal to S_p, the resistance can be truncated to give R^* (Nowak & Tharmabala, 1988), see Figure 1b. The probability of failure may then be calculated as $P_f=P(R^*<S)$. If there is no knowledge on the resistance, the probability of failure may be calculated as the probability that the actual traffic load effect, Q_{actual}, is higher than the proof load effect, Q_{proof}, (Christensen et al., 2023), $P_f=P(Q_{proof}<Q_{actual})$, as the actual dead load, G_{actual}, is deterministic and present both during and after the test, see Figure 1c.

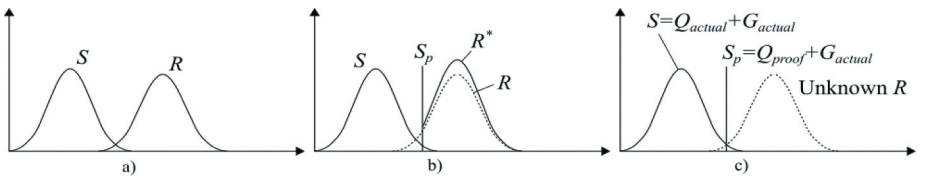

Figure 1. Probability density functions for a) probabilistic assessment b) proof load assessment with a resistance model and c) proof load assessment without a resistance model.

2.2 *Traffic load modelling*

When modelling traffic loads, the Eurocodes use LM1 (European Committee for Standardization (CEN), 2003). LM1 is based on Weigh-In-Motion (WIM) data from 1986, from which the heaviest vehicle measured had a gross weight of roughly 75 tonne (Sedlacek et al., 2008). LM1 contains both a tandem axle and distributed load in each lane, see Figure 2. A limitation is that this load configuration does not reflect the complex axle configuration of real heavy vehicles, which usually consist of multiple axle groups. Instead, it is determined from influence lines to give the 1000-year extreme moment and shear for different bridge spans as extrapolated from the WIM-data.

In Denmark, a bridge classification system is adopted, where both special transports and bridges are classified based on a set of standard vehicles (Ravn et al., 2006). When a special transport permit is applied for, the special transport is classified by determining the shear and moment along simply supported beams of different lengths which is then compared to the

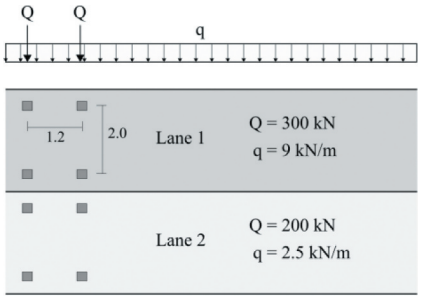

Figure 2. Eurocode LM1. (European Committee for Standardization (CEN), 2003).

same load effect of the different standard vehicles. The standard vehicles range from class 10 to class 500 denoting roughly their gross weight in tonne (Vejdirektoratet, 2017). Examples of three standard vehicles are given in Table 1. Compared to LM1, the use of such standard vehicles may better resemble the axle configurations of real heavy vehicles.

Table 1. Danish standard vehicles. (Vejdirektoratet, 2017).

Class	Axle configuration (loads in [t], spacings in [m])
100	7,0 7,0 — 1,4 — 3,2 — 9,5 9,5 — 1,4 — 6,0 — 11,5 11,5 11,5 15,1 15,1 11,5 — 1,4 1,4 1,4 1,4 1,4
150	7,0 7,0 — 1,4 — 3,2 — 9,5 9,5 — 1,4 — 6,0 — 7 × 17,8 — 1,4 1,4 1,4 1,4 1,4 1,4
200	7,0 7,0 — 1,4 — 3,2 — 9,5 9,5 — 1,4 — 6,0 — 8 × 21 — 1,4 1,4 1,4 1,4 1,4 1,4 1,4

2.3 *Proof loading*

As part of the EU ARCHES-project, (Casas & Gómez, 2013) determined proof load factors to be applied to the design LM1 load model. The goal of the ARCHES project was to raise the standard of the highway structures of Central Eastern European Countries (CEEC). CEEC proof load factors were based on WIM-data from the Czech Republic, Poland, Slovenia, and Slovakia. Dutch data was also used to calculate proof load factors for comparison. The WIM-data contained both normal traffic and special transports weighing up to 165 ton. Proof load factors were calculated both with and without resistance models for different 50-year lifetime reliability indexes, β_{target} = 2.3, 3.6 and 5.0, and for different bridge spans between 10 and 35 m.

When a resistance is assumed to be known and is included when determining the proof load factor, the ratio between the modelled resistance and load effect will influence the resulting proof load magnitude i.e., if R in Figure 1b is shifted left, S_p must be shifted right for $P(R^*<S)$ to still be equal to the target failure probability. To describe this shift (Casas & Gómez, 2013) introduced a parameter R/R_n, which is varied between 0.5 and 1.0. R_n is deterministic and is equal to the design load effect such that R_n is the resistance needed for the design equation to give a utilization of 1. R is the stochastic resistance, which is modelled with a bias = 1.12 for the chosen R/R_n and COV = 0.14.

In The Netherlands, viaduct de Beek was proof load tested using a test rig simulating only the tandem axles of LM1 (Lantsoght et al., 2017). The magnitude of the proof load from the tandem axles was determined such that the resulting maximum sectional force was equal to that of the combined LM1 tandem axles and distributed load including a proof load factor.

In Denmark a bridge was classified from class 80 tonne to class 100 tonne through proof loading with axle spacings corresponding to the rear axle group of the standard vehicle (Christensen et al., 2023). The proof loading magnitude was determined without including a resistance model based on the old probabilistic guideline (Vejdirektoratet, 2004). Presently, a new probabilistic guideline is being prepared and is expected to be published shortly (Vejdirektoratet, 2024).

3 PROOF LOAD FACTORS CALCULATED FROM DANISH CODES

3.1 *Calculation basis*

The proof load factors in the following calculations are calculated for proof loading of an existing bridge in CC3 for bending, which can be assumed to give warned failure without capacity reserve. This results in an annual target reliability of $\beta_{target} = 4.8$ (Vejdirektoratet, 2010). Proof load factors are calculated for class 100, 150 and 200, both with and without a resistance model. An existing Danish single span concrete bridge with 10 m span is used as a base case to model the resistance, R_{basis}, and the dead loads. For simplicity, the bridge is modelled as a 3 m wide beam corresponding to the notional lane within the Danish classification system and the Eurocode.

Comparably to the R/R_n approach by (Casas & Gómez, 2013), in the following, proof load factors with resistance are determined for different values of the reciprocal of the design utilization, $R_d/R_{d,req}$ or R_d/S_d, where R_d is the design resistance, $R_{d,req}$ is the required design resistance and S_d is the design load effect, see Figure 3. R can then be modelled as $R_d/S_d \cdot R_{req}$, given that R and R_{req} have the same coefficient of variance (COV) and that R_d and $R_{d,req}$ correspond to the same quantile. R_{req} is determined from the resistance model of the base case bridge as $R_{req} = z \cdot R_{basis}$, where z is determined from the design equation such that $z \cdot R_{d,basis} = S_d$.

For the resulting proof load factor to be sensible when a resistance model is included, the prior probability $P(R<S)$ must give $\beta < \beta_{target}$. Therefore, another parameter, $(R/S)_{prob}$, is introduced and is determined from such that $P((R/S)_{prob} \cdot R_{req} < S)$ gives $\beta = \beta_{target}$. Then $R_d/S_d < (R/S)_{prob}$ for the proof load to be sensible. For the calculations in this paper, R_d/S_d has been varied in the range $0.75 \le R_d/S_d \le 0.95 \cdot (R/S)_{prob}$.

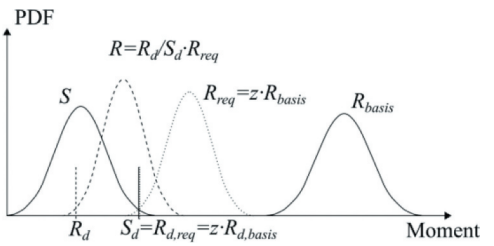

Figure 3. Approach to determine R for different values of R_d/S_d based on R_{basis}.

3.2 *Design equation*

z is determined from the design equation (1) for which variables are listed in Table 2.

Table 2. Variables in the design equation, Equation (1).

Variable	Description	Value
f_{yk}	Characteristic reinforcement yield strength	550 MPa
γ_s	Reinforcement partial safety factor	1.2
f_{ck}	Characteristic concrete compressive strength	25 MPa
γ_c	Concrete partial safety factor	1.45
K_{FI}	Consequence factor	1.1 for CC3
Q_k	Characteristic vehicle weight (same as μ_W)	Class 100: 109.2t Class 150: 157.6t Class 200: 201t
φ_k	Dynamic factor	1.228 for L_{inf}=10m
γ_Q	Traffic load partial safety factor	1.25
G_k	Characteristic structural dead load (concrete)	25 kN/m3
G_{wk}	Characteristic additional dead load (1.2 m gravel)	18 kN/m3
γ_G	Dead load partial safety factor	1.00

$$z \cdot R_{d,basis}\left(\frac{f_{yk}}{\gamma_s}, \frac{f_{ck}}{\gamma_c}\right) = S_d\Big(Q_k \cdot \varphi_k \cdot \gamma_Q \cdot K_{FI},\ (G_k + G_{wk}\Big) \cdot \gamma_G \cdot K_{FI}) \tag{1}$$

3.3 *Prior probabilistic assessment*

$(R/S)_{prob}$ is determined from the limit state equation (2) such that $\beta = \beta_{target}$. Variables of the equation are listed in Table 3.

$$g = z \cdot (R/S)_{prob} \cdot R_{basis}\big(f_y \cdot I_{fy}, f_c \cdot I_{fc}\big) - S\big(Q \cdot I_Q \cdot (1 + S_t), G + I_G, G_W + I_{G_W}\big) \tag{2}$$

The stochastic models used are based on the Danish probabilistic guideline (Vejdirektoratet, 2024). In accordance with the guideline, the material model uncertainties, I_{fy} and I_{fc}, are calculated including the model uncertainty on the computational model, material identity and determinataion of material parameters. The annual extreme vehicle weight, Q, is calculated based on the vehicle weight, W, and the number of vehicles per year, N, see Equation (3).

$$F_{max}(q) = \exp(-N(1 - F(w))) \tag{3}$$

Table 3. Variables for the probabilistic assessment, see Equation (2) and (3). Variables are based on (Vejdirektoratet, 2024).

Variable	Description	Distribution	Mean, μ	Std. deviation, σ
f_y	Reinforcement yield strength	LogNormal	590 MPa	25 MPa
I_{fy}	Model uncertainty for f_y	LogNormal	1	0.104
f_c	Concrete compressive strength	LogNormal	32.1 MPa	$0.15{\cdot}\mu_{fc}$
I_{fc}	Model uncertainty for f_c	LogNormal	1	0.153
W	Standard vehicle weight	Normal	Class 100: 109.2t Class 150: 157.6t Class 200: 201t	Class 100: 6.6t Class 150: 7.1t Class 200: 7.0t
N	Annual number of vehicles (Main roads)	Deterministic	Class 100: 200 Class 150: 100 Class 200: 100	
I_Q	Model uncertainty, traffic load	Normal	1	0.1
S_t	Dynamic supplement	Normal	$D_{base}{\cdot}D_{extra}$	$D_{base}{\cdot}D_{extra}$
G	Structural dead load	Normal	25 kN/m^3	$0.05{\cdot}\mu_G$
I_G	Model uncertainty of G	Normal	0	$0.05{\cdot}\mu_G$
G_w	Additional dead load	Normal	18 kN/m^3	$0.1{\cdot}\mu_{GW}$
I_{Gw}	Model uncertainty of G_w	Normal	0	$0.05{\cdot}\mu_{GW}$

$D_{base} \cdot D_{extra}$ from Table 3 is calculated from Equation (4) and (5), where W is the vehicle weight in kN and L is the influence length, which is 10 m.

$$D_{base} = \frac{41.5}{\sqrt{W \cdot 1000}} \cdot \left(\frac{5}{L}\right)^{0.2} \tag{4}$$

$$D_{extra} = 1 + 0.12 \cdot L^{0.4} - 0.03 \cdot \frac{W/10 - 50}{10} \tag{5}$$

3.4 *Proof load factor with resistance*

While the added load from the proof load test is deterministic, as the dead loads are modelled stochastically in this paper, the combined load effect, S_p, during the proof load test is also stochastic. Therefore, R, cannot be truncated at a single value of S_p as in Figure 1b. Instead, the posterior probability of failure can be determined as the probability of failure due to actual loading, event A, conditional on a successful proof load test, event B. The posterior probability of failure is calculated by Equation (6) in which the proof load factor, $\eta_{w/}$, is introduced with *w/* denoting that the proof load factor is calculated *with* resistance. $\eta_{w/}$ is multiplied to the design traffic load and is determined such that the annual $\beta = \beta_{target}$.

$$\begin{aligned} &\mathrm{P_f} = \Phi(-\beta) = \mathrm{P}(A|B) = \tfrac{\mathrm{P}(A\cap B)}{\mathrm{P}(B)} \\ &A:\ R = z\cdot R_d/S_d\cdot R_{basis}\left(f_y\cdot I_{fy}, f_c\cdot I_{fc}\right) < S\left(Q\cdot I_Q\cdot(1+S_t), G+I_G, G_W+I_{G_W}\right) \\ &B:\ R = z\cdot R_d/S_d\cdot R_{basis}\left(f_y\cdot I_{fy}, f_c\cdot I_{fc}\right) > S_p\left(\eta_{w/}\cdot Q_k\cdot\varphi_k\cdot\gamma_Q, G+I_G, G_W+I_{G_W}\right) \end{aligned} \tag{6}$$

3.5 *Proof load factor without resistance*

Proof load factors without resistance are determined similarly to the approach by (Christensen et al., 2023) but from the new probabilistic guideline, see the limit state Equation (7). Here the proof load factor, $\eta_{w/o}$, is introduced with *w/o* denoting that the proof load factor is calculated *without* resistance. Again, the proof load factor is determined such that $\beta = \beta_{target}$.

$$g = Q_{proof} - Q_{actual} = \eta_{w/o}\cdot Q_k\cdot\varphi_k\cdot\gamma_Q - Q\cdot I_Q\cdot(1+S_t) \tag{7}$$

4 RESULTS

This section presents the results of the described analyses. Figure 4 shows proof load factors calculated from the Danish codes and guidelines both with and without resistance. $\eta_{w/o}$ is constant in Figure 4, as the factor is nondependent on the resistance and therefore also on R_d/S_d.

For the resulting proof load factors to be comparable to those from (Casas & Gómez, 2013), additional proof load factors are calculated with a 50-year reliability index of β_{target}=3.2, instead of the annual reliability of 4.75 as specified from the Danish Code. To get the 50-year extreme traffic load N in equation (3) is multiplied by 50. The maximum moments calculated for a -10 m bridge span from both these Danish proof load factors and from proof load factors in (Casas & Gómez, 2013) are shown in Figure 5. The cut-off points for $\eta_{w/}$ is at R_d/S_d = $0.95\cdot(R/S)_{prob}$.

The axle loads of the class 150 vehicle and of $\mathrm{LM1_{CEEC}}$ at R_d/S_d = 0.6 are shown in Figure 6 along with the associated moment distribution. The tandem axle load of $\mathrm{LM1_{NL}}$ is determined, such that the resulting maximum moment is equal to that from the combined tandem axle and distributed load, as proposed by (Lantsoght et al., 2017).

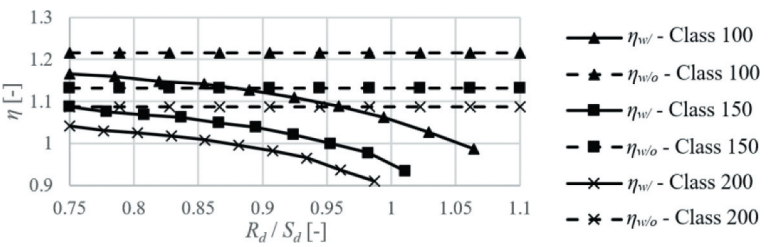

Figure 4. Proof load factors calculated from Danish codes and guidelines.

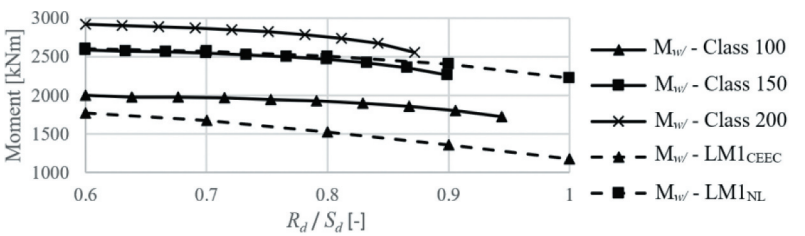

Figure 5. Danish proof load moments and proof load moments from (Casas & Gómez, 2013).

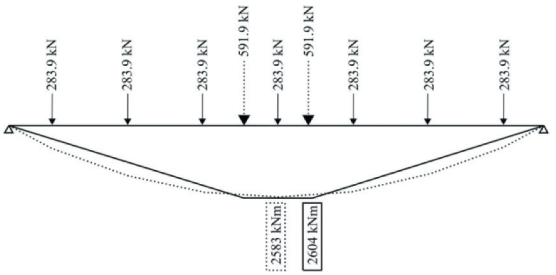

Figure 6. Class 150 (full) and $LM1_{NL}$ (dashed) axle configurations at R_d/S_d=0.6 in Figure 5.

5 DISCUSSION

Before carrying out a proof load test, it should be clear how the knowledge, that a bridge has survived the proof loading, can be used i.e., which vehicles can be allowed crossing. Here the Danish system seems to have an advantage as the standard vehicles were produced with special transport permitting in mind. When a bridge is proven for a certain class, then all special transports in the same class or lower can be permitted crossing. LM1 is determined from extrapolation of WIM-data with the heaviest vehicle measured weighing roughly 75-tonne. LM1 seems therefore not linked to special transport allowance. Using WIM-data containing special transports weighing up to 165-ton, (Casas & Gómez, 2013) calculated CEEC and Dutch proof load factors to be applied to LM1. These proof load factors, although to be applied to LM1, were thus determined with higher consideration for future special transport allowance. Still, the proof load factors were based on 1000-year extreme load effect extrapolated from past measurements, meaning that only one load level, which is meant to encapsulate all special transports, can be chosen. In the Danish system a different load level can be chosen for each bridge based on the desired bridge class. This can be an advantage, as the class can be chosen lower or higher depending on the special transport classes planned to be allowed crossing or depending on the expected bearing capacity of the bridge. This difference can be seen from Figure 5, where only one proof load moment is plotted for either CEEC or The Netherlands, whereas different levels are plotted for Denmark.

The Danish standard vehicles compared to LM1 seem to have a higher resemblance to real vehicles. The standard vehicles are designed with increasing number of axles and increasing axle weight with increasing class, whereas LM1 consists of one axle tandem and a distributed load. In practice this distributed load may be hard to simulate in a proof load test. Therefore, (Lantsoght et al., 2017) proposed to increase the tandem axle load, such that the resulting section forces are equal to that of the combined tandem axle and distributed load. However, this may lead to unreasonably large axle loads and as a result exaggerated local effects compared to the load effects resulting from real special transports. This phenomenon may be seen from Figure 6, which shows significantly higher axle loads for $LM1_{NL}$ compared to those of the class 150 standard vehicle, although the two load configurations result in comparable moments in Figure 5.

In the literature, proof load tests have been reported using proof load factors calculated both with and without resistance. Figure 4 shows that $\eta_{w/o}$ approaches $\eta_{w/}$ with decreasing z_{proof}/z_d, which means that the higher the utilization from the partial safety method, the smaller the value of resistance information becomes. However, due to the inclusion of a resistance, the results for $\eta_{w/}$ are highly case dependent, whereas the results for $\eta_{w/o}$ are more universal and may be constant along road stretches. Furthermore, the precision of the model uncertainty on the computational resistance model, and thus also $\eta_{w/}$, can be questioned (Schmidt et al., 2020). In the Danish proof loading project, failure tests will be carried out on concrete slab bridges to quantify the model uncertainty of given resistance models and thus, hopefully, give rise to better stochastic resistance modelling. It shall be noted that the calculations in this paper are carried out as an academic exercise, where a bridge with only one lane is used as base case, which may not be representative of too many bridges. Future work in the project will be to determine proof load configurations for multiple-lane bridges using real traffic data.

6 CONCLUSION

This paper compares Danish approaches to proof load configuration with approaches using the Eurocodes Load Model 1. For comparison with LM1 proof load configurations from the literature, Danish proof load factors both with and without resistance are calculated based on the Danish probabilistic guideline. A seemingly clear advantage of the Danish bridge classification system compared to LM1 is the higher resemblance of the traffic load configuration to real special transports. It was found that using LM1 may result in unreasonably high axle loads to be applied in a proof load test, which, although giving reasonable beam moment and shear, may lead to exaggerated local effects. As an example, to reach a moment of roughly 2600 kNm in a 10 m beam, the axle load magnitude to be applied to prove LM1 is 59 tonne, while for the Danish class 150 standard vehicle it is only 28 tonne.

It was found that the gain from including a resistance model is higher for lower design utilizations. The highest difference between the proof load factors calculated with and without resistance is roughly 20 %, while the lowest difference is roughly 5 %. However, as was discussed, the method including a resistance model is more case dependent and may suffer from questionable precision of the resistance model. Therefore, this may not conclusively prove one method to be superior to the other.

Static and dynamic monitoring of bridges with contactless techniques

Institute of Engineering Geodesy and Measurement Systems, Graz University of Technology, Austria

F. Schill
i3mainz – Institute for Spatial Information and Surveying Technology, University of Applied Sciences Mainz, Germany

ABSTRACT: Modern geodetic sensors are capable of capturing static and dynamic monitoring data of civil structures with up to several hundred Hertz. In order to assess the potential of such sensors, a comparative field study at a multi span highway bridge in Austria was performed. In the field tests different geodetic sensors such as robotic total stations (RTS) and terrestrial laser scanners (TLS) both in 3D and profile configuration were used to observe the structural behaviour during controlled static and dynamic load tests. Two trucks were placed at different positions on the steel-concrete composite bridge and the displacements of two bridge decks were observed. Additionally, both trucks were crossing the bridge at constant speeds (5 km/h and 30 km/h). In this study it is shown that remote sensing techniques are an appropriate tool for bridge monitoring and can ensure undisturbed operation of civil structures, as well as high accurate deformation measurements.

1 INTRODUCTION

While geodetic sensors such as robotic total stations (RTS) are mostly used for static-only measurements, the development of more advanced instruments enables the possibility to capture dynamic phenomena of objects as well (Lienhart et al. 2023). Other sensors as accelerometers or tilt sensors could either derive static or dynamic information but rarely could gather both details at a time. These drawbacks could be overcome by modern geodetic remote sensors, as the instruments can capture static deformations, but as well dynamic behavior with up to several hundred Hertz. However, geodetic sensors are not commonly used yet for dynamic monitoring. Among the few examples are GNSS based monitoring of bridges and high-rise buildings (Schönberger et al. 2022, Shen et al. 2019, Im et al. 2013, Yi et al. 2013) and RTS or terrestrial laser scanner (TLS) based monitoring of bridges (Lienhart et al. 2017, Psimoulis et al. 2008). In all these publications only few different technologies are being used and often under uncontrolled loading of the structures.

This paper presents a comparative study and investigates how different sensor technologies complement each other. Furthermore, the achievable accuracy difference between static and dynamic measurements is investigated. Geodetic sensors in the form of Profile Laser Scanners (PLS), 3D TLS and RTS are used to observe a multi-span highway bridge with different loading scenarios. The geometrical and temporal performance of capturing the bending of a bridge girder is examined. It shall be shown, that with geodetic sensors not only static deformations, but as well dynamic movements of the object can be captured when used in dynamic mode.

Remote sensors do not need sensor installation on objects, but there are some remote sensing methods that need installation of passive elements such as targets for tracking. Thus, the sensor is classified as a semi-remote sensor. Other sensors such as laser scanners or terrestrial

radars are completely remote and no targets at the structure are needed. A list of different sensor types and their capabilities can be seen in Table 1.

2 LOAD TESTING AT AN AUSTRIAN HIGHWAY BRIDGE

The Austrian Brenner highway is part of the European route E45 and crosses Europe in north-south direction from north of Finland to the south of Italy. The passage across the Austrian alps is a crucial part of the route and as well crucial to the European transnational movement of goods. The highway passage across the alps was mainly build in the 1960s, and in this time also the Gschnitztalbrücke was build.

The structure itself is a steel-concrete composite and is shaped as a 7-span continuous beam, whereas the outer two spans are 70 m long, all the others have a length of 84 m. The total length therefore is 560 m long. The monitoring of the load test focused on the two spans (span 6 and span 7) next to the south bearing of the bridge, as seen in Figure 1.

2.1 *Test procedure*

Part of this monitoring was a load test which was carried out in May 2023. One direction of the highway bridge was temporarily closed to place two trucks on it, each weighing more than 50 tons, to create different load scenarios. Thereby, the trucks were put statically on span 6, then one of the trucks moved on to span 7 and after that, the second truck followed to span 7, so that there are 3 load scenarios, as shown in Figure 2. Additionally, four dynamic tests took place, where the trucks passed the bridge with speeds of 5 or 30 km/h on the first and second lane.

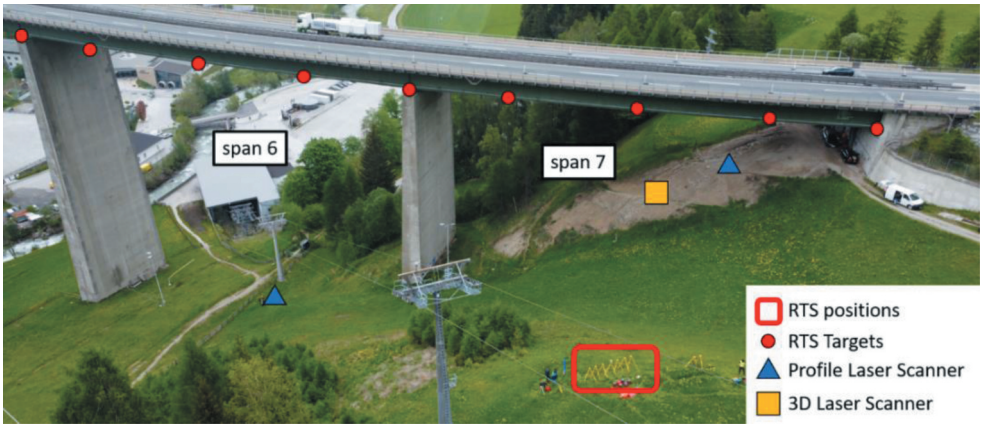

Figure 1. Overview image of the two observed spans of the bridge with the position of the remote sensors.

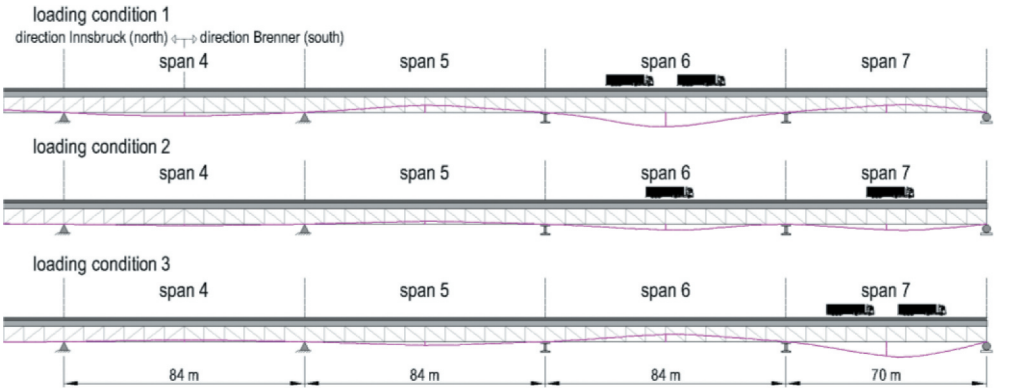

Figure 2. Schematic side view of the bridge with three loading scenarios of static load tests and schematic bending lines of the structure.

2.2 *Test setup*

Six Leica MS60 RTS were set up next to each other to follow the movement of six monitoring prisms mounted directly on the steel girder at span 6 and 7, see Figure 1. In addition, a Leica TM50 RTS is used to take successive measurements on the prisms mentioned above as well as on the prisms attached directly to the bearings of the bridge.

A PLS was located under each of the two observed spans, enabling both dynamic and static observations. At span 7 a Z+F Imager 5016 3D laser scanner is used in profile mode, and a Z +F Profiler 9012 is used at span 6. Additionally, a Leica RTC360 is located at span 7 for 3D static observations, as the measurement takes around 60 seconds.

3 USED SENSORS

The focus of this study is on RTS and TLS, as well as PLS (Schill & Eichhorn 2019), which are very similar in terms of their basic operating principle. All instruments gather polar coordinates consisting of angles in vertical and horizontal directions as well as distances to the observed point. A crucial difference between the instruments is, that RTS follows a single target, and take measurements to this exact point with a nominal measurement rate of up to 20 Hz (Leica 2020), while a TLS or PLS measures in consecutive angles and takes measurements to the surface itself that is in line of sight. The used TLS can measure 1 - 2 million points per second. In case of the PLS this is combined with up to 200 profiles per second (Zoller + Fröhlich 2017). Because of the operating principle, PLS can only detect 2D displacements in a profile, while the RTS and TLS measurements provide 3D information of the observed prism or the object surface.

3.1 *Robotic Total Station (RTS)*

The dynamic measurements of the six RTS are taken with the Leica Streaming App with a nominal measurement rate of 20 Hz. As a result, a data entry for each measurement with information of horizontal and vertical angles, distance measurement, compensator, and a time stamp is generated. This time stamp is a continuous counter in milliseconds from the moment of turning on the instrument. As the time stamps are only internal times, the different RTS need to be synchronized to each other. This synchronization is realized with a 360° prism on a pole and performing a significant movement while all the RTS are tracking the prism. Additionally, a GNSS receiver is mounted above the prism to capture the movement via dynamic GNSS measurements. These captured movements serve as a correlation pattern to not only synchronize the different RTS to each other, but also set the measurements into a global time system provided by the GNSS.

3.2 *Terrestrial Laser Scanner (TLS)*

TLS capture millions of points in the entire visible environment, resulting in a 360° panorama in the form of a point cloud. The laser beam emitted and reflected by the object being measured is analyzed and contactless distance measurements are carried out. As the angles of the emitted laser beam are known, three-dimensional coordinates can be derived.

The sequential acquisition is realized by rotating simultaneously in 2 directions: the laser beam is deflected by a high-frequency rotating mirror and the TLS is rotating around its standing axes.

3.2.1 *Profile Laser Scanner (PLS)*

If TLS are used in profile mode (Schill et al. 2019), the instrument only uses the high-frequency rotating mirror, but in contrast to 3D TLS does not rotate around its standing axis, so that the laser beam gets deflected into the same profile repeatedly.

By reducing the spatial resolution to such a single profile, the temporal resolution can be increased significantly. In this way, PLS can be used either to record dynamic and spatially distributed motion behavior, such as displacements of objects of interest. Or to statically capture the surface geometry within a profile with increased precision by time averaging the measurements taken while the structure is not moving. With more than one epoch of statically recorded surface profiles, static displacements can be derived with high spatial resolution and high precision.

For both applications, a spatial approximation of the profiles measured on the object surface takes place. In the simplest case, it is realized based on a spatial averaging of the closely spaced profile points. By doing so, the system accuracy can be increased for both applications.

4 RESULTS

4.1 *Robotic Total Station*

4.1.1 *Dynamic Robotic Total Station*

It must be considered that the single measurements of the RTS are not done uniformly regarding timing. Also, the time differences are not normally distributed, but rather gather in groups that have spacings of the minimal time difference of about 50 ms. Additionally, there is a time drift in the data of the RTS. There were made multiple time correlations with 4 RTS, whereas the drift of 3 of them is rather similar with a time drift of about 40 ppm. One instrument shows a bigger drift in the beginning of 115 ppm which later comes down to a drift of 60 ppm. The change in drift could be due to heating effects of the instrument (Gojcic et al. 2018), but needs further investigation to determine the specific systematics.

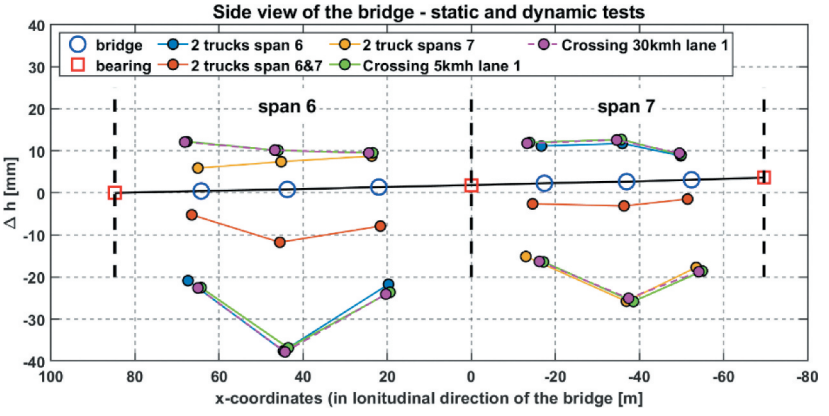

Figure 3. Deformations derived with RTS from dynamic measurements of static and dynamic (green & magenta) load tests. Prisms of bearings are only measured during static load tests.

In general, the drift creates a time delay of a about 1 s over a time span of 5 hours. Depending on the desired synchronization accuracy, the drift problem could either be overcome by correlating the instruments more often, or just apply a predetermined time drift for each individual RTS, as the drifts do vary from one to the other instrument.

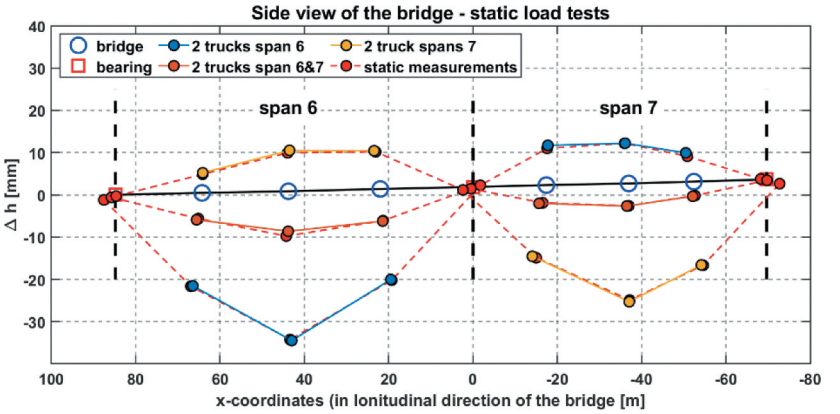

Figure 4. Deformations during static load tests derived from static (red) and dynamic measurements.

The most important results that should be obtained from the measurements are displacements in the form of height changes. As the RTS takes angle and distance information of every single point, not only the change of elevation can be detected, but as well a change of position can be derived. This supports the understanding of the structural system and its reaction to loading.

The maximum and minimum deformation of height caused by two trucks passing the bridge with 5 km/h and 30 km/h can be seen in Figure 3 together with the static load tests. To obtain the deformation of the static load test, the measurements are averaged over the time where the bridge is statically loaded. The left and middle prism in span 6 is significantly differing between static and dynamic tests. This comes from the crossing of the trucks because span 6 gets lifted when the trucks are passing span 5, therefore the maximum height change differs if dynamic and static load tests are carried out. Considering this, the extreme values of the displacements of Figure 4, the dynamic measurements can capture the same displacement in a drive by test, as the static measurements during static loading.

4.1.2 *Static Robotic Total Station*

During the static load tests, one RTS takes measurements in multiple sets of all mounted prisms sequentially. The measurements are taken once without any loading of the bridge as a reference measurement, all following measurements are set in respect to this reference.

As the static measurements include all prisms, not only the bending and displacement of the steel girder, but also the movement at the bearings can be calculated. Additionally, the strain between the prisms can be derived of the change of its 3D positions. Comparing the results of static and dynamic measurements of the same load tests, as shown in Figure 4, the variations are rather small.

4.2 *Terrestrial Laser Scanning (TLS)*

4.2.1 *3D TLS*

The static load tests were recorded with three different TLS. A PLS and a 3D TLS in profile mode were used, which are described in more detail in section 4.2.2. Additionally, a Leica RTC360 was used to record the static tests epoch wise in 3D for span 7, see also Figure 1.

In Figure 5 the underside of the bridge and the results of an exemplary static load test are presented. The vertical displacements were calculated with the M3C2 algorithm (Lague et al.

2013) and are color coded from blue (negative) to red (positive). Every epoch was recorded with one laser scan, leading to a precision of the displacements in the lower millimeter range. The maximum deformation (blue) occurs approximately in the center of span 7 and spreads symmetrically from the edge.

One advantage of acquisition with a 3D TLS is the high spatial resolution; not only the one main beam can be observed, but the entire visible structure. Further information can therefore be derived from the measurement data, e.g. that the maximum deformation of the cantilevered carriageway is in the order of approx. 10 mm greater than the main beam, see right side of Figure 5.

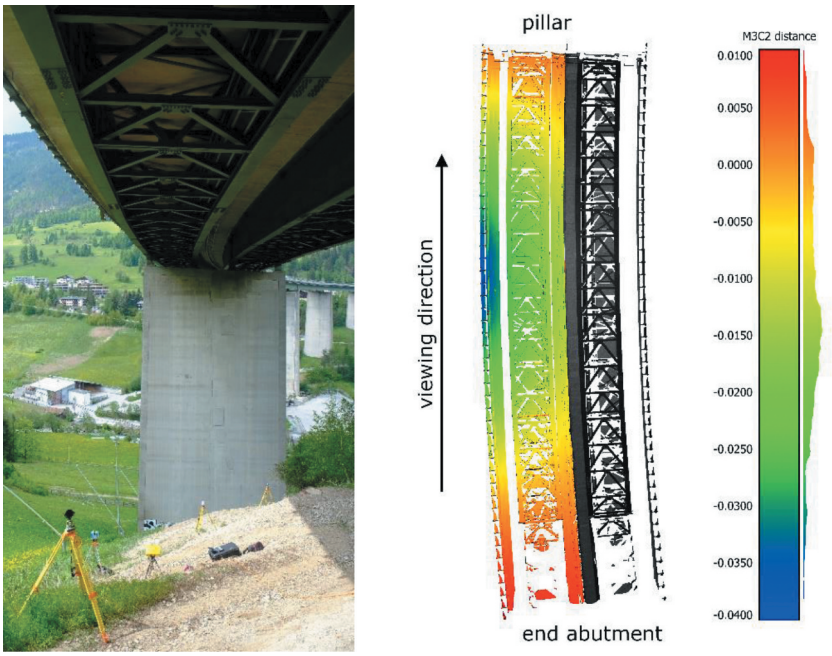

Figure 5. Left: Photograph of the underside of span 7; right: Color coded vertical displacements of an exemplary static load test of span 7, with both trucks at the outer edge in the middle of span 7, compare with Figure 2. The other direction of travel is shown as an intensity visualization, as this direction of travel was not closed to traffic. The viewing direction of the photograph is visualized with an arrow in the middle.

4.2.2 *Dynamic Profile Laser Scanning (PLS)*

A disadvantage of 3D acquisition with TLS, on the other hand, is the long measuring time, so this method can only be used for static load tests, as seen above. In addition to the static load tests four dynamic tests were performed, that cannot be analyzed with a 3D TLS. As explained in section 3 it is possible to overcome this issue by reducing the spatial resolution to a single profile to get a temporal resolution of up to 200 Hz. In addition, the profile approximation can be used to increase the precision of displacement detection in the submillimeter range (Schill et al. 2022).

Shows the exemplary results of one dynamic experiment, where both trucks are passing the bridge with 5 km/h. The upper graph shows a time series measured with the PLS approximately at the position of the center prism at span 7. In accordance with Figure 2, the rising and lowering of the bridge deck can be seen, starting when the two trucks are in span 4, leading to a slight rise in the height for span 7. Subsequently, the points in time can be recognized when the trucks are in the spans 5 (lowering), 6 (blue, maximum rise) and 7 (red, maximum lowering).

In the lower graph the spatially distributed displacement measurements of the profile scanner are shown for the latter two points in time, which are also marked in the upper graph in

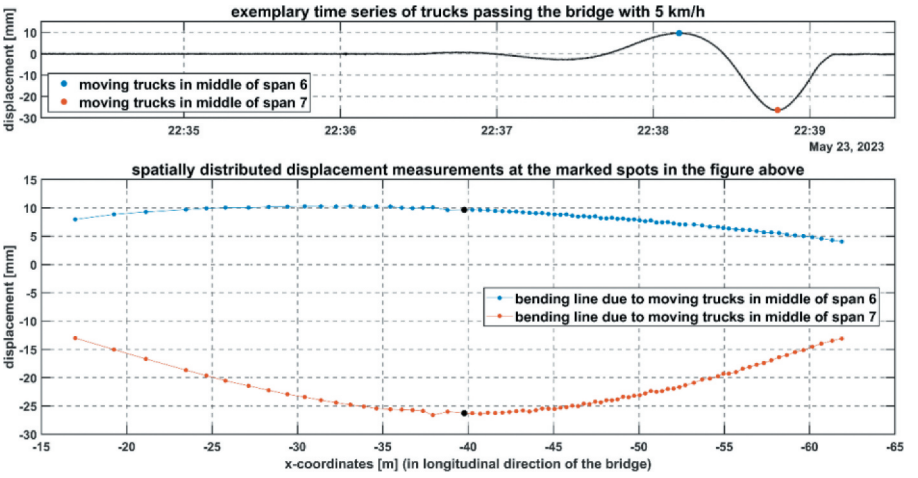

Figure 6. Dynamically captured bridge displacements of PLS measurements on span 7. The lower figure shows the bending line of the steel girder at the time of the marked points in the same color in the upper figure. The x-coordinates correspond to Figure 4.

corresponding colors. These two exemplary points in time are designed to illustrate the potential of just one PLS. In this example, up to 80 spatially distributed displacement time series can be derived with sub-millimeter accuracy and a temporal resolution of under 0.02 seconds.

4.2.3 *Static Profile Laser Scanning (PLS)*

PLS can also be used to analyze static load tests, further increasing precision and spatial resolution through additional time averaging during the load holding phases. In Figure 7 the results of three repeated load test scenarios are shown. Approximately 600 displacement values could be derived in a profile area of just under 50 meters. Most of the mutual deviations from two completely independent experiments are in the order of 0.1 mm and below. Only the load position with one truck on span 6 and one truck on span 7 shows larger deviations. However, these deviations can also be caused by slightly different positions of the trucks on the bridge between tests.

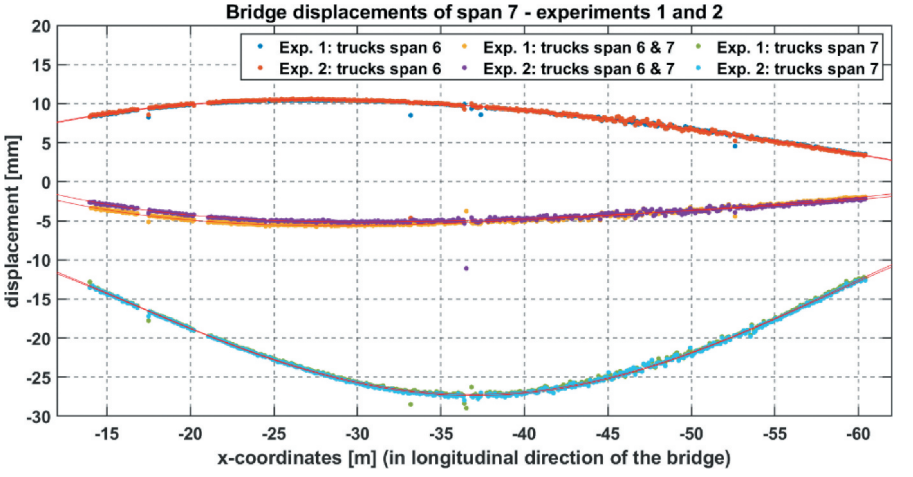

Figure 7. Bridge displacements captured by profile laser scanner. Two identical experiments with 3 load conditions (see also Figure 2) are shown.

5 CONCLUSION

It could be shown, that both RTS and PLS are highly capable of detecting static and dynamic deformations of bridges. If both, static and dynamic results are compared, the performance of the sensors is promising in both applications.

RTS can capture single points with a measurement rate up to 20 Hz and can gather real 3D deviations of this point with high accuracy. Nevertheless, the temporal drift of each individual sensor hast to be considered, in particular when its used for a longer period at a time, as the drift can accumulate up to 1 s after 5 hours.

3D TLS capture its full surroundings in a period of about 60 seconds, which can be used for static 3D deformation analysis of structures, with millimeter precision. When the rotation of the TLS around the standing axis is suppressed, a profile remains as measurand. In doing so, the temporal resolution can be increased significantly, and up to 200 profiles per second can be captured. With temporal or spatial averaging, the accuracy of the recorded profile increases to the sub-millimeter range. In addition, a large number of spatially distributed displacement values can be derived.

Overall, a comprehensive understanding of bridge displacements under static and dynamic load scenarios can be achieved with relatively little effort. The use of geodetic remote sensors can therefore address the challenges of an ageing infrastructure by providing more actually measured information. The next step should be a comprehensive integration of these remote measurements into digital twins to enable an integrated analysis accompanying the life cycle of infrastructure buildings. With precise knowledge about the bridge system it may be possible to contribute to moving force identification (Firus 2022) using dynamic remote sensors.

ACKNOWLEDGEMENTS

We want to acknowledge the support of the Austrian Highway Agency (ASFINAG), especially Peter Augschöll for the possibility of performing a load test on the bridge.

ABSTRACT: Proof load testing for assessment can involve a large risk due to the high loads. Stop criteria can reduce this risk. Stop criteria are necessary for shear, which is a brittle failure mode. This paper describes the development of shear stop criteria for slab strips. The shear stop criteria are developed by combining theoretical concepts related to cracking, as well the relationship between bending- and shear-critical regions, along with insights from the Critical Shear Crack Theory and the Critical Shear Displacement Theory. The shear stop criteria are validated with fourteen beam tests. The result is a set of shear stop criteria in a "traffic light system" with a green light level related to serviceability, and yellow and red light related to the ultimate limit state for shear. These stop criteria serve as the basis for a global approach for proof load testing of reinforced concrete bridges.

1 INTRODUCTION

Proof load testing for assessment has gained recognition in the past years as a promising method for bridges for which capacity reserves are expected that cannot be demonstrated with an analytical assessment (Alampalli et al., 2021; Lantsoght, 2023). During a proof load test, a load representative of the factored live load is applied to the bridge. These high loads imply high risks. Therefore, stop criteria are used. Stop criteria are thresholds to the measured responses of the bridge. Once these thresholds are reached, the proof load test should be stopped and further loading is not allowed, as it could result in irreversible damage or potentially even collapse of the bridge.

In the Netherlands, a large number of reinforced concrete slab bridges require assessment, and some of these are good candidates for proof load testing (Lantsoght et al., 2017). However, to come to a wide adoption of the practice of proof load testing for assessment of existing reinforced concrete slab bridges, stop criteria for shear are necessary, as a large number of the existing reinforced concrete slab bridges are found to be shear-critical upon an analytical assessment (Lantsoght et al., 2014).

Theoretically derived stop criteria for flexure are available and validated (Lantsoght et al., 2019). For shear, stop criteria have been proposed based on a small number of experiments (Lantsoght et al., 2018; Yang et al., 2018), but more profound theoretical research was deemed necessary in combination with experiments. The current research on shear stop criteria consists of two steps: 1) theoretically deriving shear stop criteria for reinforced concrete slab strips and validating these criteria with experiments on beams without stirrups, and 2) extending these stop criteria to

DOI: 10.1201/9781003483755-36

slabs and validating these stop criteria on straight and skewed slabs. This paper reports the findings of the first stage.

2 THEORETICAL STOP CRITERIA FOR SHEAR

2.1 *Indicator based on simplified aggregate interlock expression*

Aggregate interlock is one of the main shear-carrying mechanisms. A stop criterion based on aggregate interlock should be linked to a measurable parameter. Crack width is considered as the most suitable measurable parameter to link to aggregate interlock. For the stop criterion, the simplified aggregate expression of the Critical Shear Displacement Theory, CSDT, (Yang et al., 2016) is used. This theory leans on the critical shear displacement Δ, which is difficult to measure during a proof load test. Therefore, a proposal that is based on the crack width w at the level of the tension steel and the acting shear stress τ at the cracked section has been proposed (Yang et al., 2018). Moreover, it is assumed that the aggregate interlock capacity V_{ai} can be taken as a lower bound for the shear capacity V. As a result, the shear capacity expression becomes the expression of the aggregate interlock capacity:

$$V = f_c^{0.56} s_{cr} b \frac{0.03}{w - 0.01}\left(-978\Delta^2 + 85\Delta - 0.27\right) \tag{1}$$

In Eq. (1), f_c is the concrete compressive strength, s_{cr} is the height of a fully developed crack, b is the member width, w is the nominal crack width at the level of the steel reinforcement, and Δ is the shear displacement. Rearranging terms so that all measurable parameters in a proof load test are on the left-hand side of the equation and replacing the shear displacement Δ by the critical shear displacement Δ_{cr} results in:

$$V(w - 0.01) = 0.03 f_c^{0.56} s_{cr} b\left(-978\Delta_{cr}^2 + 85\Delta_{cr} - 0.27\right) \tag{2}$$

with the critical shear displacement Δ_{cr} as:

$$\Delta_{cr} = \frac{25 d_l}{30610\phi_{eq}} + 0.0022 \leq 0.025 \tag{3}$$

and the equivalent rebar diameter ϕ_{eq} can be determined as:

$$\phi_{eq} = \frac{\Sigma\phi_i^2}{\Sigma\phi_i} \tag{4}$$

The height of the fully developed crack can be determined as:

$$s_{cr} = \left(1 + \rho n - \sqrt{\rho n + (\rho n)^2}\right) d_l \tag{5}$$

with ρ the reinforcement ratio, n the ratio between the Young's modulus of the steel and the Young's modulus of the concrete, and d_l the effective depth to the longitudinal reinforcement. The lefthand side of Eq. (2) can be simplified into the shear indicator I_{CSDT} relating the shear stress τ and nominal crack width w as follows:

$$I_{CSDT} = \frac{V(w - 0.01)}{bs} \approx \frac{V(w - 0.01)}{bd} = \tau(w - 0.01) \tag{6}$$

The critical shear indicator $I_{s,cr}$ then becomes:

$$I_{CSDT,cr} = 0.03 f_c^{0.56} \frac{s_{cr}}{d} \left(-978\Delta_{cr}^2 + 85\Delta_{cr} - 0.27\right) \tag{7}$$

with Δ_{cr} from Eq. (3) and s_{cr} from Eq. (5).

2.2 *Indicator based on Critical Shear Crack Theory*

In the Critical Shear Crack Theory, CSCT, (Muttoni & Fernández Ruiz, 2008), the shear strength depends on the crack width and roughness of a critical shear crack (expressed as a function of the maximum aggregate size d_g). In other words, the CSCT considers aggregate interlock as the main shear-carrying mechanism. One of the main assumptions in the theory is that the critical crack width w can be taken as proportional to the multiplication of longitudinal strain ε_x and indication of crack spacing d at a control depth of $0.6d$ from the top fiber. Using these considerations, the shear strength V_R is expressed as:

$$\frac{V_R}{bd\sqrt{f_c}} = \frac{1}{6} \frac{2}{1 + 120 \frac{\varepsilon_x d}{16 + d_g}} \tag{8}$$

with f_c the concrete compressive strength (in MPa), b the width, d the effective depth, ε_x the longitudinal strain at the control depth derived from the bending moment demand in the critical section, and d_g the maximum aggregate size in mm. Replacing the shear resistance V_R by the sectional shear V, an indicator can be derived with f_c in MPa and d_g in mm:

$$\begin{aligned} I_{CSCT} &= \tfrac{V}{bd\sqrt{f_c}} = \tfrac{1}{6} \tfrac{2}{1+120\frac{\varepsilon_x d}{16+d_g}} = \tfrac{1}{3} \tfrac{1}{1+120\frac{w}{d_g}} \\ I_{CSCT} &= \tfrac{V}{bd} \left(1 + 120 \tfrac{w}{d_g}\right) = \tau \left(1 + 120 \tfrac{w}{d_g}\right) \leq \tfrac{\sqrt{f_c}}{3} \end{aligned} \tag{9}$$

In this expression, the measurable parameters are V (as a function of the applied load) and ε_x, which can be derived from the strain at the level of the tension reinforcement and assuming a linear strain distribution as:

$$\varepsilon_x = \frac{0.6d - c}{d - c} \varepsilon_{x,rebar} \tag{10}$$

with d the effective depth and c the height of the compression zone.

2.3 *SLS crack width limit*

In addition to the considerations, the crack width limitation from the serviceability limit state (SLS) as prescribed by NEN EN 1992-1-1:2005 (CEN, 2005) is studied. The limiting crack width is a function of the exposure class. For reinforced concrete bridges, the SLS limit for crack width is w_{SLS} = 0.3 mm. Using the consideration from the previous section, the average crack width w_{avg} can be determined, and compared to the SLS limit as:

$$w_{avg} = \frac{\varepsilon_{c,average} l_g}{n_{cr}} \leq 0.3mm \tag{11}$$

The number of cracks n_{cr} represents the average number of cracks within the gauge length l_g. The difference between the crack spacing between major cracks and secondary cracks at the reinforcement level is considered using a factor of 0.5, resulting in:

$$n_{cr} = \frac{l_g}{0.5 l_{crm}} \tag{12}$$

with l_{crm} the average crack spacing.

An indicator of the Serviceability Limit State (SLS) is crucial as it serves as a signal for potential repairs after proof loading. Exceeding the SLS limit state can cause limited damage, however, the crack width is restricted so that it will not impair the proper functioning or durability of the structure.

3 EXPERIMENTS

Slab strips of 10 m length × 0.3 m width, and with heights of 500, 800 and 1200 mm were tested to validate the proposed shear stop criteria (Koekkoek & Yang, 2016; Yang, 2021). The slab strips were simply supported and subjected to a single concentrated load. The span length was 9 m, and the distance between the load and the support varied among the experiments. Only one experiment was carried out per beam. The load was applied with a hydraulic jack in displacement-controlled way with a loading speed of 0.02 mm/s. The load was increased stepwise until failure. Figure 1 shows the test setup used in these experiments.

The concrete class was C65/80. The reinforcement consisted of ribbed bars with f_{ym} = 550 MPa. Figure 2 shows the reinforcement layout in the beams. It can be seen that one span is provided with stirrups, to avoid an unexpected failure mode.

Table 1 gives an overview of the parameters of the fourteen selected experiments. The table reports the cube concrete compressive strength $f_{c,cube}$, the rebar configuration, the reinforcement ratio ρ_l, the shear span a, the effective depth to the longitudinal reinforcement d_l and the shear span to depth ratio a/d_l. The naming system of the specimen relates to H for high members, the reinforcement ratio (roughly), and the last digit refers to the number of the identical specimen. The table also includes the test results as P_u, which refers to the load level at which the specimen failed in shear, or for the case of the specimens with low a/d, the load at which the critical shear crack opens.

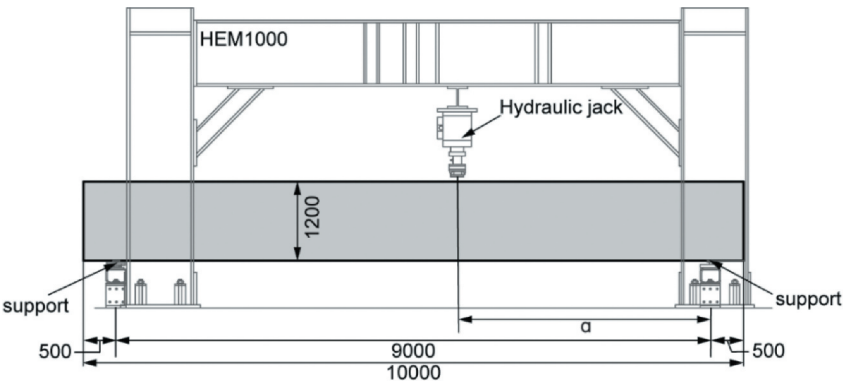

Figure 1. Sketch of test setup. Units in [mm].

The instrumentation on the specimens consisted of traditional sensors such as linear variable differential transformers (LVDTs), laser triangulation sensors (lasers), and the load cell at the hydraulic jack. The structural responses that were measured are deformations in horizontal and vertical direction with the LVDTs as well as deflection under the concentrated load with the lasers. The load cell is sued to report the applied load. Moreover, two-dimensional digital image correlation (2D DIC) is used to monitor the crack pattern and the full displacement field. The displacement field is obtained by using the MatchID (MatchID, 2022) software, as

4 COMPARISON BETWEEN EXPERIMENTS AND STOP CRITERIA

In order to simulate a real-world measurement of a proof load test, in which the location of the critical cross-section is not known beforehand. The stop criteria are determined at a series of cross-sections of the listed beams along the longitudinal axis. Here the value of crack width or longitudinal strain of a given cross section is determined by a virtual LVDT obtained from the DIC results. The load level when the stop criterion at a given cross-section is reached is noted as P_{ind}. The value of P_{ind} is compared to the measured shear load when shear failure (P_{cr}) is obtained from the test. In general, the ratio between P_{ind}/P_{cr} and M/Vd follows a parabolic trend, see for example Figure 4. In the figure, the factor $\lambda=a/d_l$ for each specimen is given in parenthesis. Overall, the stop criteria related to the shear theories were reached closer to failure in the regions with $M/Vd < 2$. In the region near the loading point between $1d$ and $0.5d$, where the M/Vd is the largest, this corresponds to the area influenced by the largest bending moments and the crack opening and the stop criteria were reached first. This is in line with the model described in CSDT, that a cracked section with smaller M/Vd tends to be more difficult to reach shear failure.

To facilitate the comparison between the various beam experiments with different a/d_l, the M/Vd ratio was normalized by the factor $\lambda= a/d_l$, as shown in Figure 5. This normalization allowed the identification of two main regions: 1) the region corresponding to l_{crm} from the support (larger M/Vd ratios) where the shear resistance is mainly influenced by the crack opening, and 2) the region with the lowest M/Vd which corresponds to shear failure, and where the shear resistance is governed by the shear displacement and the inclination of the cracks.

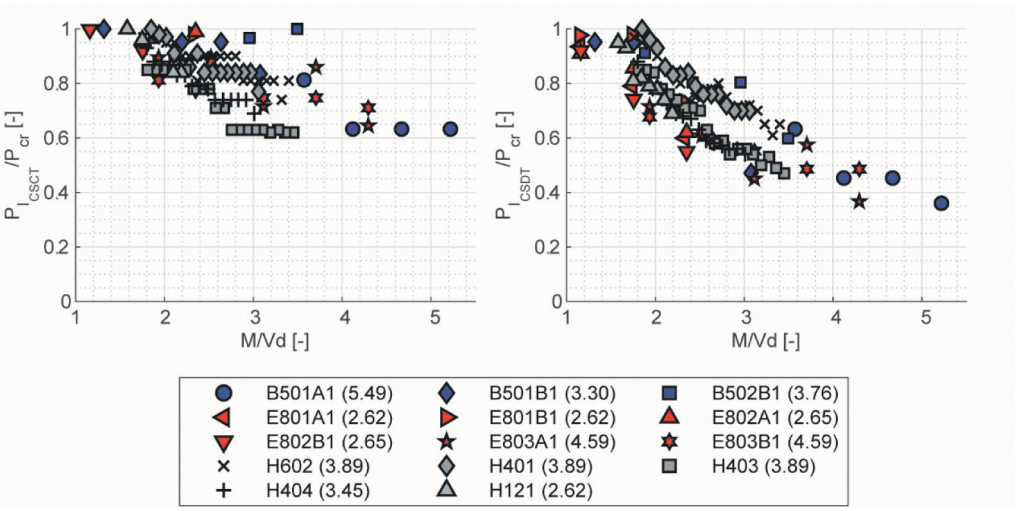

Figure 4. Results of the indicator based on the Critical Shear Crack theory and the Critical Shear Displacement Theory as a function of M/Vd.

The summary of the results of the comparison between the stop criteria and the measurements, subdivided into these regions can be found in Table 2. The results of large M/Vd include the measurements between $0.8<M/Vd\times(1/\lambda)<1$ and the low M/Vd consists of the measurements with $M/Vd\times(1/\lambda)<0.7$. Overall, the results of this comparison show that the cracking indicator is reached first, as expected. For the shear indicators, the indicator based on the CSDT is reached generally before the indicator of the CSCT, and both indicators present similar values for the associated coefficient of variation. Generally, the stop criteria in the low M/Vd region are reached around 84% of the failure load, which would be too close to the critical load for application in proof load tests. However, the stop criteria in this region could serve as

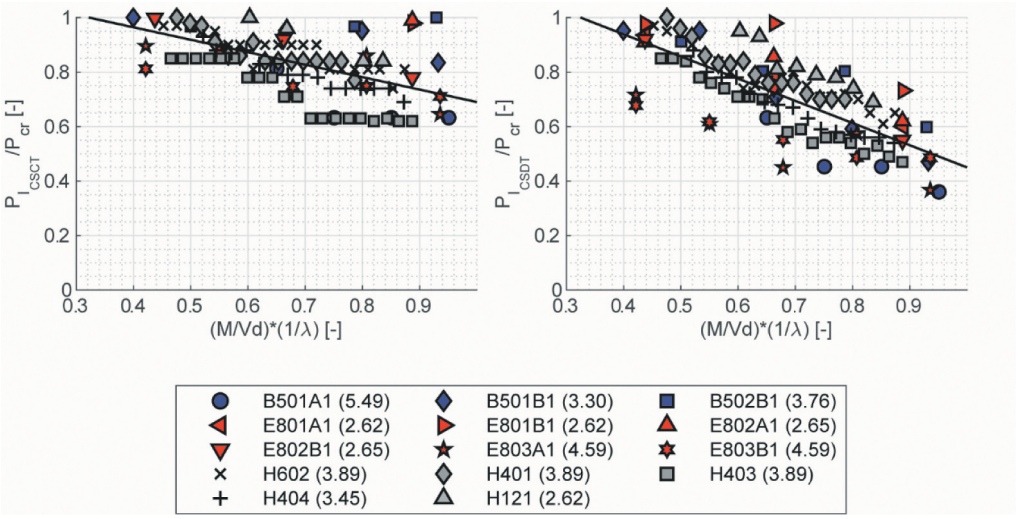

Figure 5. Results of the indicator based on the Critical Shear Crack theory and the Critical Shear Displacement Theory as a function of M/Vd normalized by factor λ.

warning signals for imminent failure. Overall, the proposed stop criteria are suitable for the reinforced concrete slab strips tested and they provide a different margin of safety as a function of the location along the shear span.

The Serviceability Limit State (SLS) crack width limit was, on average, reached at 51% of the failure load in the large M/Vd region, with a standard deviation of 0.11 and a coefficient of variation of 0.22. In the low M/Vd region, it was reached at an average of 74% of the failure load, with a standard deviation of 0.15 and a coefficient of variation of 0.21.

5 RECOMMENDATIONS FOR SHEAR STOP CRITERIA FOR SLAB STRIPS

To better understand the risk associated with reaching a stop criterion, the stop criteria are organized in a traffic light system, as also used by (Zhang, 2022). The system uses the following colors and interpretations: 1) green light corresponds to serviceability limit state and is related to cracking in the region close to the load l_{crm}, 2) yellow light corresponds to the ultimate limit state for shear and potential irreversible damage, and is related to the increase in the crack opening or the average longitudinal strain, as well as the opening of the critical shear crack in the low M/Vd region, and 3) red light corresponds to imminent failure for the ultimate limit state for shear, and is based on the indicator of increase in crack opening and the shear failure criteria from the theoretical shear models. It is recommended to monitor these regions using traditional measuring techniques such as LVDTs or 2D DIC to obtain measurements of crack widths or longitudinal strains. The recommended gauge length is $0.8d$. Detailed information about the study of the optimal gauge length can be found on (Zarate Garnica

et al., 2022). These regions and the different levels of the stop criteria are also indicated in Figure 6.

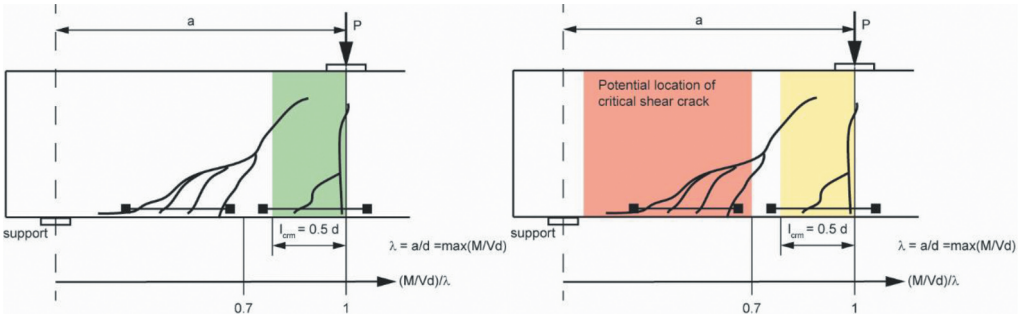

Figure 6. Overview of stop light system for shear stop criteria for RC slab strips.

6 SUMMARY AND CONCLUSION

This paper shows the development of stop criteria for the ultimate limit state for shear and for the serviceability limit state for cracking from theoretical principles. These stop criteria are then compared to the experimental results from fourteen beams, and different critical regions in the shear span are identified. Finally, a traffic light system for the stop criteria is proposed.

From this research, the following conclusions can be drawn:

- A serviceability limit state cracking indicator can be used as a stop criterion in the region of the shear span close to the load to identify the beginning of flexural cracking.
- The two theoretically derived shear stop criteria, based on the Critical Shear Displacement Theory and the Critical Shear Crack Theory, perform equally well, with the stop criterion based on the CSDT generally being reached first.
- The shear stop criteria can be used to warn for imminent danger for collapse in the region corresponding to the lowest M/Vd.
- It is recommended to monitor the shear span using LVDTs or 2D DIC to obtain measurements of crack width or longitudinal strain.

ACKNOWLEDGMENT

The authors wish to express their gratitude and sincere appreciation to the Dutch Ministry of Infrastructure and the Environment (Rijkswaterstaat) for financing this research work. We are deeply indebted to our colleague Albert Bosman for his work in the laboratory, and design of the test setup. Thanks also to Jakub Pawlowicz for his work in the laboratory during the phase of the testing.

Development of a guideline for proof loading of bridges

S. Engelund
COWI A/S, Aalborg, Denmark

J.D. Sørensen & J.W. Schmidt
Aalborg University, Aalborg, Denmark

C. von Scholten & R. Bang
The Danish Road Directorate, Copenhagen, Denmark

ABSTRACT: The Danish Road Directorate has developed a guideline for proof loading of road bridges. The guideline ensures that proof load tests are planned and executed in a consistent manner and that test results may be used to update the load-carrying capacity of the considered bridge. The guideline describes how proof load tests may be planned, executed, and interpreted to demonstrate that the considered bridge can withstand a given load with sufficient reliability. One of the primary hypotheses is that many bridges have a load-carrying capacity that may be larger than the one determined by traditional computational analysis. This is mainly because the computational models, that are used to determine the load carrying capacity, of a given bridge does not predict the actual response of the considered bridge with sufficient accuracy. Most models are inherently conservative and underestimates the actual load carrying capacity of the considered bridge. Load testing is a cost-effective method to demonstrate that a given bridge has a sufficient load carrying capacity.

1 INTRODUCTION

The Danish Road Directorate has since 2016 led a research project concerned with proof loading of bridges. The purpose of the project is to make proof loading of bridges a useful tool that may be used to update the load-bearing capacity of bridges. The Danish Road directorate has published a guideline for proof loading of bridges, (Vejdirektoratet, 2023b). The guideline has been prepared with a view to ensuring that proof load tests are carried out on a consistent basis, that test loads can be carried out safely and that test loads provide a sufficient basis for an update of the load-bearing capacity of the considered bridge.

The proof-loading methods were developed to comply with the unique Danish guidelines, (Vejdirektoratet, 2017), (Vejdirektoratet, 2010) and (Vejdirektoratet, 2023a) for classification of the load carrying capacity of existing bridges. The provisions enable consistent administration and handling of heavy vehicles in Denmark.

The guideline has been developed using the results of several research projects that focused on the following topics:

- The use of non-destructive methods to register the state of the bridge during the load testing (Christensen et al., 2021) and (Christensen et al., 2022)
- Evaluation of the magnitude of the proof load on the basis of probabilistic methods, (Christensen et al., 2023) and (Schmidt et al., 2020)
- The use of advanced analytical methods to predict the load carrying capacity of concrete slap bridges, (Jensen, 2019)

DOI: 10.1201/9781003483755-37

These topics have also been subject to much attention by various research teams. The use of non-destructive methods has also been investigated by (Alam et al., 2015) and (Lantsoght et al., 2019). Evaluation of the magnitude of the proof load has been investigated by (Faber et al., 2000) and (Lantsoght et al., 2017).

2 THE DANISH CLASSIFICATION SYSTEM AS BACKGROUND FOR GUIDELINE

In Denmark, a unique classification system is used by the administration of the permits that must be issued to the owners of heavy vehicles that wish to travel by a given route. The heavy vehicle is permitted to use a given route given that all the bridges on the given route have a bridge class that is larger than the vehicle class. If this requirement is not met, an alternative route must be found, or the goods are rearranged to meet the required vehicle class.

The bridge class is determined using several standard vehicles with a given axle configuration and axle loads. The bridge class is defined as the heaviest standard vehicle the bridge can carry with sufficient reliability (together with a class 50 vehicle in the other lane if the bridge carries more than one lane), see (Vejdirektoratet, 2017).

The vehicle class is found by comparing the sectional forces introduced by the considered vehicle in a simply supported beam to the sectional forces introduced in a simply supported beam by the standard vehicle. The vehicle class is defined as the vehicle that provides the same sectional forces in the beam as the considered vehicle. The classification of a bridge deck naturally depends on the span of the considered bridge. Further, different elements of the same bridge may have different bridge classes.

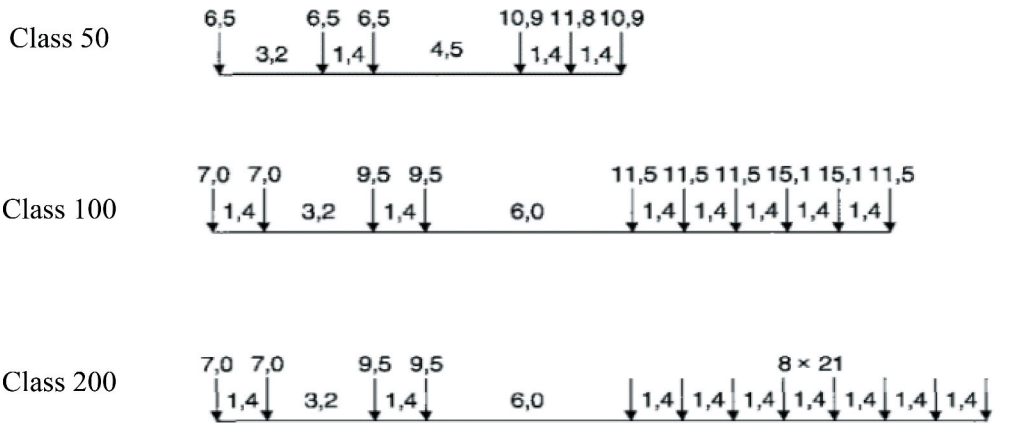

Figure 1. Examples of axle configurations of classification vehicles (weights are given in tons), see (Vejdirektoratet, 2017).

Examples of the lowest (class 50), strategic roadmap vehicle (class 100), and the class 200 vehicle are shown in Figure 1. There are 22 different bridge classes ranging from class 10 to class 500. The bridge class is roughly equal to the total weight in tons of the largest standard vehicle that is allowed to pass the given bridge.

The Danish Road Directorate has developed the so called "strategic road map" which shows all roads where vehicles up to class 100 can drive safely without applying for a permit.

3 PLANNING OF PROOF LOAD TESTS

The Danish proof loading guideline concerns the planning and execution of proof loading of concrete bridges. General guidance on proof lading of concrete bridges with a span of 2 m – 12 m is given in the guideline to ensure that proof loading is done consistently. The results

generated using the guideline should thus provide a sufficient background to update the load carrying capacity of the considered bridge.

3.1 *Bridge inspection*

Prior to the load test an initial inspection of the condition of the considered bridge must be carried out. The focus should be on the following:

- Review of the geometry of the structure to determine whether it corresponds to the provided drawings and static documentation.
- Assessment of the structural behaviour and boundary conditions
- Assessment of the size of natural loads that cannot be controlled in connection the execution of a proof loading. This includes e.g. wind load and water pressure
- Registration of cracks, deflection and other conditions that may be of significance in connection with the assessment of the test's stop criteria.
- Registration of any deterioration mechanisms that may affect the load-bearing capacity of the structure.

3.2 *Initial assessment of the load carrying capacity*

The planning of a proof load test of a given bridge must be based on an initial assessment of the load carrying capacity of the bridge using analytical methods. Based on the initial assessment the load carrying capacity of the bridge with respect to several different failure modes (bending, shear, punching etc.) may be demonstrated. Further, the critical failure mode(s) and the critical load configuration(s) that is (are) decisive for the load carrying capacity of the bridge may be identified. By this initial assessment it should also be determined whether the critical failure mode is a ductile or a brittle failure mode. I the critical failure mode is a brittle failure it should be considered whether a proof load test should be carried out. By the initial assessment all relevant information gained from the bridge inspection should be considered.

3.3 *Acceptance criteria*

According to prEN1990-2 (CEN, 2021b) B.5.2 load testing may be used to update the failure probability of a structure based on a known load. The target test load, defined as the load the structure must carry in addition to the self-weight and permanent load and other acting loads if relevant, should be determined such that:

- the probability that the action effect is not lower than the action effect caused by the applied test load corresponds to the target reliability if no prior knowledge on the resistance is available; or
- the updated probability of failure given survival of the action effect caused by the applied test load corresponds to the target reliability if prior knowledge on the resistance is available.

The guideline developed by the Danish Road Directorate is based on the first mentioned of the two approaches given above. This approach has been chosen because the proof load tests that have been performed so far show that the actual load carrying capacity of the bridges is significantly larger than the load carrying capacity predicted using analytical models (even when using mean values of the material parameters). This shows that the analytical models do not predict the load carrying capacity of the considered bridges with sufficient accuracy but are highly conservative. The models are subject to a considerable model uncertainty and the mean value of the model uncertainty is not equal to one. When no accurate model for the prediction of the load carrying capacity is available it is difficult to take information concerning the resistance of the bridge into account.

3.4 *Load configuration and magnitude*

In planning a proof load test, using the simplest load configuration, which produces a given load effect in the structure may seem attractive. Suppose the critical failure mechanism of

a given bridge is bending failure at the midspan of the bridge deck. In that case, it may seem attractive to perform a proof load test where a point load is applied at midspan and determine the target load such that the probability that the load effect introduced by actual loads is higher than the load effect introduced by the point load (proof load) corresponds to the target reliability. This approach fails to consider that one of the significant reasons why proof load tests often reveal a higher load-carrying capacity of the considered structure is that the actual load effects introduced in the structure are different from the load effects predicted based on the computational models.

Let m_a denote the model uncertainty related to a given computational model that is used to predict the load effect of the actual traffic load acting on the considered bridge and let m_p denote the model uncertainty related to the same computational model when it is used to predict the load effect of the proof load. If the model uncertainty related to the computational model is independent of the load configuration the model uncertainty m_a will be equal to the model uncertainty m_p. In this case it will be possible to determine a configuration of the proof load that introduces the same load effects in the structure as the actual loads acting on the structure. However, in general the model uncertainty will depend on the load configuration implying that it is not possible to determine a simple load configuration that may be used by a proof load test. A proof load test should generally be performed such that the load configuration used by a proof load test, to the greatest possible extent, reflects the configuration of the actual loads acting on the considered structure.

In the guideline for proof loading of bridges developed by the Danish Road Directorate it is recommended that the proof load test of bridges is carried out using loads that represent the actual traffic loads. The proof load is designed such that it represents the axle loads from two vehicles. An example of the load configuration is shown in Figure 2 below.

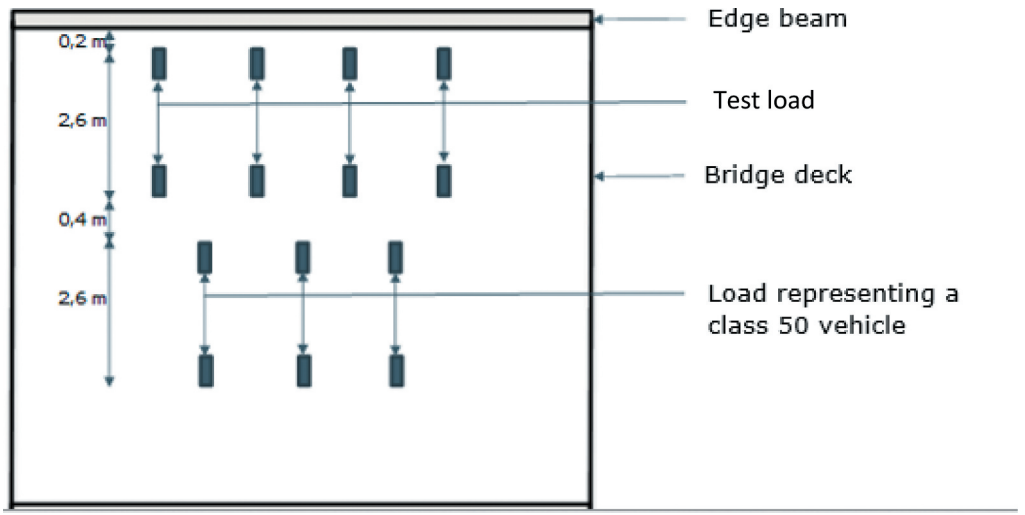

Figure 2. Load configuration for proof load testing.

The magnitude of the load is determined on the basis of the acceptance criteria given in section 33 using the probabilistic models for probabilistic classification of bridges developed by the Danish Road Directorate, (Vejdirektoratet, 2004) and (Vejdirektoratet, 2023).

3.5 *Positioning of the load*

When planning a proof loading test, the location of the reinforcement in the bridge deck needs to be considered. Additional longitudinal and shear reinforcement could be present, meaning that the most critical test location may differ from the locations where the maximum section forces occur. Consequently, the essential failure mechanisms may initiate at other

locations where the bridge has less resistance. The most undesirable location of the applied classification vehicle load will typically be as close to the edge beam as possible. On bridges with a width less than 5.4 m, where the vehicle load is placed in one lane only, a distance of 0.2 m to the edge beam should be used. The distances correspond to a loaded lane width of 3.0 m and a vehicle width of 2.6 m, (Vejdirektoratet, 2017), see Figure 2. The vehicle should be placed in the same position on bridges widths larger than 5.4 m. a standard class 50 vehicle should be placed in the adjacent lane. The actual conditions should be evaluated before prof-loading to ensure the loading procedure is possible.

3.6 *Stop criteria*

Stop criteria define the threshold between acceptable and unacceptable conditions when proof loading. The stop criteria can be defined for ductile failure mechanisms. For brittle failures no such threshold can be defined. The stop criteria must be defined for any relevant failure mechanism and reflected in the applied monitoring. Accordingly, these values should be measurable and available in real-time during proof loading to ensure they can be overseen during testing. Identification and use of the stop criteria shall prevent bridge damage when performing proof loading and thus ensure that the safety level is acceptable.

3.7 *Monitoring*

Stop criterion values can relate to the structural response, crack widths, deformations, target load, etc., which are primary parameters that should be measured in connection with proof loading. Such parameters can be measured using land surveyors, LVDTs, Laser sensors, digital image correlation, etc., and supported by measurements such as rotation, strain gauge, optical fibers, etc. It should, however, be noted that environmental conditions can influence equipment placement and influence the results significantly, which should be accounted for. The crack stop criteria have identical values as described in the serviceability limit state described in DS/EN-1992-2 DK NA, where the maximum crack widths are 0.3 and 0.2 mm for non-prestressed and prestressed bridges, respectively. In addition, the Danish guideline allows settlements at the supports up to 2 mm. Unloading the structure to an extent that enables evaluation of permanent plastic deformations should be possible. It is thus essential to ensure linearity of deformations during proof loading. It should be noted that such deformations can be affected by the loading procedure, crack formations, geometric conditions, boundary conditions, foundation conditions, etc., which should be reported if present.

4 EXECUTION OF A PROOF LOAD TESTS

A proof loading project was arranged in southern Denmark to evaluate the procedure given in the guideline on actual structures. During this project load tests were carried out on five bridges. Each load test was carried out within a period of few hours. Based on the experience from these load tests it is the authors belief that a load test may be performed within a period of about one hour.

One of the tests was performed on a concrete bridge with a span of 6.5 m carrying two traffic lanes. Prior to the test the load carrying capacity of the bridge was estimated to comply with bridge class 80. The bridge is shown in 3 below.

The planned test setup for the bridge is shown in Figure 4 below. The loading consists of a variable load that represents the classification vehicle and a fixed load representing a class 50 vehicle. The class 50 vehicle has axle loads of approximately 17 tonnes. The load configuration is not identical to the load configuration shown in Figure 2. However, the actual load configuration must be adjusted according to the materiel used by the test.

In Figure 5 below the actual test setup is shown. Loading was applied using advanced heavy vehicles, where the axle loads are adjustable Notice that three axles provide the loading on the bridge and that the two axles adjacent to the three axles providing the loading on the bridge are retracted and provide no loading.

Figure 3. Concrete bridge with 6.5 m span.

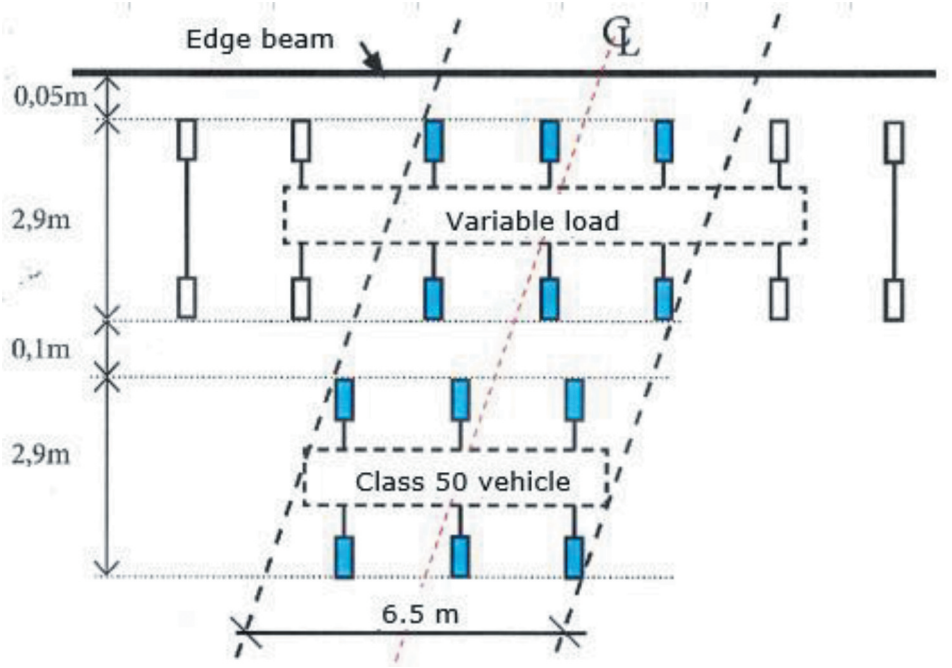

Figure 4. Test setup, see (Christensen et al., 2023).

Figure 5. Actual test setup.

During the testing the load was increased in steps and the response of the bridge was measured after each load step. The monitoring was conducted using Digital Image Correlation to detect cracks in the concrete. Further, the deformations of the structure were determined by a surveyor.

The measured response of the structure did not exceed the stop criteria and the structure showed a linear relation between the load and the response during the load test. The bridge was subject to axle loads of 29 tonnes which shows that the bridge has (at least) a load carrying capacity corresponding to class 100.

5 DISCUSSION AND CONCLUSION

The combination of the ongoing research project worked well as an input generator for the Danish proof loading guideline of concrete bridges. However, one of the main factors that enabled this synergy was the Danish classification system, which describes well-defined load models of heavy vehicles. The classification system and related provisions made it possible to approach a consistent multidisciplinary direction throughout the guideline document addressing the load effects, placing of vehicles, schematics of proof loading procedures, monitoring, etc., leading to a method that can be used for proof loading. A successful pilot project was initiated to prove the guideline's concept. An example of the outcome was shown when proof loading of an actual bridge was compared with values depicted in the guideline. This guideline method upgraded the road stretch from class 80 to class 100. In addition, experiences and outcomes have already been used as input for the upcoming Eurocode background document, prEN1990-2, Basis of assessment and retrofitting of existing structures: general rules and actions. However, some of the document's shortcomings relate to testing structures with potentially brittle failure mechanisms, such as non-shear reinforced slabs, punching shear, etc.

Consequently, the document concerns proof loading of structures deemed susceptible to bending failure and ductile behavior. Further research related to stop criterion thresholds of potentially brittle structures is researched in an ongoing project initiated by the Danish Road

Directorate, COWI, Technical University of Denmark, and Aalborg University. One of the aims of this project is to provide output that can be used to extend the Danish guidelines.

ACKNOWLEDGEMENT

Special thanks to the Danish Road Directorate for their pivotal role in the Danish concrete bridge testing project. We are grateful for your support and look forward to our continued collaboration on load testing practices in Denmark. Additional thanks are addressed to all colleagues and partners who participated in the Danish bridge testing project - technicians, workers, and scientists. Your knowledge and competence have been instrumental in our shared success.

Load testing on existing prestressed concrete bridges to determine long-term effects on strain measurement

Harald Burger, Thibault Tepho & Oliver Fischer
Technical University of Munich, Munich, Germany

Nicholas Schramm
Büchting + Streit AG, Munich, Germany

ABSTRACT: Structural Health Monitoring is an effective tool for extending the life of aging bridges with load-bearing capacity deficits. To interpret and verify the data from sensor systems on structures, in-field load tests for calibration can be used. Such tests were performed for a long-term monitoring project on two prestressed highway slab bridges in Munich. The sensor system was designed to detect fractures in prestressing steel and concrete cracks and to derive a site-specific traffic load model. To achieve this, fiber optical sensors based on the Rayleigh backscattering technology were used for crack detection, while permanent strain gauges provided continuous traffic load measurements. For calibration purposes, it was possible to compare the results from different sensor types. The strain levels recorded are low and the test results indicate that strain gauges are highly accurate under different environmental conditions, while fiber optic sensors are less accurate. During the calibration process, long-term effects were identified that did not significantly affect the data.

1 INTRODUCTION

Around 50 % of bridges on German federal highways are over 50 years old (BASt 2023). Since then, traffic and permitted axle load increased. Technical knowledge has developed, and the relevant standards have been updated to address specific issues. For these reasons, some bridges have a deficiency in their load-bearing capacity, even though they were built correctly at the time, and are now in good structural condition with no significant damage.

Prestressing steel with a risk of stress corrosion cracking is one such problem. Stress corrosion cracking can cause brittle fracture of the prestressing steel. In this case, there would be no warning in the event of a component failure. Until 1978, prestressing steel with these properties was produced in West Germany (mainly trade names Neptun and Sigma Oval). In East Germany, Henningsdorf steel was used until the early 1990s, which had a risk of stress corrosion cracking. Recommendations for dealing with this problem were published in the 1990s and continuously updated. These recommendations were included in a guideline (HA SpRK 2011), which provides a calculative proof of sufficient warning behavior as a crack before structural failure (crack-before-failure).

The guideline includes defining inspection instructions to guarantee a sufficient level of safety. The inspection interval should exceed the standard three-year interval (DIN 1076). Alternatively, a long-term monitoring system can be installed and operated. In this case, it is important to calibrate the sensor system to obtain reliable data, especially for long-term measurements. Schacht (2019) and Bolle (2017) describe monitoring applications and the performance of load tests for calibration for this use case.

A monitoring system is in operation on two bridges in Munich with prestressing steel sensitive to stress corrosion cracking since 2021. The monitoring system differs from those

DOI: 10.1201/9781003483755-38

mentioned in Schacht (2019). In addition to strain gauges, distributed fiber optical sensors (DFOS) for measurement technology based on the Rayleigh backscattering are used for crack detection. There are currently no guidelines for an in-field calibration of these sensor types, despite their numerous applications (e.g., Bado 2021, Bednarski 2022). This study aims to demonstrate the feasibility of in-field calibration for various strain measurement sensors used in long-term monitoring and to investigate long-term effects on the data.

2 KREUZHOF BRIDGES

2.1 *Description*

The "Kreuzhof" bridges (BW 40/45 and BW 40/46) are located southwest of Munich at the link to the A95 federal highway as interchange to a four-lane road. Figure 1 illustrates the bridges. BW40/45 carries the four main lanes in opposite directions and a separate ramp with two lanes. The second ramp, with a total of two lanes, is carried by BW40/46. The bridges were completed in 1967 as part of an infrastructure project for the 1972 Olympics. Currently, the bridges span a four-lane road. Both bridges are three-span slab bridges with longitudinal tubular voids and a maximum total length of 76.0 m. The concrete slabs are prestressed by the bonded post-tensioning system according to the approval of the company Polensky und Zöllner.

The bridge BW 40/45 is 37.5 m wide with a varying skew angle from 13° to 26°. The outer spans are between 19.9 m and 21.8 m, the midspan's length is between 29.9 m and 31.6 m. The cross-section is structurally decoupled with a longitudinal joint into two slabs with a variable height of 1.10 m to 1.40 m. The bridge BW 40/46 is partly curved in plan and 8.0 m wide. The span lengths are around 20.5 m – 29.0 m – 20.5 m. The cross-section is 1.15 m high.

2.2 *Stress corrosion cracking*

The bridges are in good structural condition but have calculative deficits due to the prestressing steel. The type of steel used is inadequate regarding stress corrosion stability. This material problem has led to failures in older constructions in the past. Therefore, improvements to the robustness and durability of prestressed structures were introduced in 1995. These improvements are based on the concept that cracks are a warning of collapse. The steel grades concerned are no longer certified, but existing structures still incorporate such prestressing steel (fib 2003).

The national authorities in Germany have developed a regulation for existing bridges on how to handle these structures (HA SpRK 2011). The regulation includes a proof of robustness, which involves a crack-before-failure analysis not only on individual cross-sections, but also on the overall structural system on a stochastic basis. This is done in two steps. The remaining prestressing steel in a cross-section is calculated when the first crack appears under frequent combination in service limit state. Then, the safety of the structure must be proven with the reduced steel amount under characteristic load combination.

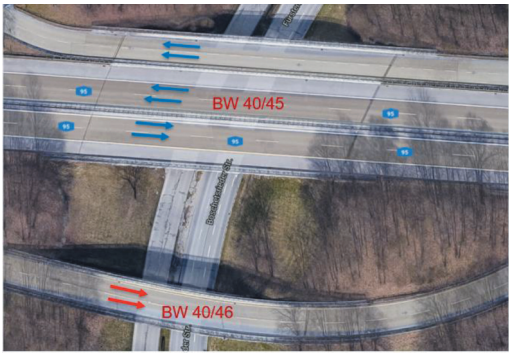

Figure 1. "Kreuzhof" bridges with traffic direction display (taken from [www.google.com/maps]).

The proof for the two "Kreuzhof" bridges was unsuccessful. A large number of wires would have to break before a crack would be detectable and the result would be a complete failure. The remaining amount of prestressing steel is not sufficient to support the characteristic load combination. Verifications were provided positive for inner supports and the inner span. However, it is not possible to detect cracking in the area of the inner supports due to the existing bridge deck. Detailed inspection instructions must be defined for all areas, including those with calculative warning behavior. Based on these results, a monitoring concept was developed for both bridges.

2.3 *Monitoring concept*

In particular, the monitoring pursues the following objectives:

1. detection of potential prestressing steel fractures
2. detection of cracks or damage to the structure
3. derivation of site-specific traffic load model

Acoustic emission sensors were installed to detect steel fractures directly (1). These sensors have been continuously recording data since their installation in 2021. If an acoustic emission (AE) event is detected, local and global structural response (2) will be checked along with webcam data. Inclinometers and distributed fiber optical sensors (DFOS) are installed for this purpose. Inclinometer data was continuously recorded. DFOS measurement data is collected every three to four months or in the event of an AE occurrence using Rayleigh backscattering technology. This redundant sensor system enables the exclusion of errors in the data analysis.

With the use of a site-specific traffic load model (3), the design check according to chapter 2.2 can be updated. Moreover, a more accurate estimation of the number of acceptable steel fractures before failure of the structure is possible. The data on traffic actions were provided from different sensor types: Strain gauges record the structural stress in the longitudinal direction, laser scanners are used to detect, count, and classify vehicles passing over the bridge. Additionally, accelerometers and temperature sensors were installed to identify unknown effects during data interpretation. The system continuously recorded data for one and a half years.

Strain measurement plays a major role in this monitoring system. The use of two different sensor types (DFOS and strain gauge) allows data comparison during calibration. However, calibration still requires a known reference value. To achieve this, load tests were conducted using trucks.

3 LOAD TESTS AND INSTRUMENTATION

The test load concept of the bridges is based on the specifications of the (COST 323) final report, which provides sample timetables and tests during different environmental conditions for calibrating and testing Weigh-in-Motion (WIM) systems. The reliability of the results increases with the number of load conditions available for testing. The scope of a test load is always dependent on the project's boundary conditions.

The test loads on the "Kreuzhof" bridges were primarily necessary to calibrate the sensor system for derivation of a site-specific traffic load model. During the load test on the bridges, also the structural condition was monitored. For this reason, the maximum permissible vehicle load per lane was used to detect any existing cracks or damage.

3.1 *Load test*

A total of four tests were performed over four different days including driving with trucks in moving traffic (dynamic test) and stopping a truck at nine designated locations along closed lanes (static test). Dynamic and static testing was conducted in December 2021 and May 2022, respectively, using three different vehicles listed in Table 1. LKW 3 only participated in the May 2022 test. The axle load of the trucks (listed in Table 1) was weighed and varied minimally in each test.

Dynamic tests were carried out using LKW 1 and LKW 2. The trucks drove across the bridge at speeds ranging from 20 km/h to 65 km/h over a hundred times on both days. The tests investigated various vehicle configurations, including driving one behind the other and driving side by side. The static test consisted of three phases, with the lane used for the test being closed in each investigated road segment. During the first phase, LKW 1 stopped at the designated stop locations. Figure 2 (top) shows four of the nine locations. In December 2021, only one truck was used. During the first phase in the second static test in May 2022, LKW 3 drove with moving traffic at a maximum speed of 20 km/h in lane two. LKW 1 was stationed at one of the stops per direction. The aim was to apply the highest permissible vehicle load to detect any cracks resulting from damage.

In the second phase, the LKW 1 drove backward at walking speed across the entire bridge. In the last phase, the truck drove forward, also at walking speed, across the bridge.

Table 1. Approximate weight in ton per axle for the used vehicles.

name	axles	A1	A2	A3 (– A5)	Total (maximum)
LKW 1	5	6.9	10.3	24.1	41.3
LKW 2	3	8.6	10.7	6.7	26.0
LKW 3	5	7.6	9.0	24.3	40.9

3.2 *Strain sensor setup*

This study focuses on analyzing and presenting the results of the southern slab of the bridge BW40/45. Due to the limited measurement frequency, DFOS data collection was restricted to static tests. he DFOS measuring device (Odisi 610x) had a limited number of channels, allowing only one simultaneous measurement with four fiber optic sensors. Figure 2 (bottom) shows the location of the relevant DFOS and strain gauges on the bottom of the slab.

The DFOS are BRUSens V9 sensors embedded in a groove. Detailed information about the application method can be found in (Burger et al. 2023). The concrete strain gauge used is the

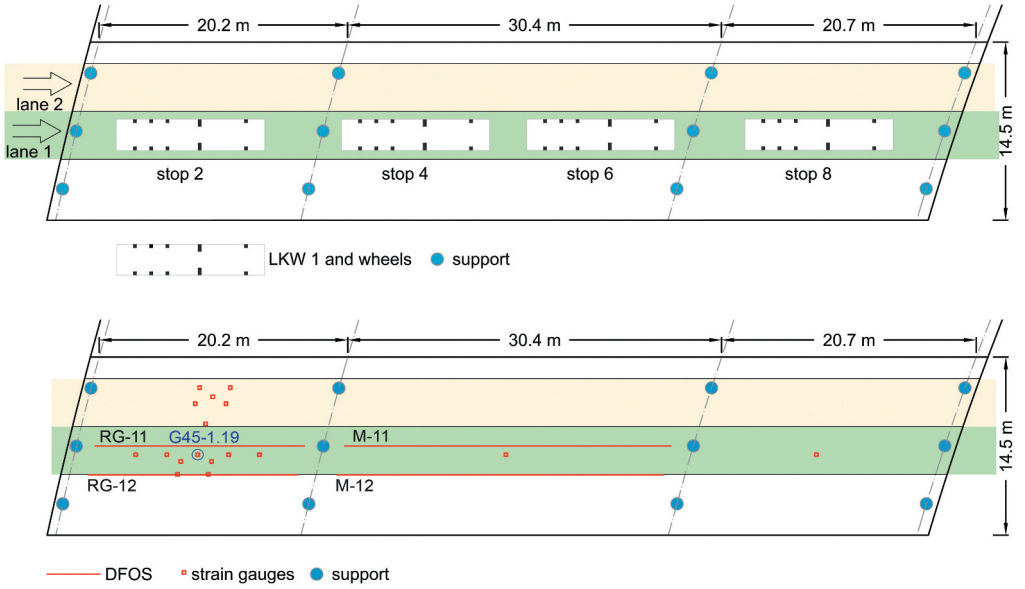

Figure 2. Layout of the southern slab of bridge BW40/45 with different stops during static load test (top) and relevant strain sensors during the static load test (bottom).

PL-120-11 from TML company, which is 120 mm long. These gauges are positioned in various locations below the lanes to determine the number, distance, weight, and lateral distribution of axle loads.

A 120 mm long strain gauge can be compared with approximately 46 datapoints along the DFOS, as shown in Figure 3. The 46 DFOS points can be statistically evaluated for each time stamp. This evaluation is graphically illustrated at the top right of Figure 3. Thus, a general measurement noise over time can be minimized within DFOS data, and extract further information simultaneously. The distance between the DFOS and the neutral axis is about 3 mm smaller. This theoretically results in 0.5 % less elongation for the DFOS.

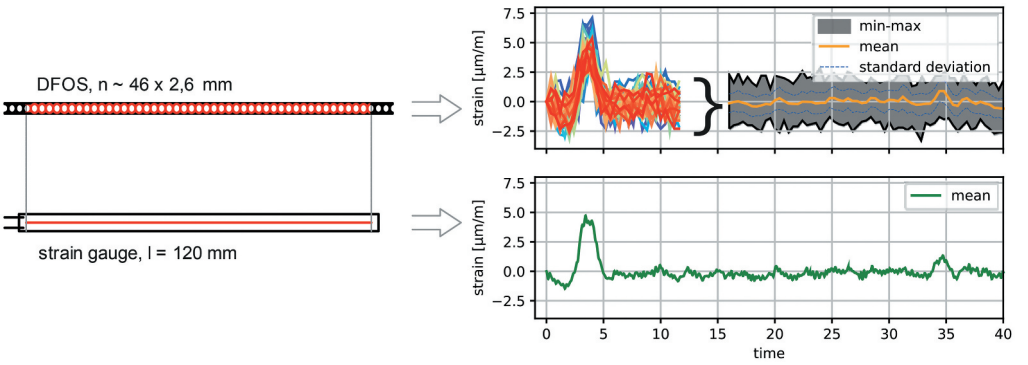

Figure 3. Concept of comparison data from DFOS and strain gauge.

4 EXPERIMENTAL RESULTS

This study shows only a brief excerpt of the static load test results. Specifically, the measurement data from DFOS RG-11 and RG-12, as well as the strain gauge G45-1.19 (blue marked in Figure 2) in the outer span, were analyzed. The measured signals from strain gauges correspond to the strain influence line at the location of the gauge. The data was set to zero for the evaluation at the start of the test load. The temperature is approximately constant over the test period. A constant temperature ensures the consideration of only mechanical load under different ambient conditions.

All strain measurements recorded with fiber optic sensors have been performed at 2.5 Hz, while data from strain gauges are recorded at 400 Hz. Strain gauge data is already filtered using the third order Butterworth filter as a low pass filter with a frequency cutoff of 4.5 Hz, adapted from (Nowak et al. 2023). This value corresponds approximately to the natural frequency of the slab.

4.1 *Comparison DFOS and strain gauge*

During load testing, even minor errors can significantly influence the evaluation due to the shallow strain level. Figure 4 shows the results of the static load test in December 2021. Phase one lasted from t = 37 sec until 290 sec. The stops one, two, and three are located in the outer span where the strain gauge G45-1.19 is installed. The strain remained constant during the stops. The three plateaus until t = 125 sec represent the three stops with a maximum strain measured by the strain gauge at stop two, about 6 µm/m (0.006 ‰). At the beginning of every plateau, a short oscillation appears due to the vehicle's braking process. Stops four, five, and six plausibly cause negative strains, but they cannot be distinguished. The strain from the last three stops is difficult to identify due to the high stiffness of the structure.

During phase two, which lasted from t = 336 sec until 431 sec, the load vehicle drove backward to its starting position in front of the bridge at approximately 3 km/h. During phase 3, from t = 466 sec until 515 sec, the vehicle drove forward over the structure at an approximate

speed. 8 km/h. The highest strain resulted in a maximum difference of 1.23 µm/m (0.00123 ‰) between the strain gauge and DFOS (distance between red and yellow graph in Figure 4, top). Whereby the standard deviation per time stamp for data along the DFOS is already 1.87 µm/m (0.00187 ‰; blue line in Figure 4, bottom). The values are very high considering the maximal strain measured.

During the measurement period, various smaller peaks stand out from the noise. These peaks were caused by heavy vehicles in lane 2 during the test and can be filtered for evaluation. Signals from light traffic (cars) are difficult to detect due to the shallow strain level. However, they have a minor role in determining a site-specific traffic load model. The signal characteristics are essentially the same as those calculated on the three-field beam (20.5 m – 30.0 m – 20.5 m). In addition, the strain gauges signal from phase three has nearly identical characteristics and amplitudes to that observed in the dynamic tests.

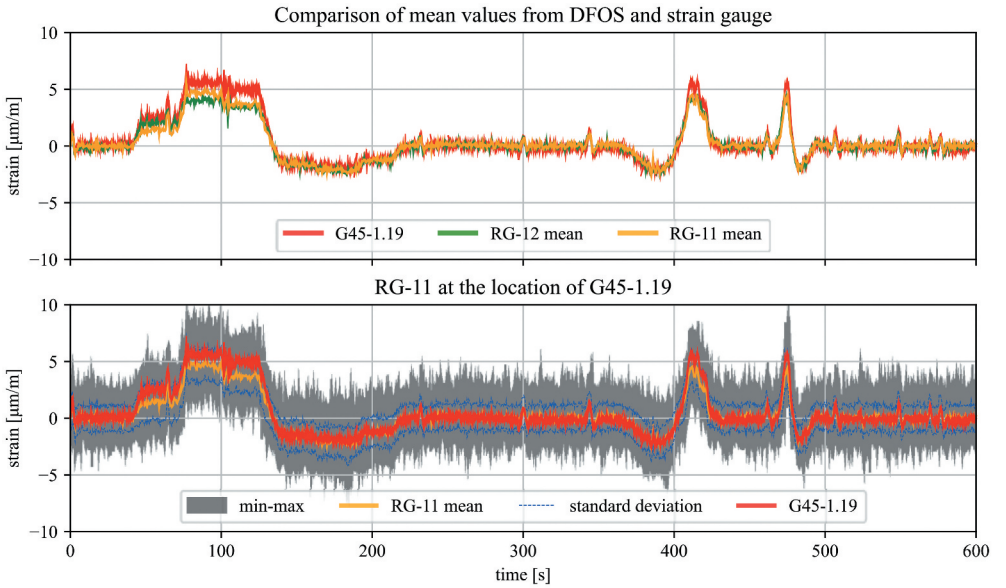

Figure 4. Results of strain gauge and DFOS during static load test.

4.2 *Determination of long-term effects*

To determine long-term influences, it was necessary to reproduce the boundary conditions from the first test were reproduced on the second test day. The same vehicle, LKW 1 (Table 1), was used, but the total weight was 1 % lower in May due to lower cargo load. The locations of the stops in lane 1 were the same, considering specific tolerances when driving a 12-meter-long truck. Weather conditions were different. The temperature on the bottom of the bridge deck during the static load test in December 2021 was 2.8° C on average without sunshine. During the load test in May 2022, the temperature was significantly higher and averaged 20.2° C with clear skies and sunshine. The temperature at the top of the bridge was higher due to solar exposure.

To compare the results from December 2021 and May 2022, the highest strain of the sensors during the static load test is considered. In stop two of phase one of the test, the truck stopped directly above the strain gauge G45-1.19, resulting in the highest strain measured by both sensor types. The stop lasted for at least $\Delta t = 20$ sec. During Δt, the strain only changes due to the load on the lane 2 and measurement noise. Therefore, minimal and maximum values, the median and the mean are considered. Table 2 shows the results for the strain gauge G45-1.19. Note that this level of accuracy cannot be achieved with the fiber optic measurement system. Figure 5 illustrates the median recorded at the two load tests. A comparison of each strain gauge along the DFOS shows an average of 1.00 µm/m (0.001 ‰) higher strain in May 2022

and a maximum difference of 4.45 µm/m (0.00445 ‰). The standard deviation of the difference is 1.27 µm/m (0.00127 ‰). Additionally, the mean scattering width between the minimum and maximum during Δt is 1.18 µm/m (0.00118 ‰) higher in May.

The orange graph in Figure 5 displays the side-by-side configuration of LKW 1 and LKW 3 in May 2022. The maximum strain measured is not exactly double. This load distribution corresponds to the results of the dynamic tests. All the results indicate linear elastic structural behavior of the bridge slab without any observed damages such as cracks.

Table 2. Results of strain in µm/m (10^{-3} ‰) during static load tests, phase 1, stop 2, measured by strain gauge G45-1.19.

Δt = 20 sec	Median	Mean	Max	Min
December	5.61	5.62	5.98	5.34
May	5.65	5.63	6.02	5.28
Δε	0.04	0.01	0.04	0.06

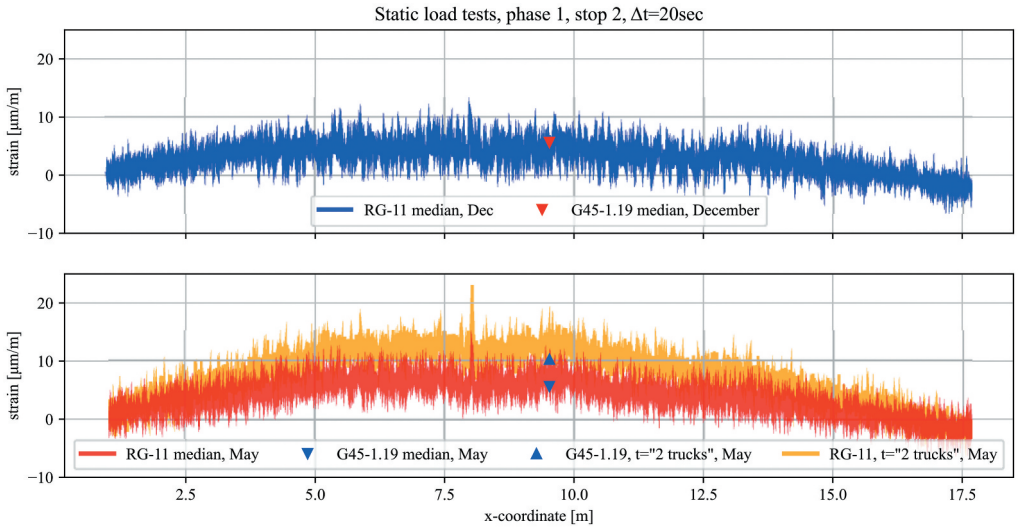

Figure 5. Results of strain gauge and DFOS during static load test in December 2021 (top) and May 2022 (bottom).

5 CONCLUSIONS

To effectively operate a long-term strain-monitoring system, it is necessary to calibrate the sensor system. The test load concept should be adjusted to the project's specific boundary conditions, such as the structure's geometry, monitoring run time, expected loads, etc.. If strain gauges and DFOS are used for strain measurement, it is useful to compare the results in order to validate the data, as it is also done in laboratory tests with DFOS and different measurement systems (Berrocal 2021, Herbers 2023).

To ensure the long-term functionality of the sensors, load tests must be conducted under various environmental conditions. This suggestion is also mentioned in (COST 323) and (Bolle 2017). In the case of the test loads on the "Kreuzhof" bridges, no significant long-term effects were found from different environmental conditions, which provides a functional monitoring system. The obtained monitoring strain data can be further used to update a structural model, similar to the approach used in (Agredo Chávez 2023).

ACKNOWLEDGEMENT

The authors would like to thank the Department of Civil Structures of the City of Munich for the project assignment and the pleasant cooperation.

ABSTRACT: OT-slab road bridges and their capacity were investigated in a comprehensive Danish research project. Such bridges are constructed with prefabricated prestressed overturned T-section beams with in-situ concrete cast on top and are combined with transverse reinforcement for shear load transfer. Often existing bridges suffer from low capacity evaluations insufficient to meet current and future traffic-load requirements. However, recent studies indicate higher capacities than predicted in applied theory. This capacity increase seems to be due to slab behavior rather than strip behavior where insufficient interaction between the OT-elements is presumed. This paper presents evaluations of OT-bridge slabs, based on results from a Danish bridge testing project, (V1), initiated in 2016. The study evaluates capacities in relation to the strip method and yield line theory where Danish standard classification vehicle loads are applied. The results indicate that the strip method may underestimate the capacity of the tested OT-slabs that the yield line theory may be a more suitable assessment method up to the demonstrated load magnitudes.

1 INTRODUCTION

In the Danish Road network, the existing OT-slab concrete road bridges, or inverted T-section slab bridges, stand out as a frequently used short-span bridge type with problematic bridge classifications that often fail to meet today's traffic load requirements. These bridges are constructed using prefabricated and prestressed Overturned T-section (OT) beams, complemented by an in-situ concrete layer poured on top. Additional transverse reinforcement is strategically placed to ensure transverse shear load transfer (Ostenfeld & Jønson, 1950). OT-slab bridges are found in various countries, but it's important to note that they may include different variations of OT-beams (Aadnesen & Husevaag, 1982; Sriskandan, 1977).

In the last decades, numerous studies have undertaken the task of identifying the in-situ behavior and capacity of the existing bridge stock. A common observation from these studies is that the current evaluation methods are conservative and that the actual capacity is usually higher than predicted theoretically (Bagge et al., 2018; Bakht & Jaeger, 1990; Christensen et al., 2023). The capacity of OT-slab bridges has traditionally been evaluated using the strip method (Hillerborg, 1974). However, recent studies in a Danish bridge testing project have

DOI: 10.1201/9781003483755-39

indicated that such an assumption may provide an underestimation of the slab capacity; this hypothesis is indicated by previous studies as well (Halsey & Miller, 1996; Mirtalaei, 1991). In these studies, however, the number of full-scale experiments was limited.

The Danish bridge testing project (V1) was initiated in 2016 to investigate the load-carrying capacity of existing short-span bridges in Denmark and to establish a proof load test method representative of the Danish bridge and vehicle classification system (Vejdirektoratet (The Danish Road Directorate), 2017). The project applied a multidisciplinary approach involving three main research areas: 1) Experimental testing and monitoring, 2) Modelling and simulation, and 3) Probabilistic and decision analysis (Schmidt et al., 2020). Out of the considered bridges, one of the main bridge types in focus was the OT-slab bridge.

Consequently, since 2016, several test results have been generated on OT-slabs. The test results are applied in numerous studies related to the bridge testing project. This paper will provide a comparison in a broad perspective and relate the measured capacities and behavior to known evaluation methods. Based on this, the following research questions have been defined:

- How do the OT-structures perform with regard to the standard vehicles in the Danish classification system?
- How do the OT-structures perform with regard to the evaluation methods of yield line theory and the strip method?
- How can the presented results be used to consider OT-slab structures in the future?

2 EVALUATION METHODS

For a concrete slab, OT-slabs are quite complex since they consist of prefabricated and prestressed beams with in-situ cast reinforced concrete (RC) on top. All interfaces between the OT-beams and the top concrete may be considered a concrete joint. Factory concrete and in-situ concrete typically have different properties as well. Because of this, capacity evaluation of OT-slabs has been governed by the strip method, which may be applied as a lower-bound solution. An upper-bound solution could be hypothesized to be the use of yield line theory. Cross-sectional evaluations for both methods have been carried out using the FAGUS software (cubus, 2023).

The strip method applied considers a strip in the span direction, which is treated as statically independent from adjacent beam elements. In this case, it is assumed that no shear capacity between the elements is present and that the in-situ cast concrete does not provide any contribution to the capacity and is considered as dead load only. In doing this, the evaluation may be based on a common beam evaluation, which for OT-slabs includes an OT-beam with top concrete attached. The determined capacity may be scaled to a desired width. In this paper, the width for full-scale bridges is assumed to be the width of a notional lane (3 m) in the Danish classification system.

For the applied yield line theory, yield moments in the transverse direction are considered along with the yield moments in the longitudinal direction. The transverse reinforcement is thus assumed to be able to redistribute the applied load through the concrete interfaces (up to its bending capacity), and the shear bearing capacity is assumed higher than the bending capacity. In the considered OT-slabs, a reinforcement net is present in the top concrete. This is necessary to evaluate using the yield line method. All yield line evaluations are performed in the software Optum MP, (Optum, 2023).

3 IN-SITU BRIDGE AND SUBCOMPONENT TESTS

Three full-scale bridge tests on OT-slab bridges have been carried out (Schmidt et al., 2018). The bridges were set for decommissioning, and the tests were planned as potential failure tests. However, they all reached higher capacities than anticipated in the given calculation basis. As a result, one of the bridges was cut into strips and tested again (Christensen et al.,

2021). In these tests, more of the response and behavior was revealed. Another bridge had beam elements cut out, which were tested in the laboratory. In addition, a single proof load test has also been performed (Christensen et al., 2023). Since this was a proof load test, the load levels were significantly lower than in the failure tests.

3.1 *The test bridges*

The test bridges had different characteristics and dimensions but were of the same OT-type. Photographs of some of the tested bridges are shown in Figure 1abc. A typical cross-section of the used OT-beams and a combined bridge cross-section is shown in Figure 1d (from bridge 1576), for general bridge characteristics see Table 1. All evaluations in this paper are based on mean values for material strengths. The evaluations are thus meant for comparison with the real bearing capacity and not the design value. For the in-situ bridges, material strengths were found through material testing of bridge 1576. The most significant parameters are: 1) pre-cast concrete $f_{cm} = 72$MPa, 2) in-situ top concrete $f_{cm} = 41$MPa, prestressed tendon yield and ultimate strengths $f_{ym}\tilde{1}500$MPa, and $f_{um}\tilde{1}800$MPa. The regular reinforcement was not tested, and the yield strength, $f_{ym}\tilde{5}90$MPa, is thus based on drawings.

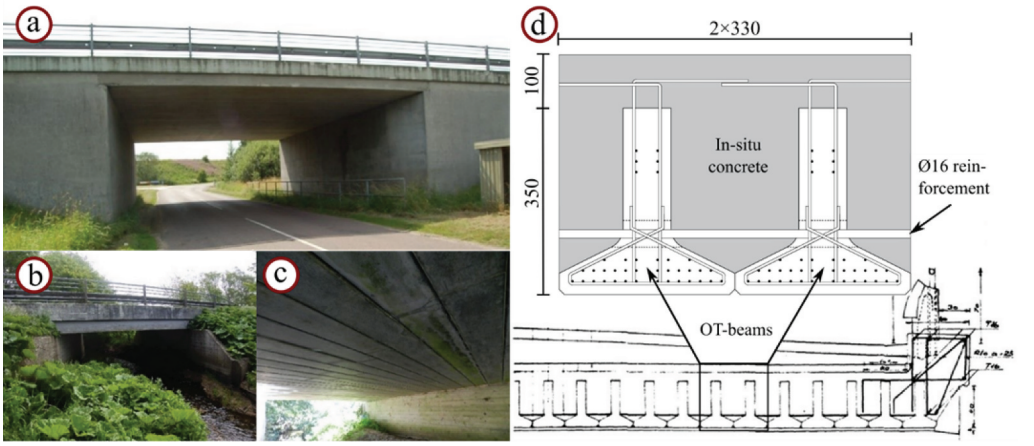

Figure 1. A) Bridge 1577 before testing. b) Bridge 3700 before testing. c) The bottom surface of Bridge 3700. d) Cross-section and combined cross-section of Bridge 1576.

Table 1. Bridge characteristics of the in-situ test bridges.

Bridge number	1577	1727	Strip 1 (1727)	Strip 2 (1727)	1576	3700
Span [m]	11	9	-	-	6.6	6.5
Skewed [deg.]	-	-	-	-	32	29.5
OT-beams	37	37	11	11	72	34
OT-height [mm]	450	450	-	-	350	350
OT-width [mm]	330	330	-	-	330	330
Prestress tendons	32	32	-	-	36	22
Road build-up [m]	0.45	0.45	0.45	0	1.2	0.4

3.2 *Cut-out beams from Bridge 1576*

The simplest test in the test matrix was the beams cut from bridge 1576. These consisted of two adjacent beams, including top concrete (L = 5.3 m). The beams were tested in four-point bending with 1.4 m between the loading points (axle distance of the Danish system). The response curves for the five specimens are shown in Figure 2a along with a beam evaluation

and two wheel loads of a class 500 ton vehicle of the Danish classification system (the heaviest vehicle in the Danish classification system).

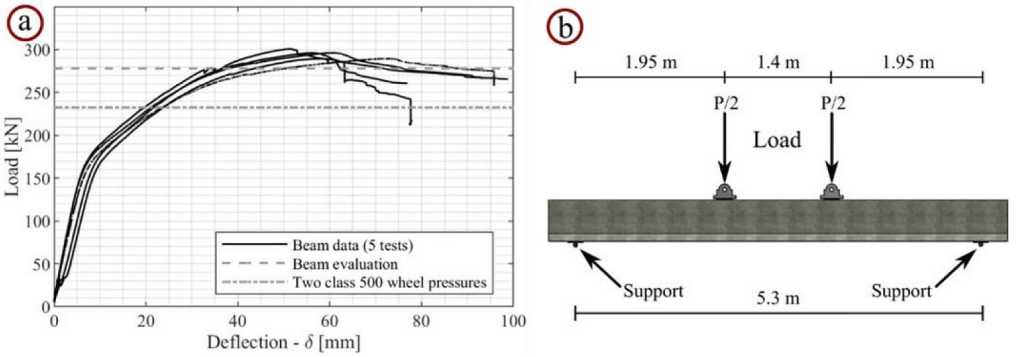

Figure 2. A) Response curves for the five OT-elements. Original results presented in (Jensen et al., 2018). b) Cross-section of the tested beams with two OT-beams, transverse reinforcement, and in-situ concrete.

It is seen that the beam evaluation fits well with the experimental results and that the beams are stronger than the wheel pressures of the class 500 ton vehicle (the largest of the system). Figure 2b shows the cross-section of the tested beams. The average ultimate capacity was 294 kN. The beam evaluation was 278 kN.

3.3 *In-situ test methods*

The high-magnitude failure tests were performed using a novel high-magnitude load testing rig, designed for controlled loading of short-span slab bridges (up to 12 m). The test setup was designed to facilitate loading with wheel and axle load configurations representative of the Danish standard vehicles (Vejdirektoratet (The Danish Road Directorate), 2017). It utilized a cradle system with loading frames simulating wheel pressures. Ballast and hydraulic pistons were used for the load application of the primary vehicle, Vehicle A. The secondary vehicle, Vehicle B was a passive fixed load. The test setup can be seen in Figure 3a. On bridges 1577, 1727, 1576, and 3700, both vehicles A and B were applied. The two strip tests of bridge 1727 had a total width of 3.63 m and were thus too narrow for both vehicles. Therefore, only vehicle A (the classification vehicle) was applied. The single proof load test on an OT-slab bridge utilized special heavy vehicles with hydraulic control of individual axles for load application (Christensen et al., 2023). Such vehicles are seen in Figure 3b.

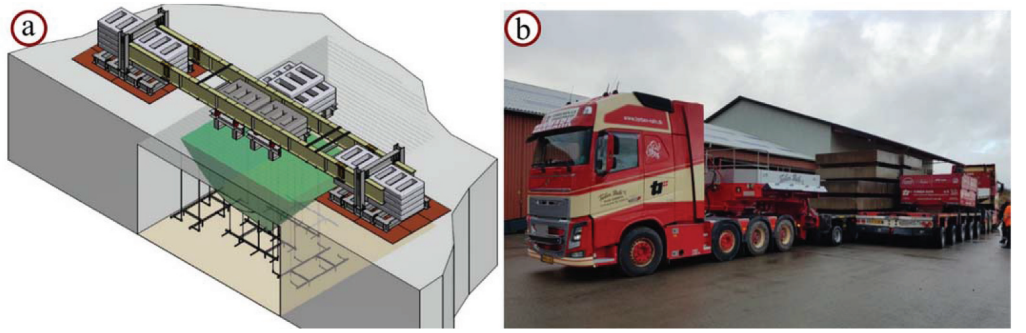

Figure 3. A) Novel high-magnitude loading rig first presented in (Halding et al., 2017). b) Special heavy vehicles with hydraulic control.

In both load setups, the load is applied according to the Danish classification system and in one case using actual heavy vehicles that drive the Danish road network. This is deemed more representative than e.g., the application of Load Model 1 (LM1) of the Eurocode (European Committee for Standardization (CEN), 2003), which may require significantly higher wheel pressures that do not reflect the vehicles of the Danish classification system.

3.4 *In-situ results and evaluation*

Using the characteristics in Table 1 and the described evaluation methods, the bridge capacities have been determined. Note that the following assumptions have been made: 1) The road build-up has not been included in the capacity evaluation, neither as self-weight nor as a contribution to the capacity. In addition, no load distribution has been applied through the road build-up. Table 2 shows the estimated capacities along with the design loads of a class 500 ton vehicle and the applied test loads. Note that all loads describe the total applied load on the bridges and that the total mean load of vehicle B was 330 kN.

The response curves for the two strip tests are shown in Figure 4. They should not be mistaken for full-scale tests since they are more correctly described as wide beam tests, which are dependent on some interaction between OT-beam elements. If there is no interaction, only the beams underneath the wheel pressures can be activated, therefore both a calculation for the full width and the beams underneath the wheel pressures have been included. It is seen that the full-width beam evaluation fits well with the strip tested without asphalt, while the strip with asphalt seems stronger. In addition, the strips were much stronger than the mean loads of a class 500 ton vehicle.

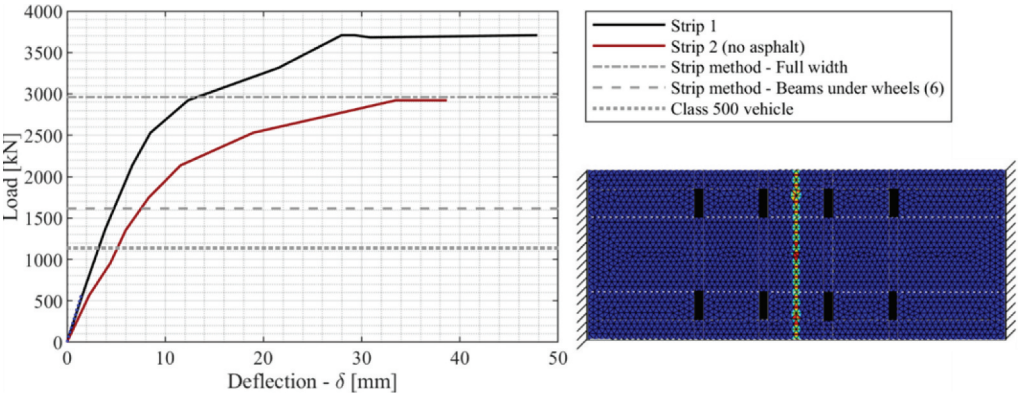

Figure 4. Response curves for the two in-situ strip tests. Original results in (Christensen et al., 2021).

The response curves of the full-scale bridge tests are shown in Figure 5. Figure 5a shows Bridge 1577, Figure 5b shows Bridge 1727, Figure 5c shows Bridge 1576, and Figure 5d shows Bridge 3700. The evaluated capacities and classification vehicle are also depicted.

Bridges 1577, 1727, and 1576 appear much stronger than the mean values for the class 500 ton vehicle while the proof loaded bridge 3700 only just reaches this load. No, failure or visible cracks were observed at the applied maximum loads. However, with a deflection of only 2 mm, it seems safe to say that the capacity is much higher. The first three bridges all surpass the strip method results, but none reach the yield line results. Everything in the performed tests points at a sufficient load distribution.

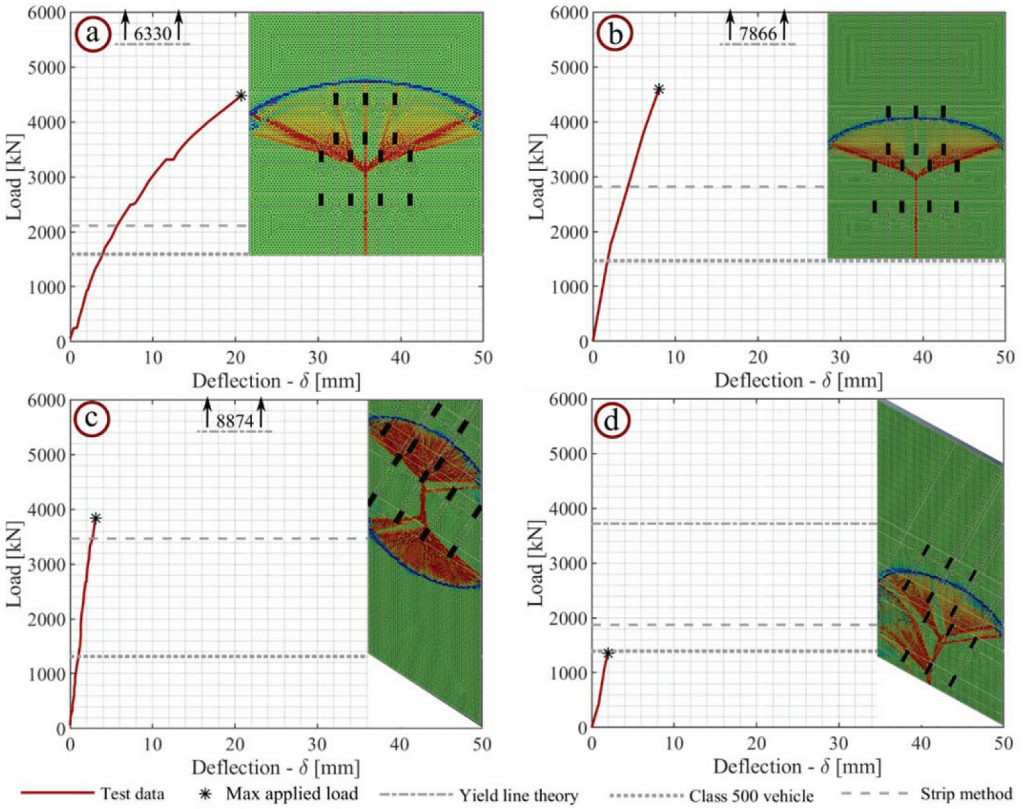

Figure 5. Response curves and load placement for four tested in-situ bridges. a) Bridge 1577. b) Bridge 1727. c) Bridge 1576. d) Bridge 3700. Original results in (Christensen et al., 2023; Schmidt et al., 2018).

Table 2. Estimated bridge capacities, a class 500 vehicle, and test results. All loads and capacities in kN.

Bridge number	1577	1727	Strip 1 (1727)	Strip 2 (1727)	1576	3700
Strip method	2110	2816	974*		3464	1872
Yield-line theory	6330	7866	2962**		8874	3718
Class 500	1594	1468	1138		1314	1392
Applied load	4481	4600	2922	3708	3842	1354

*Determined as the capacity of the beams directly under applied wheel pressures (no redistribution).
**Determined for the full width of the strip (3.63 m).

4 SCALED LABORATORY TESTS

A good interaction between OT-beam elements was observed in the in-situ bridge tests. The topic was assessed to require further investigation; this because a more verified interaction could open an opportunity to assume slab behavior and apply yield line-based methods.

A test was designed for the laboratory that could serve as an evaluation of the shear interaction between the OT-beam while providing data on the response until failure. The test setup was designed to utilize three-sided support of an OT-slab with seven downscaled OT-beams. Figure 6 shows the test setup and cross-section (Figure 6a) and proposed behavior (Figure 6b).

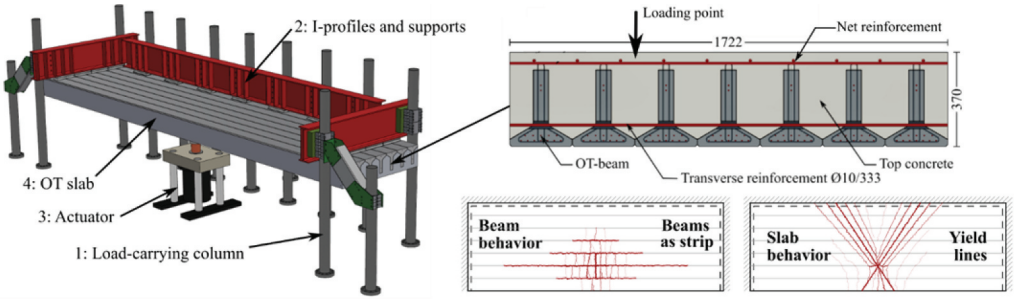

Figure 6. A) Laboratory test setup and OT-slab cross-section consisting of seven OT-beams. b) Suggested behavior extremes; beam behavior and slab behavior (Christensen, Halding, et al., 2022).

The slabs had dimensions of 8.40m x 1.72m x 0.37m and were loaded with a single point load between the second and third beams. For more information on downscaling, etc., see (Christensen, Halding, et al., 2022). The response curves of the two tests can be seen compared to yield line theory and beam evaluation in Figure 7 and to a class 500 ton vehicle wheel load. Even for these down-scaled slabs, the capacity is higher than beam evaluations and class 500 ton wheel loads. The revealed crack patterns showed both beam behavior and slab behavior, but the capacity was equivalent to slab behavior and yield line theory (Christensen, Halding, et al., 2022).

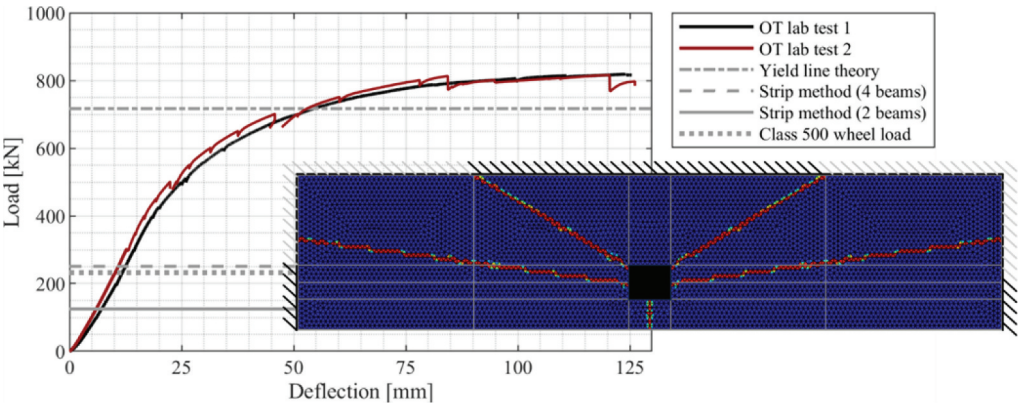

Figure 7. Load/deflection curve for the two OT-slab tests. Original results presented in (Christensen et al., 2021; Christensen, Zhang, et al., 2022). At maximum load, the support conditions changed due to slab behavior causing a lift of the corners; this is included in the yield line model, see areas marked with grey.

5 DISCUSSION

To some extent, the results of the full-scale bridge tests (Table 2 and Figure 5) appear to go towards the applied upper-bound solution of yield line theory. However, the full-scale tests did not reveal the full plastic regime of the OT-slabs; this for two reasons: 1) Unexpected high loads and available ballast ran out, and 2) Proof loading purposes limited the load application. In this situation, the strip tests of Bridge 1727, beam tests of Bridge 1576, and laboratory slab tests related to Bridges 1577 and 1727 provide strong indications of the capacity potential of the tested bridges.

All tested structures exhibited slab behavior until the applied maximum load. For instance, the laboratory OT-slabs which were designed as an ultimate capacity test of the concrete

interface between the OT-beams, showed significant cracking. This observation indicates that the transverse reinforcement actually ensures the desired slab behavior. The results thus support previous findings of two comparative studies (Halsey & Miller, 1996; Mirtalaei, 1991). Consequently, it can be justified that the interface between OT-beams and the associated transverse load transfer may provide sufficient capacity to generate a yield line formation (if properly constructed).

All tests showed capacities significantly higher than the mean values for the largest vehicle in the Danish classification system (Class 500 ton) and its axle loads; this even for the strips with reduced width (Figure 4). The beam tests with two OT-beams carried loads larger than the design value of two wheel loads of the class 500 vehicle ton (Figure 2) and the OT-slab supported along three edges (Figure 7) showed that even a load almost four times the class 500 wheel load could be transversely transferred through the beam interfaces from a single loading point. It should be noted that in a classification or proof loading situation, the loads of a class 500 ton vehicle will be significantly higher, but in the present paper, only a comparison of capacities is performed. As standard vehicles and associated load configurations are used for both classification of bridges and granting of special vehicle permits, the applied loads are assumed to sufficiently represent the extreme load effects that may be experienced by a bridge.

The results from the strip tests of Bridge 1727 with a width of 3.63 m and the beam tests in the laboratory of Bridge 1576 showed that the strip method/beam evaluation adequately estimates the actual capacity of the structures. The full-scale tests showed that the strip method largely underestimates the capacity of OT-structures because load redistribution is not included. In addition, the extreme stress test in the laboratory using a single point load showed that the concrete interface in similar OT-structures has sufficient transverse capacity. Therefore, with the knowledge that there most likely will be a capacity reserve, the strip method may be used as a first estimate but seems inadequate as a definite solution. The yield line method seems to be a more suitable approach to evaluate OT-slabs if sufficient transverse capacity between the OT-beams is considered.

6 CONCLUSION

The Danish bridge testing project V1 has provided significant insight into OT-slab bridges and their behavior. The results show that the OT-slabs generally exhibit slab behavior (linear until high capacities) and are therefore more correctly evaluated by taking into account more transverse capacity than previously anticipated; this facilitating the use of the yield line method. The test results are insufficient to conclude that this can be done until maximum capacity, however, the measured capacities have a magnitude that indicates that the OT-slabs do not seem to represent a challenge in relation to the heaviest vehicle in the Danish classification system (Class 500 ton) - Loads which are much higher than the structures original classification. Consequently, it is likely that OT-bridges capacity poses a reduced challenge in the Danish road network.

ACKNOWLEDGEMENT

Special thanks to the Danish Road Directorate for their pivotal role in the Danish concrete bridge testing project. Additional thanks to Assistant Professor, Philip Skov Halding, at the Technical University of Denmark, for his part in data collection and documentation during his time as a Postdoc.

Lessons learnt from load testing in the UK

D.P. Cousins
Accolade Measurement, Welwyn Garden City, UK

ABSTRACT: Accolade Measurement have been conducting load testing in the UK since 1993. Notable examples include suspended trusses of the Cleveland Bridge in Bath, reinforced concrete deck hinge joints of the M4 Usk River Bridge after they were strengthened by post-tensioning, a jetty at Jarrow and a vehicle parking floor at Luton. Tests have involved load application by rolling heavy vehicles, concrete kentledge blocks and water bags. Measurements of displacements and strains have used permanent structural health monitoring systems, temporarily fixed sensors, total stations and digital image correlation; each of which have their advantages and limitations. Other tests on cantilevers, parapets, lifting systems, buildings and mezzanine floors have addedto the body of knowledge. Where numerical assessments are unsuitable and leave uncertainties, proof load tests have demonstrated capacity for vehicle loading. This paper draws on experience of Accolade and the author's career, to present some interesting cases and highlight lessons learnt.

1 BACKGROUND

Load testing of bridges is only occasionally conducted in the UK and never routine. Guidance from National Highways (the owner and operator of all trunk road bridges in England), sets the standard for bridge management in the UK, widely accepted also as the benchmark for bridges owned by other highway regions, Network Rail, local authorities and private bridge owners. Document CS 463 (National Highways, 2019) enables the use of load testing to 'assist in the strength assessment of bridges', stating:

> Load testing of a bridge shall only be undertaken after calculated assessments using the best available methods and information. . .fail to show it to comply with the assessment standards.

The guidance continues to describe two forms of load testing as:

- Supplementary load testing: where controlled loads applied are less than the normal daily working loads of the structure, no greater than 90% of the unfactored serviceability limit state (or 60% in steel-concrete composite bridges) and remain within the bridge's elastic limit. This is to be used for calibrating or correcting assessment calculations and models. Long established 'Guidance for Supplementary Load Testing of Bridges' is still in regular use (ICE, 1998). In other countries this may be called 'diagnostic testing'.
- Proving load testing: (elsewhere termed 'proof load test', including this paper) where the test replaces numerical assessment by imposing a larger load than permitted traffic, but is only allowed for bridges which would otherwise be closed to traffic or demolished. To date, no further guidance on the use of proof load testing for bridges is recognised in the UK, reliant instead on the experience of the testing contractor. Guidance for proof load testing from other countries, including the USA (Transport Research Board, 2019), may be referenced at the engineer's discretion.

Unlike other countries (for instance France (Sétra, 2004)), 'acceptance load tests' are not required in the UK for new bridges, though may be specified for substantially novel or large bridges

DOI: 10.1201/9781003483755-40

(see Queensferry Crossing, below). Confusingly, the ICE guidance (ICE, 1998) calls this a 'proof load' – but which this author suggests should be removed from UK engineering terminology.

Increasingly, proof load tests are required for existing bridges of incalculable capacity or uncertain load distribution, hoping to maintain load carrying capacity, extend service life and minimise expensive, environmentally damaging strengthening or reconstruction. This author is familiar with bridge owners or consultants seeking examples and evidence of past experience before deciding to conduct a load test. There is assumed to be a lack of precedence or procedures for technical approval needed in the UK. It is hoped that this paper provides some of that guidance.

2 CASE STUDIES

2.1 *Cleveland Bridge*

A single span highway bridge constructed originally in 1826 of five cast-iron arches, was reconstructed in 1928 retaining the arches, alternating with four reinforced concrete trusses, to support a new concrete deck (Figure 1a). Each truss is suspended at both ends on eleven steel bars of 31.75mm diameter, found to suffer from corrosion. Assessment calculations assumed the arches to be no longer structural. In 2021, the bridge was temporarily closed to traffic for safety.

Installed sensors for long-term measurement include: 16 displacements at truss ends, using linear variable displacement transducers (LVDT); 42 vibrating wire strain gauges on selected hanger bars; 1 LVDT at a notable group of cracks in reinforced concrete; and 2 cameras for digital image correlation (DIC) monitoring of seventeen finer crack movements in the same zone.

A supplementary load test was conducted overnight in October 2022, with normal traffic limited to one lane of the carriageway in contraflow. Two gritter trucks were applied, of 10.2 tonnes and 17.8 tonnes (Figure 1b), with their positions measured by a laser distance gauge and fed into the same data acquisition unit, thus avoiding manual records.

Data collected was later displayed as influence lines for each vehicle passing the bridge. Load sharing relationships between the four trusses were evidenced from vertical deformations. Vehicle load supported in the trusses was calculated from the strains, evidencing additional contribution of the cast-iron arches despite not directly monitoring them.

No damage was detected in the load test and no irreversible deformations were measured. This, combined with ongoing remote monitoring, which is assisted by anomaly detection using machine learning, enabled the bridge managers to reopen the bridge in both directions for vehicles up to 18 tonnes.

Figure 1. Cleveland Bridge a) Section view and b) load application for supplementary test.

2.2 *Usk River Bridge*

A five-span motorway underbridge totalling 135m length, carries the M4 motorway over the Usk River. Constructed in 1967, it includes flexible hinge joints in reinforced concrete beams at four contraflexure positions providing freedom of rotation yet maintaining shear connection. Beam depth is reduced to 1/3 of the typical depth for just 38mm in length. Reinforcement bars pass through the reduced depth including horizontal dowels and flanking diagonals (Figure 2a). As the hinge rotates due to beam deflections, these bars are highly stressed.

In cold temperatures, the bridge deck can be subject to horizontal tension meaning there to be no reliable compression through the joint (unlike 'Mesnage' or 'Freyssinet' hinge joints in

compression columns (Schacht & Steffen, 2015)). On rotating, the joint cracks through concrete and deck surfacing, allowing chlorinated road water to pass directly down into the hinge joint, which had led to pitting corrosion on reinforcement at the critical centre, confirmed by intrusive investigations. Fatigue assessment and laboratory model testing were conducted extensively between 2005 and 2010 (Cousins, 2017), which sparked this author's excitement in complex deteriorated structures. Repairs were conducted in 2017 which led to the joints being externally post-tensioned to create a constant compression across the hinge joints. The bridge was subject to supplementary load tests by Cardiff University and Accolade Measurement at multiple stages during investigations and after the strengthening:

- In 2005, a mobile crane of 60 tonnes mass was applied, but measurements focused on the external faces which were later shown unrepresentative of internal hinge joints.
- In 2007, the test was repeated with a 96 tonne mobile crane. Additional sensors were used to compare the rotations of internal and external hinges. The vertical profile of the deck was measured by total station extensively. These were used to calibrate finite element models for the bridge assessment.
- In 2020, a repeat test was conducted with a 60 tonne vehicle (Figure 2b) to investigate the influence of the post-tensioning on hinge stiffness, comparable to the 2005 test. Results demonstrated no detriment from the works to the load distribution in the bridge.

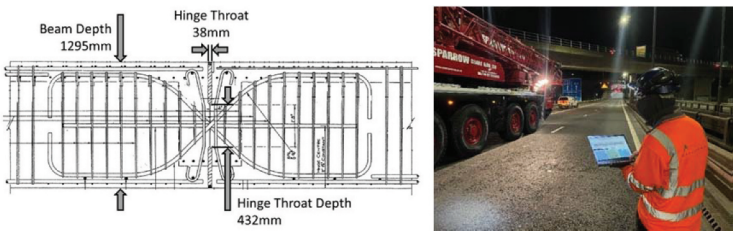

Figure 2. Usk River Bridge a) Deck hinge concrete details and b) Loading and live data displays, 2020.

2.3 *Union Chain Bridge hanger caps*

The Union Chain Bridge was constructed in 1820, crossing the River Tweed between England and Scotland. In celebration of its 200-year anniversary, the bridge was partially dismantled for refurbishment. Cast iron, components known as 'hanger caps' sit on the main chains and support vertical hanger bars. Some of these were found by magnetic particle inspection to include cracks in their top surface emanating from the concave corners of the centre hole.

It was possible to replace all hanger caps with new steel parts formed by computer numerical control (CNC) machining, but which would have been expensive and wastefully disposed of these original parts. An opinion was given that the cracks were superficial, probably existent from original casting and should not pose a risk of fracture in future service. In order to investigate this, a proof load test was conducted on five hanger caps (Figure 3a).

Caps were supported imitating the bridge chain and vertical load imposed by jacking onto a steel wedge insert, similar in shape to the hangers. Force was applied equal to five times the maximum service load of a hanger bar. Crack widening was measured with vibrating wire strain gauges. Conducted inside a shipping container provided safety in case it were to fragment.

In all cases, the cracks were seen to widen up to a maximum of 0.1mm, but fully return to their starting condition when load was removed, which evidenced no propagation of the cracking even under extreme loading. Hanger caps were deemed suitable to return to the bridge and remain in service, maintaining these historical parts.

2.4 *Queensferry Crossing, Edinburgh*

Load testing of the Queensferry Crossing was conducted in August 2020, which is described in detail by Cousins, et al. (2022). Three vertical towers hold suspension cables of the main spans, crossing the tidal estuary. Two road traffic lanes plus a hard-shoulder flow in each direction,

straddling the towers and cables. The bridge hosts what is believed to be the world's largest structural health monitoring system, consisting of 2184 physical sensors, reading at up to 1000Hz.

A supplementary load test was required in the construction specification to demonstrate the functionality of the structural health monitoring and confirming behaviour of the bridge.

The test was conducted overnight, when traffic was minimally disrupted and there was less variation in temperature. Six 44-tonne trucks passed over the bridge in formation three vehicles wide. Position of the vehicles was recorded by one GNSS rover unit on the lead vehicle. Normal traffic in the direction of the test load were held back temporarily by police vehicles. Traffic in the opposing direction remained free flowing. Consideration was given to the possibility of complete closure of the bridge for the load test, but the traffic management, expense and disruption caused would have been unfavourable. It was determined acceptable to have short duration closures in one direction only, and the 'noise' from other traffic was not obtrusive to the results.

Results showed that the bridge stiffness was within 10% of design estimations.

2.5 *River Tyne jetty*

A concrete jetty supported on piled foundations in the River Tyne at Jarrow was to be repurposed. A new pipe bridge from shore to the jetty would be constructed landing onto two pile caps of the existing structure. A proof load test in January 2022 demonstrated capacity (Figure 3b).

Localised poor areas of the concrete deck were alleviated by placing steel plates over, which concentrated loading on selected piles beneath and avoided punching shear. Loading by concrete kentledge blocks totalling 80 tonnes was applied in 7 increments, installed by mobile crane. Due to unfavourable weather, the two-day testing was truncated. After 16 tonnes was applied, wind speeds rose meaning the crane could no longer operate, progress was halted and not restarted until 40 days later. There was good evidence that at this small load, no creep developed.

Monitoring consisted of digital levelling of the jetty top surface, relative to a static marker on river bank with tolerance of ±0.2mm. The maximum movement seen in the test was only 2.56mm, but this in an upward direction and consistent across all monitored positions on the jetty. This confused the team at the time, and did not to correlate to applied load. Later a better correlation was found to the tide level in the estuary. No damage was noted to the piles and results were deemed to have demonstrated sufficient strength in the piled foundations.

Figure 3. a) Hanger cap from Union Chain Bridge, in proof load test and b) Kentledge loading of 80 tonnes on the River Tyne jetty.

2.6 *Luton vehicle parking floor*

A structural floor for vehicle parking with an aged concrete deck could not be assessed numerically due to a lack of recorded information and subsequent deterioration. Instead, it was proof load tested in January 2016, by applying water weights. Though not a bridge, the principles of testing remain the same, as has been conducted on roofs and floors of many buildings. Confined water sacks were used to apply universally distributed loads to the surface in regions up to the ultimate limit state at 8.2kN/m^2 in eight increments, to a maximum of 316 tonnes (Figure 4a).

Loading zones were sequenced to create hog and sag effects in the deck. By measuring the water flow rate, it was possible to ensure the load is controlled and equally applied in multiple bags. A small amount of water leaked as is common in such tests and normally of no problem to clear, but in the winter conditions this froze, making the working area temporarily slippery. At one point, the temperature dropped further such that hoses became frozen and testing was delayed.

LVDTs measured vertical deformation of the deck and supporting beams at 17 locations, using plumb bobs suspended on Invar wire (for temperature stability) (Figure 4b). Prior identified cracks were monitored for width at five locations. Loads were held for up to 2 hours. A maximum of 2.08mm displacement was measured in beams and observation of hysteresis patterns during the test supported that the test had caused no permanent deformation.

Figure 4. a) Water weights used for load testing at Luton and b) plum bob and LVDT measurements.

2.7 *Millbrook and Redbridge parapets*

Not all load tests are vertically applied. Parapets of the Millbrook and Redbridge Flyovers on the A33 at Southampton were identified as deficient when an impact occurred. Precast concrete parapet units of 2m length are attached to the bridge cantilever edges by a cast in-situ joint. Subsequent to the fault, strengthening was designed and implemented by joining parapet units together at their top edge. Load testing was required to demonstrate the improved resistance.

Accolade Measurement applied horizontal proof load tests in a static representation of the impact force. Overturning moment equivalent to 13kNm/m was applied to the parapet units and held for 5 minutes, demonstrating stiffness and elastic recovery.

To minimise disruption, test equipment was mounted to a low loader trailer of 39 tonnes mass (Figure 5a). The test was applied to 219 locations distributed throughout both bridges, conducted in just 6 night-shifts between March and May 2018. Only three locations showed signs of distress, seen in cracking at the parapet base joint; one test was stopped before reaching maximum load for safety reasons. Improvements needed were thus minimised.

2.8 *Upper Teesdale bridges*

Load testing is equally applicable to the smallest of bridges. In the North-East of England, five small bridges provide a route to the source of the River Tees. When revetment works to the river banks required haulage vehicles to transport heavy rocks up the mountain, the track needed to be uprated from the sign-posted 3 tonnes weight limit. The cause for imposing such signage was not known, and records of the bridges were not available for numerical assessment. Investigation and material sampling, followed by numerical assessment calculations would have been prohibitively long and likely result in ambiguous or very conservative conclusions.

Instead, proof load tests were conducted for all five bridges over five days in June 2023 (Figure 5b). Load application involved concrete blocks of 1.2 tonnes on a flat-bed trailer, driven on and off the bridges, up to 33 tonnes. Measurements of vertical deformation were taken by LVDTs on vertical poles and live DIC, demonstrating small deflections and elastic behaviour. All bridges were upgraded for the construction work, permitting specific vehicles up to 25.5 tonnes capacity.

Figure 5. a) Parapet load test at Redbridge flyover and b) Proof load test at upper Teesdale.

3 LESSONS SHARED

3.1 *Risk*

Proof load testing can be a high-risk task. The uncertainty of the structural capacity, which has led to the need for physical testing, is cause for concern. The test must be conducted:

- By suitably experienced engineers – notably this is plural, to check each other's work. Guidance (ICE, 1998) defines the role of Test Controller, who must be a Chartered Engineer and experienced in load testing, and CS 463 (National Highways, 2019) requires the 'supervision of a Chartered Engineer with specialist expertise in bridge strength assessment or design'.
- With stop criteria defined and their rationale explained in advance,
- Incrementally increasing loads and checking for the signs of distress including on unloading,
- With the ability to identify stop criteria being breached to avoid damage,
- Without requiring access for personnel onto or under the bridge,
- Conscious of external factors which may increase the risks or alter the measurements taken, including tides, rain, snow, ice, wind and change in temperature during the test, and
- For tests exceeding 12 hours, with two equally capable teams handing over comprehensively.

While supplementary load testing is less dangerous, appropriate caution is still necessary. The design or assessment model should be investigated before testing, to predict results. Stop criteria is still defined and monitored live, though it less likely they be reached in the test.

3.2 *Measurements*

Measurements of global deformation and local distress (such as crack widening) need to be taken at a suitable scale and sample rate. The resolution of measurements should be no larger than 1/100 of the typical magnitudes expected. Repeatability (or maximum noise level) should be less than 1/10 of the typical magnitudes expected.

Readings on all sensors should be taken at a sample rate sufficiently fast to capture peak events. In most tests, the load is applied and withdrawn slowly to avoid dynamic excitations, so measurements once every second suffices. If the load or effects are dynamic or of vibrations (for instance footbridges), then measurements should be taken at a time interval 1/10 of the wave's time period. If the test is for the effects of a moving vehicle, but where the resonant response of the structure is not of interest, then the sample rate should be 1/10 of the time period for the influence line of the vehicle passing over the component. When measuring the local effects of cross beams (particularly on rail underbridges) this can mean that very high sample rates are required, since the wheel load is only influential on the cross beam momentarily.

High sample rates require anti-alias filtering. Alternating current power supplies create a signal at 50Hz, which is undesirable and is best removed by electrical filters before the analogue signal reaches the data logger. Computational post-processed filtering is possible, but less effective.

Time synchronisation of all readings (including load applied) is necessary, ideally collected on one acquisition system, otherwise a common clock using PTP or NTP protocol is necessary. Manual merging of datasets after the test is prone to errors.

Measurements should be zeroed at the start of testing with no applied load and thereafter not zeroed again. Relative measurements can be offset like a re-zero in post-processing, but the underlying dataset should remain unchanged.

Accolade Measurement include additional 'reference sensors' which are fixed such to give no response to the structural behaviour, located close to the primary measurements, using similar sensors, cabling and data acquisition. Observation of reference data can confirm the influence of thermal effects, electrical interference or other undesirables, often verifying that unexplained measurements in the data are real or not.

Digital image correlation (DIC) provides the ability to take displacement readings in locations unsuitable for physical sensors. Access to the structure is often still required to install targets for suitably accurate measurements. Whilst this is an emerging technology, Accolade Measurement supplement this with physical sensors, which provides some verification.

A permanent structural health monitoring system can be suitable for collecting the measurements. It is common that the system will need to have other sensors added for the test and the sample rate increased. Design for this expansion at initial stages is a necessary consideration, which can increase cost, data transmission requirements and power consumption.

3.3 *Loading*

Load application can be vehicles, water weights or kentledge blocks. It is necessary that the loads can be applied, and more importantly removed, quickly. During the test, load changes are the slowest task and hence any ability to hasten this is favourable.

It is often not necessary to close the road to all traffic for a supplementary load test. Where the controlled load is of larger magnitude and held constant for a longer duration than passing traffic spends on the bridge, then the interference of passing traffic can be seen distinctly as spikes, allowing selected periods of the test to be removed from the analysed data set.

Supplementary load tests need not apply a very large load. The Queensferry Crossing is capable at serviceability limit state to take many heavy vehicles, but the load test used only 264 tonnes of live loading (6no x 44 tonnes). This was sufficient, even with the uncontrolled traffic on the opposite carriageway, to measure the structural response. Where trust in the design, modelling, materials and construction is sufficient, this supplementary test can replace acceptance load tests, that otherwise require greater loading approaching the serviceability limit state.

If the structure's response is not instantaneous (as with all concrete bridges due to creep), the loading rate and hold times must be consistent, otherwise results appear like non-linear behaviour.

3.4 *Conditions*

External influences may have effects on the results. If possible, tests are conducted at stable temperatures and (for more flexible bridges) at low wind speeds; overnight is normally good and this usually coincides with low public traffic and therefore minimal disruption. For tests outdoors and lasting longer than 1 hour, temperature is likely to be influential on the instrumentation and must be minimised. In tidal or varying waters, the planning must consider whether this increases risks and/or will alter the readings. Any external factors which are suspected to influence, should be measured directly to correlate and correct for.

3.5 *Scale*

Where a particular component or assembly from a bridge is identified as critical and it can be removed (temporarily or replaced), then a load test can be conducted on the component away from the bridge, so long as suitably similar restraint conditions can be replicated. The hanger clamps from the Union Chain Bridge were detachable and selected units were load tested safely in isolation. Conversely, the Southampton parapets could only be tested on the bridge, as their fixing to the bridge deck was critical for performance.

An alternative, as per the research programme for the Usk River Bridge, is to replicate the components in a laboratory. In that case, two replica reinforced concrete hinge joints were created at 75% scale – and at an inverse square ratio, loading could be reduced to 56%. Nearly 100 strain gauges were fixed to steel reinforcement bars before casting into the concrete.

Smaller is generally better in load testing. Reducing the load, reducing the duration, and reducing the extents, all contribute to reducing the safety risks and disruption. However, we must ensure that the right data is collected sufficiently. Some failure modes are reliant on the coincidence of loads across the whole structure and hence reducing the extents is not appropriate for such proof load tests. A good way to envisage this is to produce from the theoretical model an influence surface of the bridge deck for the location or component considered.

3.6 *Data handling and analysis*

In a short term (few days) load test it is normal to collect and keep all data, enabling the reviewer to detect all patterns later. It is normal that one or more engineer is on site continuously throughout the test, providing the ability to resolve problems should they occur.

When the monitoring duration extends longer, it may be that the instrumentation is left unsupervised. 'Edge processing' the data, extracts details and reduces the uploaded data. It can be that a duplicate of the full data is kept on site and manually retrieved at intervals.

It is important that all data is backed up on separate devices as soon as possible. Duplicates may be sent away live during testing (preferrable) or taken physically at intervals.

It is necessary to display data live during any test to check for stop criteria. Visualisations include readings shown numerically or graphically, and present comparable measurements.

We have heard suggestions that warning lights or alarms should be installed based on readings exceeding thresholds. However, in our experience, only certain stop criteria can be quantified so neatly as to use in mathematical thresholds (criteria such as, maximum deformation). Stop criteria like indication of plastic deformation and creep are better spotted by the experienced test engineers' observation of graphical data. We prefer this more manual approach for collectively considering all stop criteria and maybe even those which cannot be foreseen.

4 CONCLUSIONS

Over 30 years' experience of load testing for bridges and structures is summarised in selected examples and the notable lessons are shared for the benefit of safe delivery of future tests. Other examples have been left out due to limited space, including proof load testing for an access bridge in the London Olympic Park, destructive tests of crossheads on the M4 Elevated Roadway, monitoring and testing of hinge joints with a retrofitted support system of the River Ebbw bridge, and supplementary load tests on steel-composite viaducts, but their lessons learnt are included.

It is hoped that supplementary and proof load tests will continue to be used for determining the performance of bridges for many years. With the sharing of good practice, this might be more readily available as a technique for design improvements, assessment of existing structures and extension of asset life. Updates to guidance and the inclusion of proof load testing would benefit the engineering community in the UK and abroad.

Long-term monitoring of ASR deteriorated bridges after reinforcement

M. Tsuda & S. Kagatani

S. Ura
Kokudo Kaihatsu Center Company Limited, Ishikawa, Japan

K. Torii
Central Nippon Highway Engineering Nagoya Company Limited, Ishikawa, Japan

ABSTRACT: Deterioration due to alkali-aggregate reaction (ASR) began to be observed on bridges about 10 years after opening for service, due to the use of aggregate with high ASR reactivity. Serious ASR deterioration was also found at the time of seismic retrofitting in underground footings. Moreover, rebar rupture was recognized in 13 of the deteriorated bridges. ASR-related retrofitting of these bridges has therefore been conducted continually in conjunction with large-scale repair and seismic retrofitting projects since 1998. Furthermore, crack displacement gauges were fixed to strengthened bridges to automatically monitor the crack behavior over a long time for more than a decade. This study revealed that the ASR expansion rate was significantly reduced after retrofitting and that changes in the crack width have a strong correlation with temperature changes. Underground ASR reactivity was also investigated by accelerated expansion tests simulating an underground environment and outdoor exposure tests.

1 INTRODUCTION

The Noto Satoyama Kaido Expressway (former Noto Toll Road) spanning 82.9 km came into full operation as an arterial high-standard highway in 1982 to connect Kanazawa, the capital of Ishikawa, and the Noto area, the peninsular part of the prefecture and was designated as a primary emergency transport road to ensure preferential traffic in times of disaster.

With their wide distribution throughout the Noto area, volcanic rocks including andesite are important sources of aggregate for concrete in the area where gravel resources are in short supply. Meanwhile, serious deterioration due to alkali-silica reaction (ASR) has been recognized in concrete made using crushed andesite. The risk of ASR is also considered to be potentially high all over Japan, a land of volcanoes, as layers of the Neogene period containing large percentages of ASR-causing activated silica are widely distributed over the country.

The basic policy of Japan's ASR-suppressing measures is to control the total alkali content of materials (3 kg/m^3). However, it has been pointed out that alkali elusion from crushed andesite with a high volcanic glass content from the Noto area can cause long-term ASR deterioration.

From the viewpoint of "local production for local consumption" and "reduction of environmental load", it is not realistic to select aggregates with no risk at all for ASR. It is considered rather important to create concrete structures with no ASR by formulating rules for ASR-suppressing measures suitable for aggregate from each locality to make the most of local materials. In the Noto area, crushed andesite has currently been replaced by crushed limestone, while ASR-suppressing measures using fly ash concrete have become widely used.

R	Abut-ments A1 & A2	1976	1998 - 1999	Changed from cantilever pier to abutment	8.8 m	-	Large cracking in the corner of footing	Rupture	Jacketing of footing + construction of box culverts in side-spans to change the structure

This paper reports on a study in which ASR-deteriorated concrete structures strengthened by various methods were subjected to long-term monitoring using crack displacement gauges to check the progress of deterioration, while verifying the effect of each repair/retrofitting method in suppressing ASR expansion.

2 OUTLINE OF BRIDGES AND REPAIR/ RETROFITTING METHODS

2.1 *Lithological characteristics and alkali-silica reactivity of aggregates used for bridges*

As shown in Photo 1, coarse aggregate used for the bridges under study is mostly crushed andesite, or two-pyroxene andesite to be precise, produced from Okunoto, Ishikawa Prefecture, which contains a relatively high percentage of volcanic glass as a reactive mineral.

Alkalis have been eluted into concrete over a long time from volcanic glass, clay minerals, etc., contained in crushed andesite used for these bridges.

2.2 *Bridge overview, state of damage, and repair/retrofitting methods*

2.2.1 *Bridge overview and state of damage*

Figure 1 and Table 1 show the locations and speci-fications, respectively, of ASR-deteriorated bridges along the Noto Satoyama Kaido Expressway. The construction of bridges on this expressway concen-trated in the 1970s and early 1980s, when fresh or slightly modified andesite, which formed after the Miocene of the Tertiary Period in the Northern Noto area, became available on the market for concrete aggregate with the infrastructure development in the

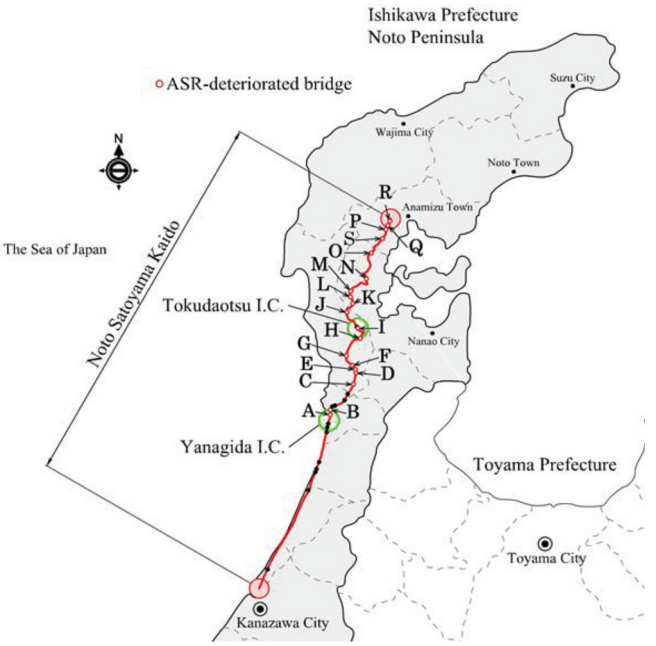

Figure 1. Location map of ASR-deteriorated bridge on Noto Satoyama Kaido.

Photo 2. The pier corner part cracking situation (Bridge P).

Photo 3. The footing with map cracking situation(Bridge E).

Noto area. Also, due to the opening of the entire No-to Satoyama Kaido in 1982, none of the bridges was subject to the "temporary measures against ASR" of-ficially established in 1986.

With this construction background, 19 bridges north of the Yanagida Interchange on the expressway out of 25, nearly 80% of the bridges, suffered ASR-deterioration. Furthermore, 13 of these ASR-deteriorated bridges (nearly 70%) underwent reinforcing bar rupture.

Photo 2 shows an instance of damage. Cracks exceeding 1 mm in width were frequently found in the corners of members of damaged bridges, mainly due to ASR expansion. Map cracking was also found in the entire top surfaces of footings as shown in Photo 3.

2.2.2 *Bridge repair methods*

Table 1 lists the investigated bridges, which were repaired/strengthened primarily by jacketing with prestressed concrete (PC), reinforced concrete (RC), or steel panels. Deteriorated footings were also repaired/strengthened by PC and RC jacketing, with some being also vertically tightened. Some of the bridges underwent significant deterioration both in the super- and substructure, leading to changes to their structural systems.

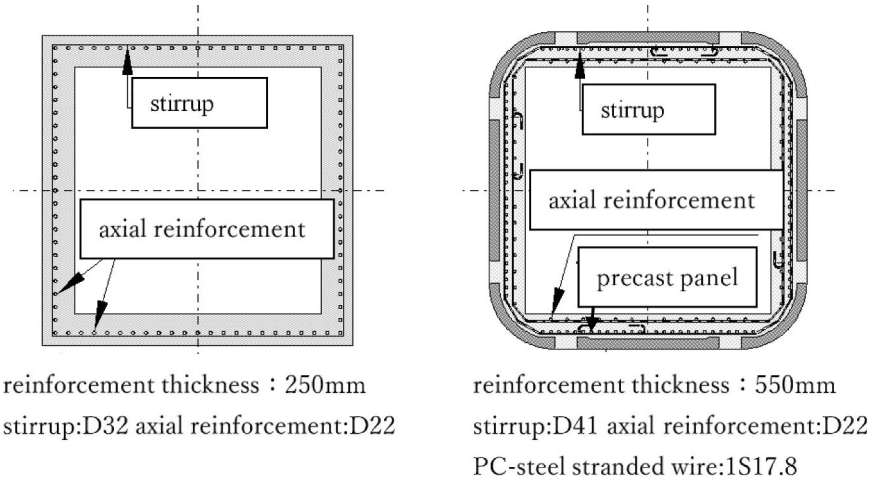

Figure 2. Outline of retrofitting carried out (Bridge I).

Repair/retrofitting of these bridges began around 1998 along with seismic retrofitting. The methods were selected not only based on the results of seismic calculation and economic efficiency but also in consideration of the degree of ASR deterioration and the functional recovery of hoop reinforcement.

- Repair method for Bridge I
  Repair/retrofitting of Piers P2 and P3 of Bridge I was designed and executed in 2003 and 2004 by PC jacketing (Figure 2) for the purpose of restraining ASR expansion and retrofitting against an earthquake. This technique comprises placing precast prestressed concrete panels around the existing piers, setting prestressing steel through the panels, and tensioning the steel in the circumferential direction.
  Repair/retrofitting of Piers 1 and 4 through 8, which was designed and executed in 2007, was required to be completed within the fiscal year, as it coincided with the recovery project from the earthquake off the coast of Noto Peninsula. Since simultaneous projects were expected at many other bridges, concern arose of a shortage of contractors for the PC jacketing, which is a special method. For this reason, RC jacketing (Figure 2) with proven results requiring fewer work processes was adopted.
- Repair method for Bridge P
  Bridge P constructed in 1978 is a simple pretensioned PC bridge consisting of a T-beam part and a four-span continuous rigid T-frame part. The cross-sectional shape of the

existing piers was rectangular. Pier PA1 is located at the joint between the two parts. Cracking occurred in the corner of this pier in the pier axis direction. The pier was subjected to seismic performance verification by seismic horizontal load-carrying capacity testing and dynamic analysis and was also found to fail to meet the seismic requirements. Comparison was therefore made among three methods: RC-, PC-, and steel panel jacketing. As a result, the pier was strengthened by PC jacketing, which provides a stronger effect of reuniting concrete and a higher cost performance.

2.3 *Service conditions of bridges*

The bridges under study were constructed almost in the same period, being in service for over 30 years. Moreover, roughly 5 kg/m² of NaCl is sprinkled over the bridges every winter to prevent freezing, whereby roadway drainage containing the deicer seeps through the expansion joints throughout the year. This forms an environment prone to accelerate ASR.

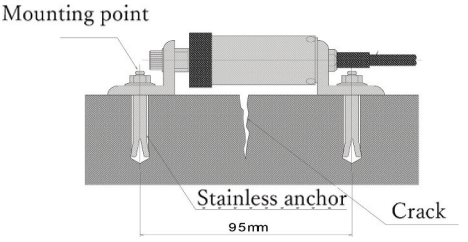

Figure 3. Detail of crack displacement transducers.

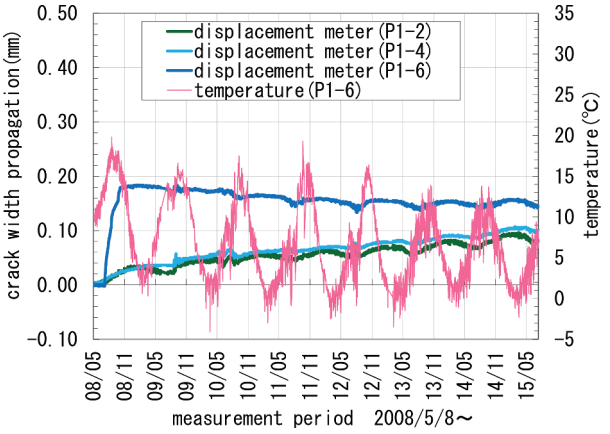

Figure 4. The results of crack propagation monitoring after the retrofitting (Bridge I・Pier P1).

Photo 4. The setting situation of crack displacement transducers.

3 CRACK MONITORING USING CRACK DISPLACEMENT GAUGES

Figure 3 and Photo 4 show crack displacement gauges with a sensitivity of 1/1,000 mm and measurement range of ± 5 mm attached to cracks to monitor changes in the crack width, thereby monitoring the crack propagation due to ASR. In view of long-term monitoring, each gauge was encased in a plastic box filled with grease, with the cracking being sealed with a resilient sealant to prevent contact with seepage from other cracks. This treatment is considered to enable the long-term monitoring to be discussed later in this paper.

A thermocouple was also placed at each monitoring point for temperature correction of the strain values. On one of the piers, multiple crack displacement gauges were placed at segments with different environmental conditions, such as in the soil and in the air, to examine the effect of temperature difference.

4 RESEARCH RESULTS AND DISCUSSION SO FAR

4.1 *Bridge I*

Figure 4 shows the results of measurement at the pillar of Pier P1, Bridge I, which was strengthened by RC jacketing. Seven years have passed since the beginning of monitoring in May 2008 upon completion of the retrofitting work. Though the crack width tends to gradually increase at an early stage of monitoring, the peak values of the fluctuations due to annual temperature changes themselves remaine nearly constant, with the increments in the crack width due to ASR expansion being not more than around 0.01 mm/year at the greatest. At P1-6 near the ground surface, the displacement increases significantly at the beginning of monitoring, presumably because of localized action of ASR expansion on the upper surface due to the increased restraining reinforcement ratio on the bottom surface. However, the values do not increase thereafter or rather tend to decrease since 6 months after the beginning, apparently having converged at the present stage.

The periodic lowering of the thermocouple readings can be attributed to the insulating effect of surrounding vegetation. Figure 5 shows the results of monitoring at the Pier P2, Bridge I, for 10 years since PC jacketing. The crack width annually fluctuates with the temperature, rising from spring to summer and falling from autumn to winter. The annual peak displacements tend to decrease from the beginning of monitoring, demonstrating that ASR expansion has been effectively restrained more by PC jacketing than by RC jacketing.

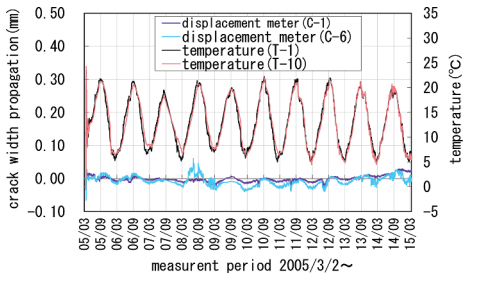

Figure 5. The results of crack propagation monitoring after the retrofitting (Bridge I・Pier P2).

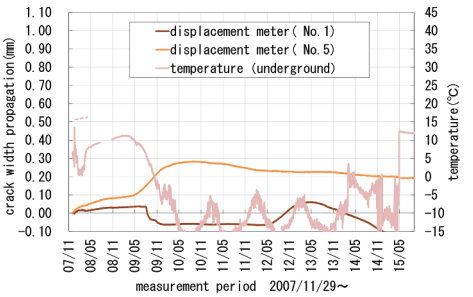

Figure 6. The results of crack propagation monitoring after the retrofitting (Bridge P・Pier PA-1).

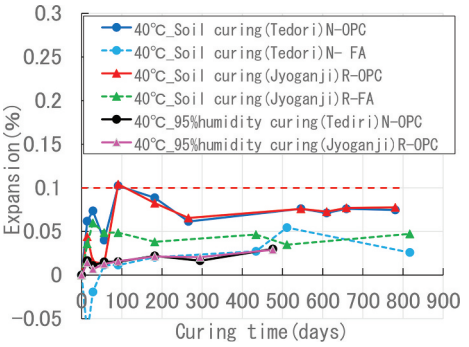

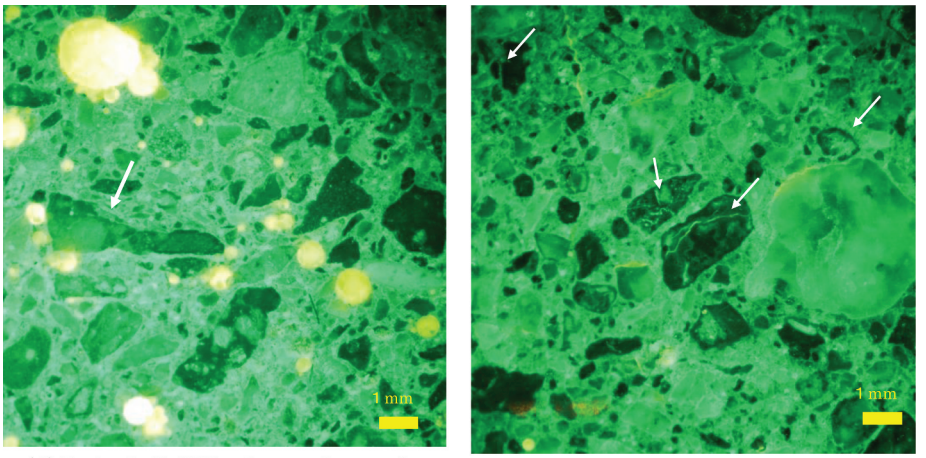

Figure 7. Results by the mortar bar method.

4.2 *Bridge P*

Figure 6 shows the measurements of crack displacement gauges on Pier PA-1, Bridge P, including those of the gauge set underground. The thermocouple measurements have shown no periodicity since 2 years after installation, presumably due to deterioration of the device. The crack displacement of Gauge No. 5 underground on the inbound lane side tends to increase for 3 years since installation but subsequently turns to decreasing tendencies, leveling off thereafter. Expansion due to ASR is therefore smaller underground than that in the air, which is more strongly affected by sunlight, precipitation, and deicers. At the time of pier retrofitting, its footing was excavated to apply a waterproofing layer on all surfaces excluding the bottom. This is also considered to contribute to suppression of the progress of ASR.

(1) Tedori N-OPC Expansion rate 0.0747(%)

(2) Jyoganji R-OPC Expansion rate 0.0776(%)

Photo 5. Fluorescence microscope observation (cross-sectional view).

5 OUTLINE AND RESULTS OF INDOOR TESTS SIMULATING UNDERGROUND ENVIRONMENT

River sands from Tedori River, Ishikawa Prefecture, and Joganji River, Toyama Prefecture, were used for the tests as non-ASR reactive and ASR-reactive sands, respectively. The difference in their ASR reactivity is derived from the component rates of reactive rocks (andesite and rhyolite) and nonreactive rocks (granite and diorite) in the aggregates. To simulate an environment (sandy soil) near an ASR-deteriorated underground structure, silica sand from Toyoura (former JIS Z 8801 Toyoura standard sand) was filled in test tanks and saturated with tap water.

Figure 7 shows the expansion rates of specimens at a curing temperature of 40°C. The curing tank was kept at a relative humidity exceeding 95%. The expansion rates of specimens without fly ash fluctuated at the beginning of curing, but ultimately increased to over 0.07% by a curing age of 781 days, regardless of the reactivity of aggregate, showing similar expansion behavior throughout the period. Their expansion rates in this sandy soil are higher than those of specimens tested by the mortar bar procedure specified in JIS A 1146 at the same 40°C, presumably being affected by alkalis eluted from the sandy soil and specimens. The expansion rates of specimens containing fly ash are lower than those of specimens without fly ash, demonstrating the expansion-suppressing effect of fly ash.

Photo 5 shows the results of fluorescence microscopy. The specimen made using ASR-reactive aggregate from Joganji River containing no fly ash shows wide cracks due to ASR gel derived from sand particles. On the other hand, a number of small cracks are observed in the

specimen made using non-reactive aggregate from Tedori River containing no fly ash. Although their expansion rates are similar at less than 0.08%, their cracking characteristics are thus found to differ from each other.

6 CONCLUSIONS

Major results of this study are summarized as follows:

(1) ASR-deteriorated bridge piers were strengthened by jacketing with reinforced concrete and prestressed concrete along with seismic retrofitting. Both methods were proven effective in suppressing ASR expansion.
(2) ASR-deteriorated footings were coated with a waterproofing layer. Subsequent ASR expansion was found to be small by crack width measurement. The waterproofing was proven effective in suppressing the progress of ASR.
(3) Indoor ASR-accelerating tests were conducted simulating an underground environment involving groundwater. As a result, the expansion rate of specimens in sandy soil was found to be higher, at the same curing temperature, than that of specimens in a moist environment with a relative humidity of more than 95%.
(4) The expansion rate of specimens containing fly ash was lower than that of specimens containing no fly ash, demonstrating the ASR-suppressing effect of fly ash.
(5) When verifying the effect of measures against ASR, it is considered important to assume long-term monitoring for more than 10 years to incorporate changes over a long time. To this end, it is considered essential to ensure the durability of monitoring equipment.
(6) This method should be used to investigate underground structures that use aggregates with high ASR reactivity and are located in alkali-containing soils. While this method can more accurately reproduce in-situ environmental conditions and accurately determine ASR-related risks, it requires the cost of soil investigation and construction of a test site, as well as a long testing time.

The use of smart bridge bearings for railway bridge monitoring

P. Olaszek, A. Sakowski & N. Kur
Road and Bridge Research Institute, Warsaw, Poland

M. Smoliński
B2 Sp. z o.o., Warsaw, Poland

ABSTRACT: The load control of the bridge structure can be an important element of structural health monitoring (SHM). The paper presents the use of smart bridge bearings (SBB) for load monitoring. SBB was developed as an adaptation of Pot Bearings (Confined Elastomeric Bearings) integrated with special force sensors which were used to monitor reaction forces. The force sensor takes advantage of the properties of the encapsulated virtually incompressible elastomer in the cylinder, which is similar to those of a viscoelastic fluid. SBBs are placed instead of all standard bearings on which the monitored span is supported. Monitoring system with SBB has been tested in laboratory and next implemented on a test basis on a plate girder bridge with short span length and with intensive traffic of passenger trains. Numerical analysis were also performed to assess the compliance of the measured time histories of reaction forces with those determined theoretically.

1 INTRODUCTION

Structural health monitoring (SHM) of railway bridges is beginning to use more and more innovative sensors. The load control of the bridge structure can be an important element of such systems. In recent years, monitoring systems for bridge structures using intelligent components such as expansion joints, bearings or dampers used in seismic protection have been presented, Savioz et al. (2018), Islami et al. (2016). The advantages of a bearing-integrated sensor are presented in a publication discussing bridge bearing developments by Kazi et al. (2018). The idea of determining the support reactions in bridge structures by measuring deformations in concrete bearing pads located directly under the bearings is presented by Salamak & Klikowicz (2014).

The previously presented applications related to the measurement of reaction forces apply only to the measurement of slow-change loads. The sensors developed and presented here allow full analysis of dynamic phenomena and an automatic procedure for distinguishing dynamic (fast-variable) from static (slow-variable) phenomena. To analyze the accuracy of the smart bridge bearings (SBB), laboratory tests and a trial implementation on a railway bridge were carried out. Numerical analyzes were also performed to evaluate and calibrate the numerical model of the structure based on the monitoring results of this bridge.

There is a trend in current monitoring systems to process and visualize data on remote servers. Internet of Things (IoT) and Cloud Computing solutions are being used – Imam et al. (2021). The principle is to transfer virtually the entire burden of data processing, software and computing power to the server, and to allow constant access to this processed data through client computers. Thus, after transmission of only pre-processed data from the measurement sensors, further data processing and visualization is done on the server. Such a concept is also used in the developed monitoring system with SBB.

The monitoring systems used SBB could be integrated with the system of bridge vibration and displacement monitoring using inertial sensors presented by Olaszek et al. (2020). They could be the basic elements of a "Future Smart Bridge" that will control both the amount of load and the structure's response to that load – Olaszek (2024).

DOI: 10.1201/9781003483755-42

2 SBB DESEIGN

2.1 *Adaptation of pot bearings*

SBB was developed as an adaptation of Pot Bearings (Confined Elastomeric Bearings) integrated with special force sensors which were used to monitor reaction forces. Such force sensor (pressure sensor) takes advantage of the properties of the encapsulated virtually incompressible elastomer in the cylinder, which is similar to those of a viscoelastic fluid. SBBs are placed instead of all standard bearings on which the monitored span is supported. In addition, the SBBs were equipped with a bi-directional inclinometer and a thermometer. The view of SBB components is presented at Figure 1.

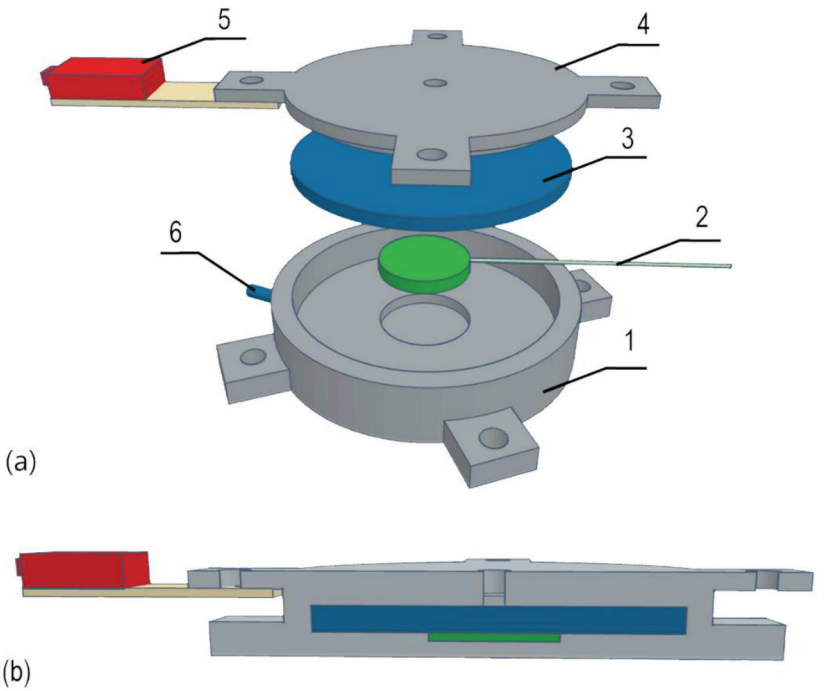

Figure 1. The view of smart bridge bearings (SBB): (a) components: 1 – pot plate, 2 – pressure sensor with cable, 3 – elastomeric disc, 4 – piston plate; 5 – inclination sensor, 6 – temperature sensor; (b) cross-section of the assembled bearing.

2.2 *Laboratory tests*

The developed prototype of the bearing with sensors passed laboratory tests. Laboratory tests included testing smart bearings for static loads. A compression machine with a high-accuracy force sensor was used for testing. The tests included scaling the force sensor and then checking its accuracy. During checking accuracy, axial and non-axial loads were carried out causing significant rotation of the bearing piston (Figure 2). The accuracy of measurement of the bearing loading force was tested with individual scaling and with a theoretically determined scaling factor based on the scaling of bearings with sizes other than the tested bearing.

The main conclusions of the research were as follows:

- The use of an elastomer pressure sensor to measure the bearing force is characterized by high measurement accuracy at pressure forces exceeding 20%-30% of the maximum force.
- The developed prototypes of an intelligent bearing with a pressure force sensor showed relatively high accuracy and resistance to non-axial loads causing significant piston rotation.

Figure 2. The view of bearing during laboratory tests on a compression machine; visible wedge plate enabling examination of reaction force indications with the piston plate twisted (Photo A. Matysek).

– Individual scaling of each sensor-bearing system ensures deviations from reference measurements (at a load close to 50% of the range) of 0.7%-1.2%.
– Scaling the sensor-bearing system based on the scaling of bearings of other sizes provides deviations from reference measurements (at a load close to 50% of the range) of 0.9%-1.1%.

2.3 *The monitoring system intelligence – signal analysis*

Based on the positive results of laboratory tests, a decision was made to undertake further work in order to obtain a product that is a fully intelligent bearing. It was necessary to develop a system for local and remote analysis of measurement results performed by a bearing installed in the bridge structure. The analysis of measurement results should be carried out taking into account two types of bridge bearing loads:

1) static load – from the structure's own weight;
2) dynamic load – from the moving load of the structure.

Figure. 3 shows a diagram of the system's operation, including the phases of signal processing and analysis. At the level 1, the reaction force signals are sampled at a frequency of 200 Hz. It takes place in a transducer built next to the bearing. Then the signal is transmitted via cable to a local computer located at the monitored bridge. The local computer collects data from all installed SBBs and is responsible for data processing at level 2. Special computer software on the local computer enables separate analysis of static and dynamic phenomena and limits the GSM transmission to the required minimum data. In order to assess dynamic phenomena, reaction force measurement is performed continuously at a frequency of 200 Hz and stored in a buffer. In the event of a load entering the bridge (which will be detected by a rapid increase in the measured reaction force), the entire reaction force time history during the train passage is copied from the buffer, stored and next transmitted to the server, along with a 5-second period before and 10 seconds after the train departure. To analyze static phenomena, the collected data on force, angles and temperature are averaged over 10 second time intervals and next transmitted to the server. At level 3, dynamic charts corresponding to all registered train journeys and static charts corresponding to daily, weekly, 30- and 90-day registration periods are automatically created on the server. Access for end-user to monitoring results is possible from level 4. It is possible to view charts using a web browser or download data using the FTP mechanism and use your own data processing algorithms.

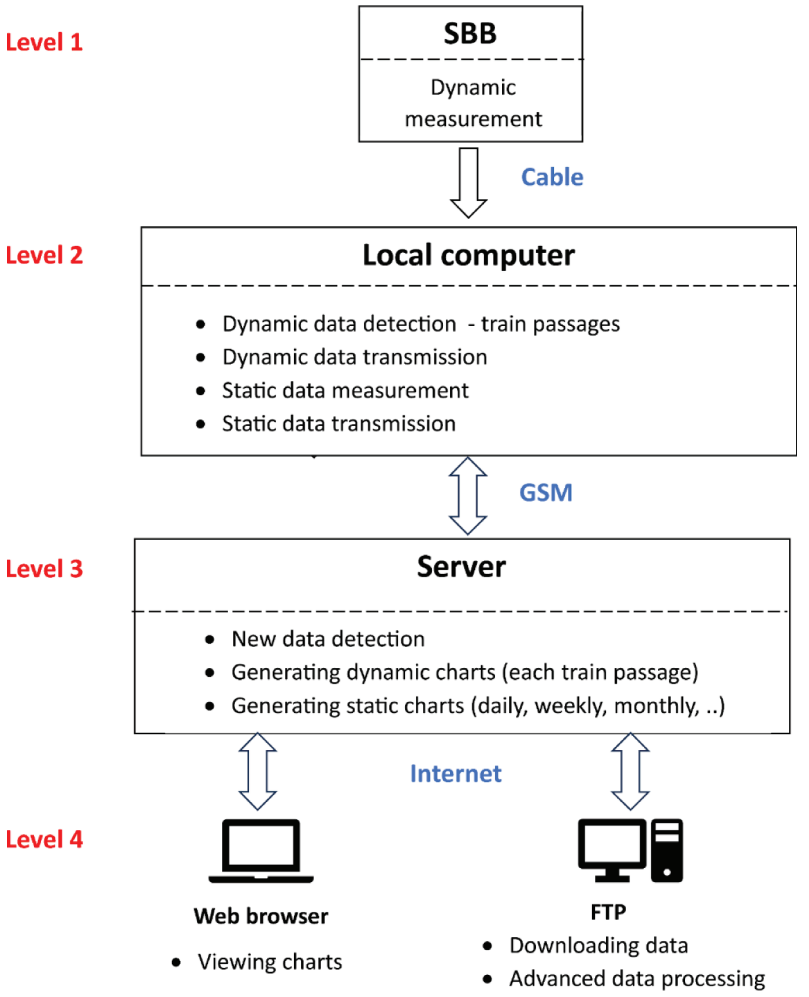

Figure 3. Diagram of the monitoring system use SBB.

3 EXAMPLE IMPLEMENTATION

3.1 *The tested bridge with SBB*

Due to the size and proportion of dynamic to static loads occurring on railway structures, a prototype of a monitoring system using SSB was developed and installed on the railway bridge.

For the test implementation of the monitoring system using SBBs, a six-span double-track bridge that was rebuilt in 1964 was selected. SBBs were installed on the extreme free-supported span of a steel structure with two plate girders. The theoretical span is equal to 7.45 m and the girder height is 0.86 m. Four SBBs were installed as shown in Figure 4. By the time the paper was prepared (December 2023), the bridge had been monitored for almost 2 years. Example results from dynamic and static analyzes will be presented below.

3.2 *Sample dynamic monitoring results*

Figure 5 Shows an example of the recorded reaction forces and the determined course of the total load from the passage of a passenger train consisting of an one locomotive and 5 passenger cars. The data relating to the locomotive are as follows: total weight: 80 tons, maximum axle load: 20 tons, overall length: 15,915 m, wheelbase for terminal axles: 11,600 m, bogie wheelbase: 3,050m.

Figure 4. The view of monitored plate girder bridge; the numbers of the bearings and their possible directions of movement were marked, and views of the bearings S1 and S3 at the first support and S2 and S4 at the second support were added. (central photo – before mounting the SBB).

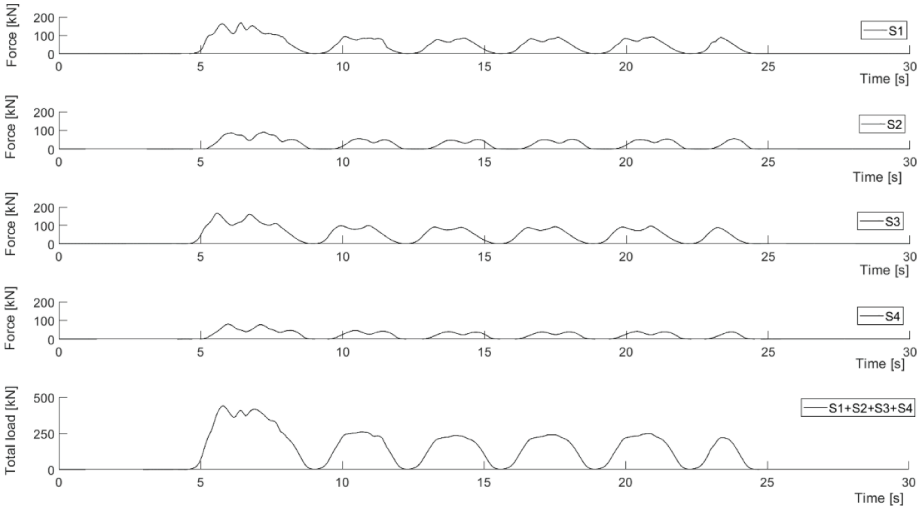

Figure 5. The passage of a passenger train consisting of one locomotive and 5 passenger cars; from the top: recorded reaction forces S1, S2, S3 & S4 and the determined time histories of the total load.

Figure 6 shows all the determined extreme values of the reaction forces on the S1 bearing for all train passages during one week of monitoring.

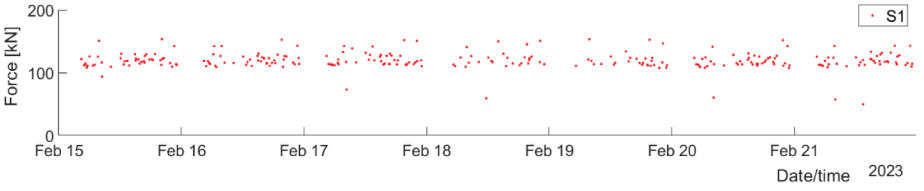

Figure 6. The determined extreme values of the reaction forces on the S1 bearing for all train passages during one week of monitoring.

3.3 *Sample static monitoring results*

Figure 7 shows an example of static impact analysis over a period of one week. The waveforms of changes in the measured reaction forces of the selected bearing (a bearing moving in

both directions) as a function of time and temperature were analyzed. The determined correlation coefficient (Stuart and Ord 1995) $\rho(R_s, T)$ of reaction force from temperature was equal to $\rho(R_s, T) = -0.94$.

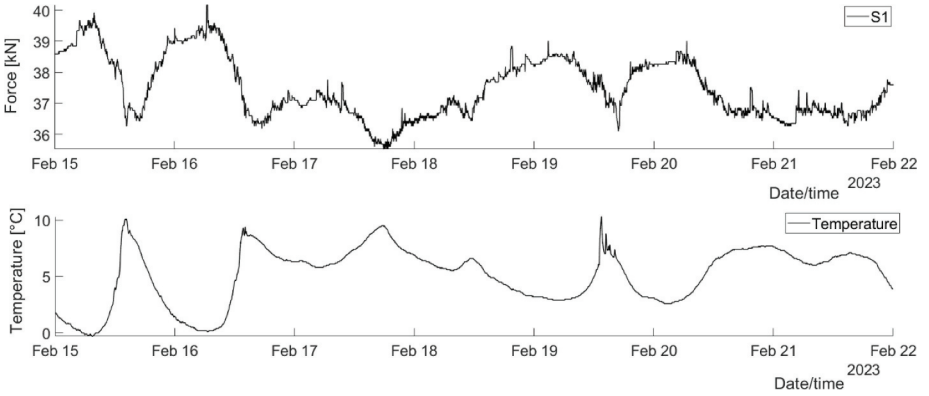

Figure 7. Recorded static waveforms of reaction force on one of the bearings and temperature during one week of monitoring.

3.4 *Measurements using monitoring and numerical analyses*

Computational analyzes of reaction force courses were performed using two numerical models:

- a two-dimensional bar model of a simply supported bridge span;
- a three-dimensional shell model of a simply supported span with a connection through the railway track to the embankment and the adjacent span.

In the latter case, rounded and non-linear waveforms of reaction forces were obtained, which were similar in shape to measured waveforms. Figure 8 shows the determined time histories of the reaction force of the S1, S2 bearings and time histories of the sum of all reaction forces using these two models and measured by SBB, for the train passage from Figure 5.

The extreme recorded weight of the front bogie of the locomotive passage in relation to the calculated data with the use of the bridge two-dimensional bar model equals about 109% and the average about 116%. Using a three-dimensional shell model, the ratios of measured and calculated values were respectively equal to about 88% and the average about 89%. It should be added that the measured average weight of the locomotive's front bogie is 100.1% consistent with the theoretical value from the locomotive's catalog data. In the case of a dozen or so other trains the deviations of measured average weight of the locomotive's bogie in relation to catalog values were below 2%.

4 CONCLUSIONS

SBB laboratory tests confirmed relatively high accuracy and resistance to non-axial loads causing significant piston rotation. Individual scaling of each sensor-bearing system ensures deviations from reference measurements (at a load close to 50% of the range) of 0.7%–1.2%. The use of an elastomer pressure sensor to measure the bearing force is characterized by high measurement accuracy at pressure forces exceeding 20%-30% of the maxi-mum force. Further work related to the development of the use of the pressure sensor in an SBB should be related to the study of the non-linear operation of the bearing at a load below 30% of the range.

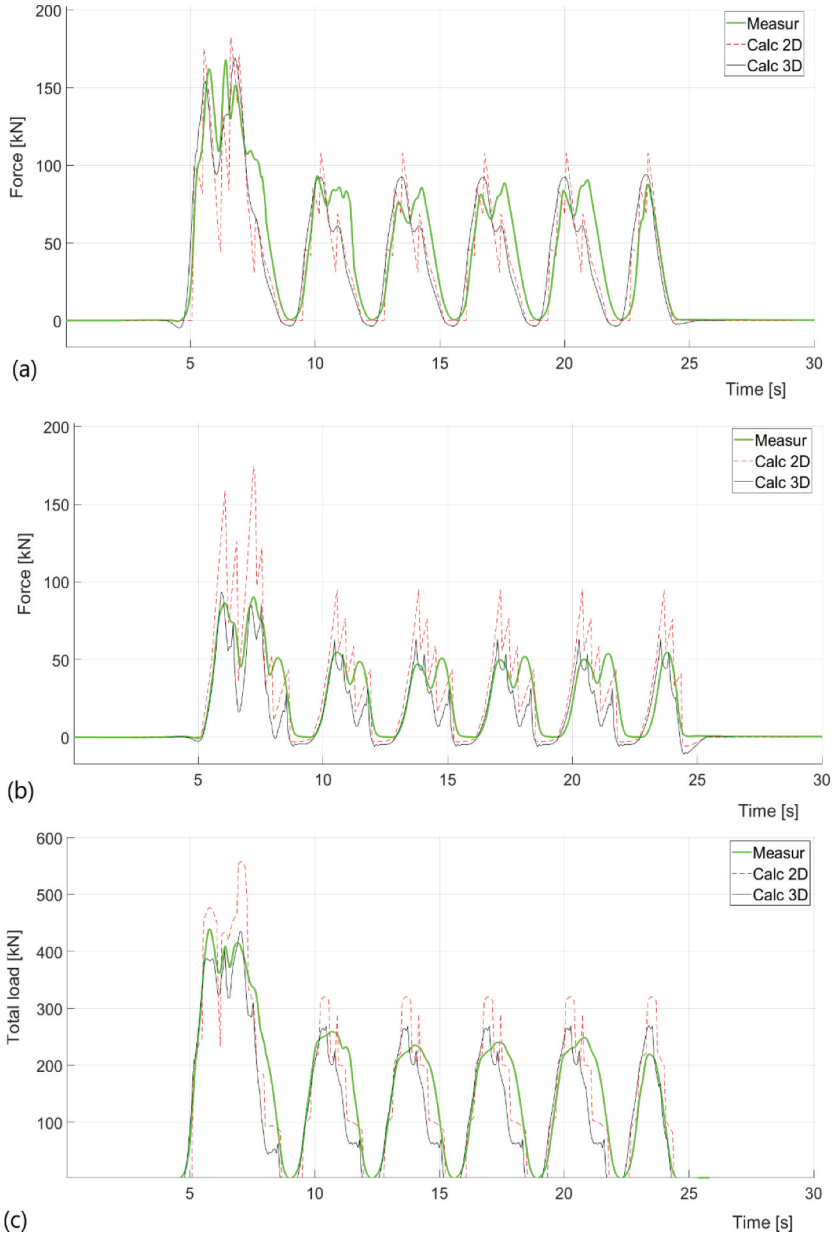

Figure 8. The determined using two models (Calc 2D & Calc 3D) and measured time histories for one locomotive and 5 passenger cars passage (from Figure 5): (a) the reaction force of the S1 bearing, (b) the reaction force of the S2 bearing and (c) the total load (sum of all reaction forces).

The monitoring system tests with the application of SBB carried out at the railway bridge confirmed the system's ability to monitor dynamic and static loads. It is possible to use the system to control the axle loads of passing trains as well as the total weight of passing trains. Deviations of measured average weight of the locomotive's bogie in relation to catalog values were below 2%. During the next tests, it is planned to compare the results with the actual, not catalog, weight of the locomotives.

Due to significant discrepancies between numerical analyzes and monitoring results it is planned to conduct further numerical analysis related to the simply supported bridge span with a connection through the railway track to the embankment and the adjacent span.

Integrating the data from SBB monitoring system with the results of the displacement and acceleration monitoring system will enable a reliable assessment of the behavior of the bridge structure. Such an assessment is particularly useful for monitoring old structures raising doubts about their load-bearing capacity and new structures raising doubts about their behavior under loads with significant speeds. In the future, it seems possible to combine the system for analyzing monitoring results with the train control system. Analysis of monitoring results over long periods confirmed their suitability for analyzing changes induced by static loads. It is possible to use the system to control possible bearing failures and support settlements.

Trafikverket, Luleå, Sweden

ABSTRACT: Railway bridges with masonry abutments represent a significant portion of aging infrastructure in north Sweden. The assessment of their structural integrity is crucial to ensure safe and efficient railway operations. This paper presents the development of a proof loading method tailored specifically for railway bridges with masonry abutments. Before conducting loading tests, the bridge condition was assessed through visual inspections using ground-based photogrammetry and Ground Penetrating Radar (GPR). Realistic loads were simulated using a carefully chosen train fleet during the tests to evaluate load-carrying capacity and structural integrity. Comprehensive data, including strains, displacements, temperature, and acceleration measurements, were collected to gain insights into the bridges' behavior under real-life loading conditions. This data played a crucial role in making accurate predictions and guiding maintenance decisions for targeted rehabilitation efforts. To enhance capacity assessments, finite element models were calibrated using the test results, enabling confident predictions of how the bridges would respond to various loads. This rigorous approach ensures the safe operation of these historic bridges during planned heavy transports while adhering to safety standards. By employing the proposed proof loading method and utilizing advanced monitoring techniques, railway authorities can effectively manage the maintenance and preservation of these crucial structures.

1 INTRODUCTION

The proof load method for railway bridges is a vital procedure to confirm their capability to withstand significant loads, to assess the feasibility of increasing load capacity, or to evaluate the bridge's performance under operational conditions (Lantsoght et al, 2017; Lantsoght, 2019; Duvnjak et al, 2019). This method becomes particularly crucial in situations where there are doubts about the bridge's condition, possibly due to missing structural plans, material degradation, or when solely relying on analytical methods does not yield conclusive information regarding the bridge's performance.

Vitån Bridge, an integral component of Northern Sweden's transportation network along the Haparanda railway line, connects Boden and Morjärv. Special transports exceeding the line capacity are planned with axle loads equal to 30 tons. This line was refurbished several years ago but has not been loaded with heavier axle loads than about 22.5 tonnes per axle, although the allowable load is 25 tonnes. As the expected loads are higher, it is crucial to progressively test the bridge's capacity in the railway line to handle heavier traffic up to 30 tonnes per axle.

DOI: 10.1201/9781003483755-43

This study delves into the bridge's condition assessment, leveraging ground-based photogrammetry and Ground Penetrating Radar (GPR) to inform maintenance and structural integrity evaluations. A 3D digital model was generated from photogrammetry, enabling detailed analysis and damage detection. GPR scanning provided insights into the abutments and soil structure.

Furthermore, proof load tests using a specialized train fleet were conducted to simulate operational conditions and assess the bridge's performance. These investigations offer valuable insights into maintaining and evaluating similar structures, emphasizing the Vitån Bridge's role in regional infrastructure and engineering practices.

2 BRIDGE DESCRIPTION

Vitån Bridge is an essential transportation link along the Haparanda railway line, as shown in Figure 1. This bridge has significantly contributed to the movement of people and goods between Boden and Morjärv, and has become a critical component of Northern Sweden's infrastructure.

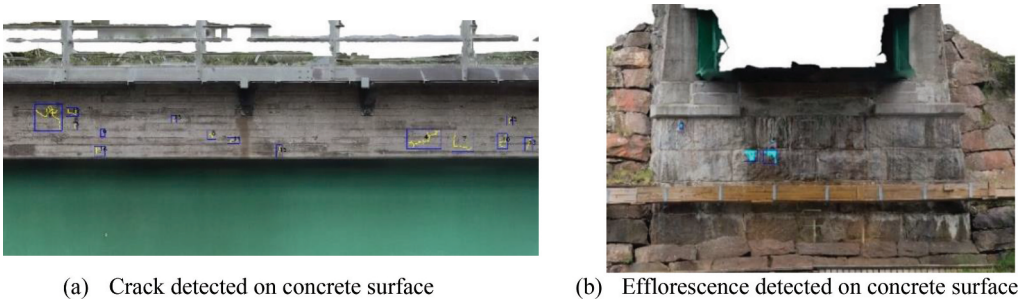
Spanning 21.1 m in length and 4.5 m in width, Vitån Bridge's superstructure is a composite beam design. This design features steel beams, fully braced and securely attached to a reinforced concrete slab using shear studs. This integration enables the steel and concrete to function as one single composite section. The composite beam is simply supported by the masonry abutments, with one end of the superstructure fixed to prevent the longitudinal movement, and the other end allowed some freedom in the same direction. The masonry abutments were constructed in 1900, while the superstructure is constructed in 2006.

Figure 1. Vitån bridge.

3 INVESTIGATION PRIOR TESTING

To gather information about the condition of the bridges before conducting the proof load tests, activities related to the visual inspection of the bridge condition trough ground-based photogrammetry, and use of Ground Penetrating Radar (GPR) were performed.

3.1 *Preliminary condition assessment using photogrammetry*



Photogrammetry is a technique employed to obtain precise measurements and 3D models of objects and their surroundings. It involves capturing images of the object or area of interest from multiple angles and the use of software to analyze and reconstruct the data.

For Vitån bridge, a comprehensive dataset of 496 photographs was captured, encompassing the entire structure from multiple perspectives. These photographs were meticulously processed to generate a precise 3D digital model of the bridge, as shown in Figure 2, serving as a foundational tool for the analysis. Utilizing advanced computer vision techniques and

Figure 2. 3D digital model of Vitån bridge.

machine learning algorithms, the model is systematically analyzed to detect surface damages. The detected damages are shown in Figure 3. This 3D model is used to define the instrumentation layout and position, Finite element model (FEM), etc.

(a) Crack detected on concrete surface (b) Efflorescence detected on concrete surface

Figure 3. Damage detection of Vitån bridge: Cracks are marked in yellow, and efflorescence is marked in blue.

3.2 *Subsurface detection using GPR*

GPR is an electromagnetic technique in which a high-frequency electromagnetic pulse is emitted into the ground, and reflections are recorded. The pulse (wave) propagates in the media (soil and bedrock) and when it encounters objects or layers with differing electrical properties, a portion of the wave energy is reflected back to the ground surface, where it is subsequently detected.

Since the masonry abutments in Vitån bridge were constructed over a century ago, their thickness and depth are unclear from existing documentation. To address this, GPR scanning was conducted before the proof load tests. The measurements also help detect any voids or other anomalies present in the bridges' abutments. In addition, GPR was used to collect information related to the soil stratification in the transition zone between the ballasted track and the bridges.

GPR scanning was performed on top of the rails and cross-sectional measurements on the abutment walls. In the radargram retrieved with a 160 MHz antenna (see Figure 4), two layers

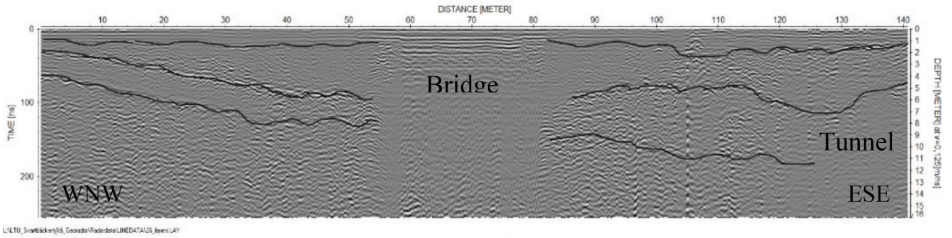


Figure 4. Radargram on different layers in track system.

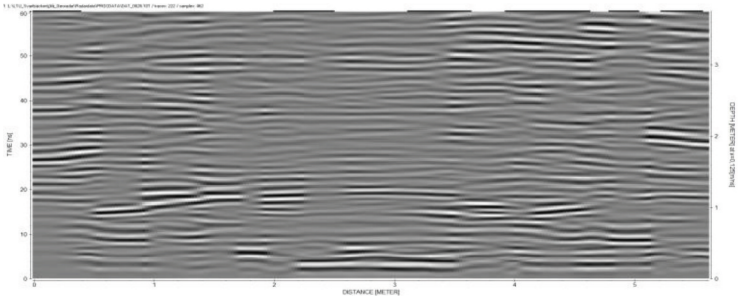

Figure 5. Radargram on first row of the northern abutment.

of filling can be identified on top of the original ground surface. The rock surface follows the shape/dip of the ground surface on the western part, slightly dipping towards the east. Soil depth is about 2 m on the western side but increases to about 4 m on the eastern side. The abutment measurements are presented in Figure 5.

4 PROOF LOAD TESTS

4.1 *Instrumentation*

A comprehensive measurement plan was developed to estimate the bridges' behavior as accurately as possible. This section summarizes the instrumentation used to measure variations of key variables during the proof load test.

The main variables assessed were strains, displacements, temperature, and acceleration of the bridges. Data was acquired from all instruments described in this section throughout the entire testing schedule, unless otherwise stated.

For Vitån bridge, four accelerometers (T-A1~A4) were instrumented in Phase I. In Phase II, two additional strain gauge (S1, S2) were added. The location of instrumentation is illustrated in Figure 6, with sensors from Phase I marked in blue and those from Phase II in red. The LVDTs were placed to measure both the vertical and horizontal deformation in masonry abutments; the accelerometers measure accelerations in the superstructure induced by the moving train. The strain gauges, which were welded to the steel girder, measure the strain induced by the loading train. Figure 7 shows the accelerometers, LVDTs, and strain gauges instrumented in Vitån bridge.

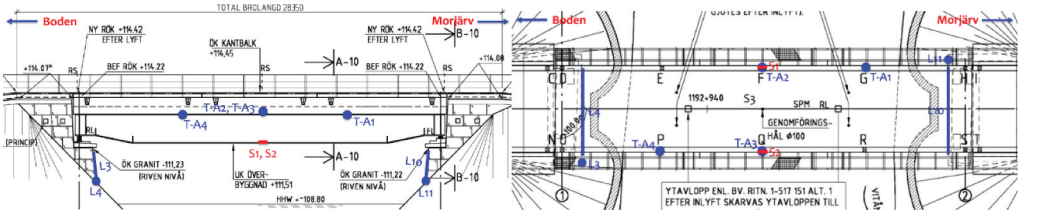

Figure 6. Instrumentation of Vitån bridge.

4.2 *Vehicle*

In the proof load tests, a train fleet (comprised of a locomotive and wagons), with specific axle loads, distribution, and configuration, is utilized to apply load on the bridge structure. The train fleet has to be carefully chosen to obtain a desired loading scenario that reflects real-life situations and simulates actual operating conditions.

The axle load and speed of the train serve as the primary variables to assess the bridge structure's performance under different loading. The train moves across the bridge at various controlled

Figure 7. Strain gauges, LVDTs, accelerometers deployed in Vitån bridge.

and consistent speeds, ensuring that dynamic load effects are taken into account during the testing process. Additionally, the train stops at specific positions on the bridge to conduct static tests, allowing for a thorough evaluation of the structure's response under stationary loads.

For the proof load tests, a 71.73 m long freight train fleet consisting of one locomotive, two coupling wagons, and four Uno wagons was employed, as displayed in Figure 8. It can be observed that the locomotive is connected to the Coupling Wagon, and adjacent Uno Wagons are connected to each other. The coupling Wagon serves to connect the locomotive and the Uno wagon. The wheelsets of the train fleet are labeled from P1-1 to P7-4.

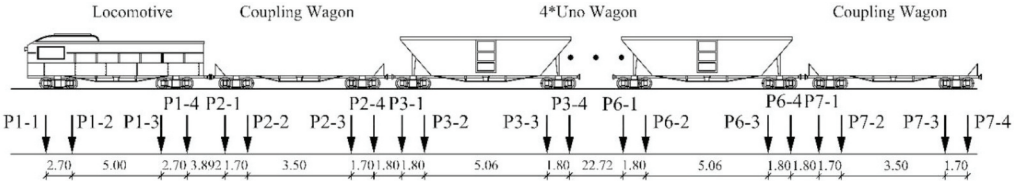

Figure 8. Geometry of the proof loading train (Unit: m).

The axle load of the locomotive and coupling wagons are fixed as 19.5 tons and 9 tons respectively under different loading scenarios. The axle load of the Uno wagons varies from 22.5 tons to 30 tons. In Phase I, 22.5 tons and 25 tons were adopted as the axle loads of the Uno wagons. In Phase II, the axle load increased to 26.5 tons, 28 tons and 30 tons in steps.

4.3 *Loading tests*

The trains are positioned in the bridges with the aim of producing maximum loads in the superstructure and substructure:

- Near the supports: For maximum shear and maximum load on the foundations
- Midspan: For maximum bending moment

The initial evaluation of the stress state for the bridge was performed using the AxisVM software. The reinforcement and masonry abutment were not introduced in this initial 3D linear analysis. Based on this initial analysis, the loading positions that induce maximum bending moment and maximum reaction force were determined. Based on the initial 3D linear analysis, the loading positions were marked before the proof load tests, as shown in Figure 9.

Five axle load levels were included in the proof loading test program. The axle load of the Uno wagons varied from 22.5 tons to 30 tons. In each load level, the train was stopped at two specific positions on the bridge to generate maximum bending moment in the superstructure and maximum reaction force in the substructure. The exact loading positions during static tests are recorded in Table 1.

During the dynamic tests, the train crosses the bridge at various controlled and consistent speeds, at load levels that match those of the static tests. In this way, it is ensured that

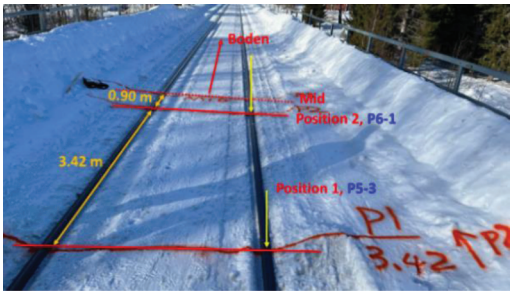

Figure 9. Marking loading positions for Vitan bridge.

dynamic load effects are incorporated into the testing process. The freight train used have a maximum speed of approximately 60 km/h. For each load level, dynamic tests were performed at different speed. Table 2 presents the dynamic load cases executed during the proof loading of the bridges. In the table, the speed, direction, and axle load of the Uno wagons date are summarized.

Table 1. Static load tests of Vitån bridge.

Phase	Axle Load (tons)	Loading Position (cm)	Wheel Set
I	22.5	-432.0	P5-3
		-83.0	P6-1
	25.0	-449.0	P5-3
		-108.0	P6-1
II	26.5	-439.0	P5-3
		-90.0	P6-1
	28.0	-432.0	P5-3
		-100.0	P6-1
	30.0	-367.0	P5-3
		-90.0	P6-1

Table 2. Dynamic load tests of Vitån bridge.

Phase	Speed (km/h)	Axle Load (tons)	Direction
I	54.0	22.5	Boden-Morjärv
	55.0	25	Boden-Morjärv
II	58.2	26.5	Boden-Morjärv
	57.0	28	Boden-Morjärv
	60.0	30	Boden-Morjärv
	55.2	30	Boden-Morjärv
	30.0	30	Morjärv-Boden
	45.0	30	Morjärv-Boden

5 CAPACITY ASSESSMENT

5.1 *Finite element modeling*

Finite Element (FE) Analysis was adopted for the structural assessment of Vitån bridge. is a pivotal technique for structural assessment. The analysis uses DIANA version 10.6 software and integrates empirical proof load tests with theoretical FEM analysis for a comprehensive assessment. The structural model includes the superstructure, foundation/substructure, track system, and soil, with each component modeled using 3D solid elements. Reinforcement in

concrete is represented by 1D beam elements with full interaction, using DIANA's 'embedded reinforcement' feature (Diana, 2022).

Accuracy is ensured through the comparison of structural drawings, 3D point cloud data, and Ground Penetrating Radar (GPR) scanning. The bridge's masonry walls and surrounding terrain are detailed using point cloud data and GPR scans, with soil modeling simplified based on GPR data. Figure 10 shows the finite element model of Vitån bridge used in the structural analyses.

Nonlinear material properties for concrete are simulated using total strain-based crack models with specific behavior curves for compression and tension. Soil material simulation considers various constitutive models, with the Mohr-Coulomb elasto-plastic model chosen for abutment materials, requiring parameters for soil elasticity and plasticity. An advanced Hardening-Soil model was also considered but not fully adopted due to its complexity. In addition to soil and concrete, linear material properties were assigned to the rail steel and sleeper concrete, and reinforcements were modeled with a linear Young's modulus and a Von Mises plasticity model. This comprehensive approach facilitates a realistic and accurate assessment of the bridge's structural integrity.

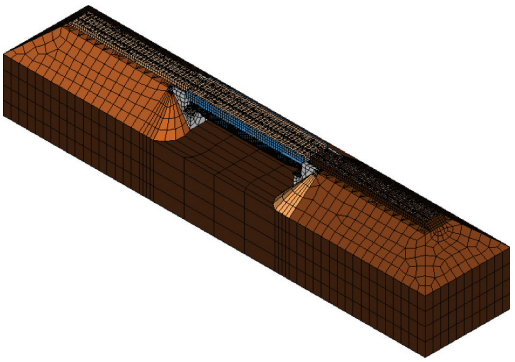

Figure 10. 3D FE model of Vitån bridge.

5.2 *Loading*

The bridge was subjected to two primary loads: the self-weight of the bridge and the proof loading from the train fleet. In the analysis, the self-weight of reinforcements was deemed negligible compared to that of the concrete and thus was not considered. The software calculated the total weight of the concrete, which was then applied as a dead load in the initial step of the analysis.

In applying the load, the FE model employed both load-control and displacement-control strategies. The displacement-control strategy proved to be more stable than the load control. In this approach, the displacement at each loading area was regulated by its center point using the TYING method in Diana (Diana, 2022). To align the applied displacement with the structural deformation, a statically determined system of rigid beams was used to distribute the vehicle point loads accurately from the nodes of prescribed displacement. The loading points' nodes were tied to the end nodes of these rigid beams to ensure identical displacements. Additionally, another rigid beam connected the center of two beams on the first level, also employing the tying method. The number of beam levels depended on the bridge's loading points, with constraints on translation along the beams and rotation around the beams' axes. Vertical point loads were applied to the central node of the top rigid beam via prescribed deformation. Finite element analysis.

5.2.1 *Static analysis*

FE analyses were carried out with axle load of 26.5, 28 and 30 tons for two loading positions in the static case. The results of analyses are presented in Table 3.

Table 3. FE results for static loading cases.

Axle load (tons)	Maximum Vertical Deformation (mm)		Maximum Reaction Force (kN)	
	Position 1	Position 2	Position 1	Position 2
26.5	-29.0	-30.1	970.9	972.3
28	-29.3	-30.5	972.1	973.6
30	-29.7	-31.1	973.7	975.2

Increasing the loading on the Vitån bridge structure led to a rise in both the maximum vertical deformation and the support reaction. Figure 11 illustrates the maximum vertical deformation under an axle load of 30 tons at P2 loading position.

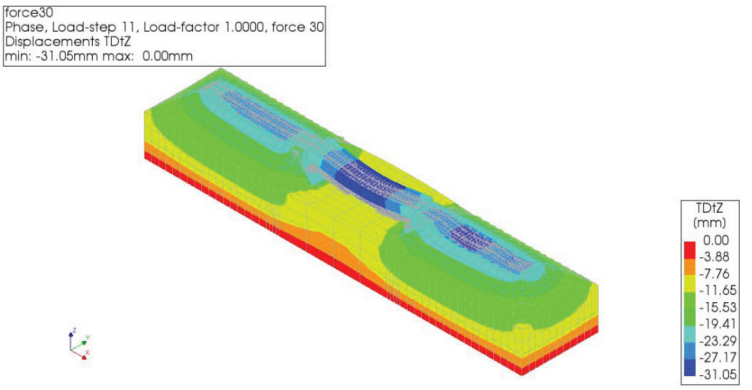

Figure 11. Static vertical displacement due to the axle load of 30 tons.

The bridge is experiencing a settlement of approximately 30 mm or more across all loading scenarios. This significant displacement is observed both at the midpoint of the bridge span and in the soil adjacent to the right abutment. Such extensive deformation is of considerable concern and could potentially lead to structural issues. Hence, ongoing monitoring of the bridge's overall deformation is recommended.

An additional scenario was investigated to determine the maximum capacity of the Vitån bridge. This analysis utilized a displacement-control loading scheme, designed to stress the structure to its failure point. This evaluation was conducted with a single loading position, as

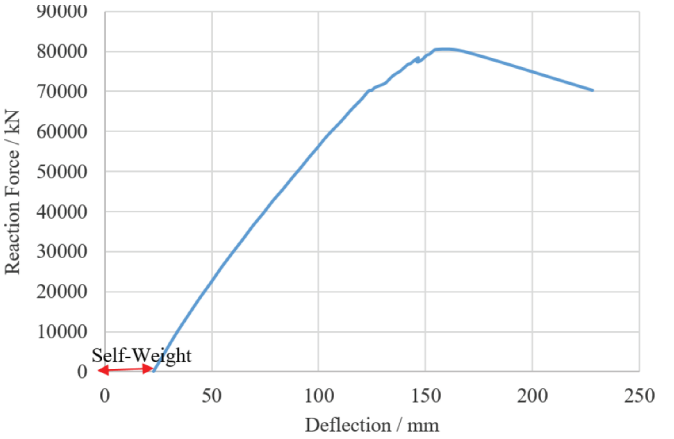

Figure 12. Reaction force versus deflection showing the elastic and plastic states of structure.

the distance between positions P1 and P2 does not markedly affect the structure's ultimate stage. The results of this analysis are presented in Figure 12, with the reaction force indicating the total load imposed on the entire structure.

5.2.2 *Dynamic analysis*

Transient dynamic analyses were conducted to assess the dynamic behaviors of the Vitån bridge under arbitrary time-dependent loads, following the moving load approach. Modal analysis was also carried out to ascertain the damping factors. This analysis aimed to identify the eigenfrequencies for the first ten modes.

The lowest and highest eigenfrequencies for the first 10 modes were 2.83 Hz and 4.56 Hz, respectively. Rayleigh damping parameters were then calculated, $\alpha = 0.52114\ s^{-1}$ and $\beta = 0.00116\ s^{-1}$ The calculated Rayleigh damping parameters, α and β, were then added to the material properties in the FE model.

To simulate the moving train loads on the bridge, a common method, incorporating the application of moving loads in the form of pulse time histories for each node is utilized. The method simply works based on the time of load arrival and node discretization.

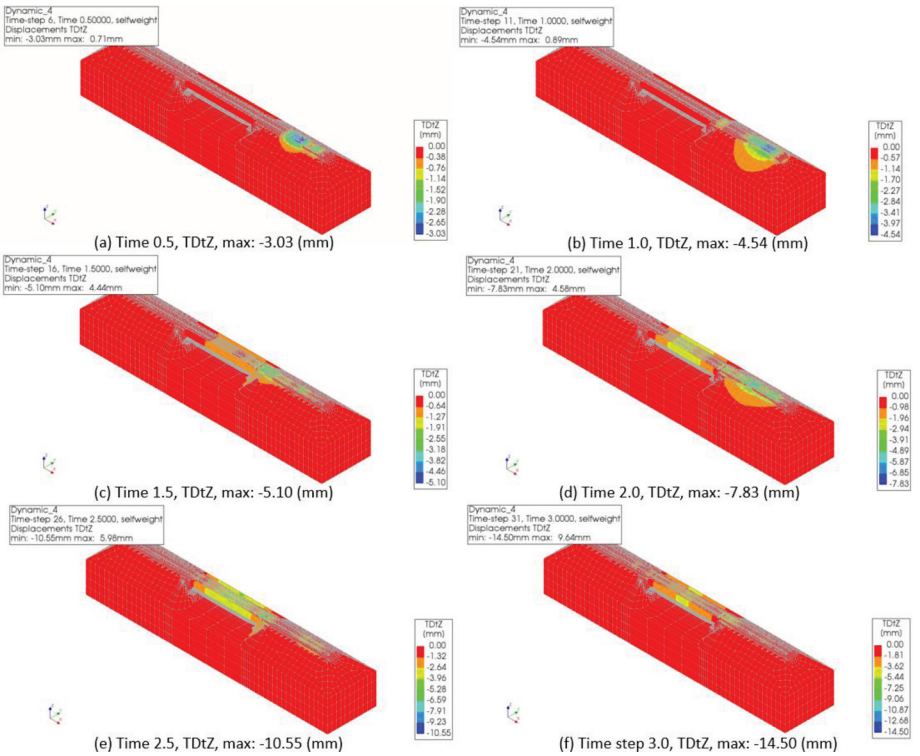

Figure 13. Vertical displacement in every 5 time-step of transient dynamic analysis.

The moving load was simulated using a triangular force distribution by Gharad and Sonparote (2016), as well as Wang et al (2016, 2020). Notably, the latter researchers linked the triangular force function at each node to the diameter and velocity of the moving train. Furthermore, Sánchez-Haro et al (2023) explored the moving load force function utilizing three distinct shapes: rectangular, triangular, and sine squared. Their findings indicated that while the rectangular shape is not suitable for the Finite Element (FE) model, both triangular and sine shapes yield favorable outcomes.

As illustrated in Figure 13, the analysis demonstrates the influence of the moving load on the bridge structure. The results reveal a maximum deflection of -27.93 mm caused by the moving load at time 5.3 s. Additionally, the maximum stress observed in the reinforcement

reaches 18.31 MPa at time 5.6 s, indicating that the stress remains comfortably below the yield strength of the reinforcing steel. These findings collectively affirm the structural integrity of the bridge under the dynamic loading scenario.

6 CONCLUSIONS AND FUTURE RESEARCH

In this study, the Vitån Bridge underwent a detailed structural evaluation using proof load tests integrated with finite element analysis, particularly under challenging winter conditions. The findings affirm the bridge's capacity to support an axle load of 30.0 tons, with no significant structural damage or major deformations noted. However, the minor deformations in the masonry abutments observed under these specific conditions underscore the necessity for further refinement of our finite element model. Moreover, the study mentioned the critical role of temperature variations in influencing the structural properties and behavior of the bridge's masonry abutments. This insight points to the importance of expanding the assessment parameters to include a range of climatic conditions, ensuring a comprehensive understanding of the bridge's structural integrity throughout the year. Key points for the future research can be drawn as:

- Model Calibration and Refinement: Enhance the finite element model, particularly the masonry substructures, to better reflect observed deformations, ensuring increased accuracy in structural assessments.
- Temperature Effect Analysis: Conduct extensive studies on how temperature changes affect the bridge's components, focusing on the masonry substructures to ensure reliable load-bearing capacity assessments year-round.
- Advanced Load Testing: Implement comprehensive load tests under diverse temperature conditions to validate potential increases in allowable axle loads and identify any latent structural vulnerabilities.

ABSTRACT: Given the ageing infrastructure, verifying the reliability of existing structures is crucial. Field testing presents a viable approach to evaluating a structure's current condition, particularly proof load testing. In a proof load test, a large load is applied to assess its reliability. Structures in sound condition are expected to display satisfactory behaviour under average load intensities. Can good structural performance under moderate load levels already prove sufficient structural reliability? The proposed method utilises data from laboratory tests on similar structural elements. A case study was conducted on a bridge to illustrate the effectiveness of the method. Data acquired from laboratory tests were pre-processed to provide the required input for the reliability updating. It reveals that sufficient reliability can be demonstrated without excessive load levels by incorporating laboratory data. However, the actual capacity of the bridge and the uncertainty associated with the laboratory data remain important factors.

1 INTRODUCTION

Ensuring the reliability of bridges and viaducts is an ongoing effort involving inspections, structural assessments, and maintenance practices. As the infrastructure ages and experiences increased traffic loads and intensities, accurate assessment methods are required to account for the changing conditions. Load testing may be used to verify a bridge or viaduct's current structural integrity. A load test conducted to prove a structure's ability to withstand future traffic loads is referred to as a 'proof load test' (Alampalli et al., 2021; Faber et al., 2000; Lantsoght et al., 2017). The magnitude of the load to be applied in the test, commonly called the target load, is pivotal in proof load testing. If the structure can resist a large load without any

DOI: 10.1201/9781003483755-44

issues, it proves it is sufficiently reliable for future use. The magnitude of the target load is directly related to the reliability requirements. Often, such reliability requirements result in relatively large loads being applied to the structure (De Vries et al., 2023a). A potential solution to this problem is to probabilistically consider all relevant information about the structural resistance, especially the performance indicators during testing. Then, load testing can demonstrate the same reliability level with lower test loads, making it a cost-effective alternative to other evaluation methods.

The current article presents a novel reliability updating method that integrates information from two distinct sources: the survival of the applied load during the proof load test and the indicator value observed throughout the testing process. When a proof load test is conducted, the load is gradually applied in small steps until the target is reached to prevent unwanted damage. Measurement of displacements, crack widths and so on usually cannot instantly tell us about the structural performance. Therefore, corresponding stop criteria interpret the structural behaviour rather than the measurements directly (Zarate Garnica & Lantsoght, 2021). For example, strains may be interpreted via sectional analysis to identify a critical value. The type of expected damage and failure mechanism will define the specific stop criteria that should be used.

2 METHOD

2.1 *Reliability updating using two information sources*

When a particular load is resisted in a proof load test, the structure's resistance is at least equal to the load effect achieved during the test ($R \geq E_{PL}$). The load effect consists of permanent loads and the load applied within the test ($E_{PL} = G + Q_{PL}$). This results in a truncation of the resistance distribution (Lin & Nowak, 1984). Naturally, there will be some uncertainty associated with this load effect. When accounted for, the truncation will be more gradual, still assigning some probability density to values lower than the intended (mean) proof load effect ($m_{E,PL}$) (Brüske, 2018). This truncation results in the first source of information following from successfully withstanding the applied load (Figure 1, point 1).

The in-situ measurements and stop criteria introduced in the previous section are commonly used to prevent structural failure. The novel method described herein uses the measurement data to *predict* the structure's resistance at moderate load levels. This prediction gives rise to the second source of information following a load step in the proof load test. The prediction may be achieved using suitable data that links observed damage to the applied loading for similar structural elements. In this context, the measurements normally conducted within the application of stop criteria are called indicators. The strain calculated from displacement measurements at the bottom of a beam or slab is an example of such an indicator. From the data obtained in the

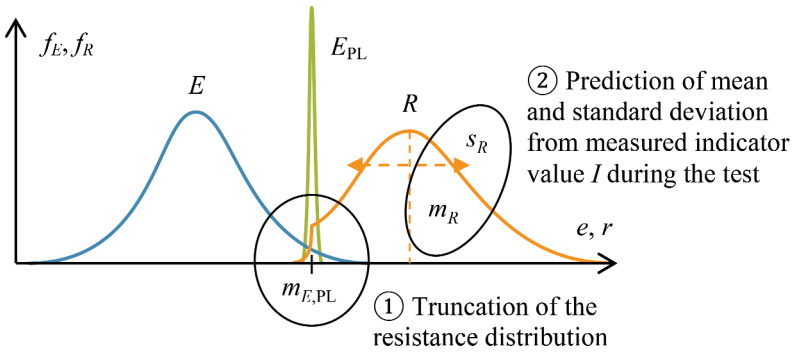

Figure 1. General principle of updating the resistance distribution from two sources of information.

laboratory tests and the indicator value observed during the in-situ test, the corresponding mean and standard deviation of the resistance may be inferred (Figure 1, point 2).

2.2 *Probabilistic model for updating*

The structural reliability is determined by evaluating a limit state function (Z), which results in a negative value when failure occurs. The limit state function for the assessment of a bridge (or viaduct) subjected to traffic load has been formulated in line with the Probabilistic Model Code (JCSS, 2015) and *fib* Bulletin 80 (fib, 2016):

$$Z = \theta_R R - \theta(G_{Dl} + G_{SDL} + C_{0Q}Q \tag{1}$$

where R is the resistance, θ_E is the model uncertainty of the load effect calculation, G_{DL} is the dead load, G_{SDL} is the superimposed dead load, C_{0Q} is the time-invariant part of the live load, and Q is the time-variant part of the live load. Here, θ_R accounts for the statistical model uncertainty in which in-situ testing is coupled with laboratory experiments. This uncertainty is small when the laboratory specimens are representative of the structure under consideration. However, large uncertainty should be expected if the structures are dissimilar or the measurement techniques and data post-processing differ. Real-world experience with the proposed method will give insight into appropriate model uncertainty values. The uncertainty in predicting the resistance from a measured indicator value will be contained in the ratio X and follows from the statistical processing of the laboratory data.

Each time the structure successfully resists a new load level, the distribution function of R may be updated to reflect the newly obtained information (Section 2.1). The updated distribution of R may be written as a multiplication of the ratio X and the load effect produced during the last successful load test cycle ($R = X E_{\mathrm{PL}}$). Since the proof load is survived, this indicates $R \geq E_{\mathrm{PL}}$ and therefore $X = R/E_{\mathrm{PL}} \geq 1$. However, this does not imply that the resistance distribution is truncated at a fixed value because of the uncertainty in the proof load effect (E_{PL}) (Figure 1). The resulting distribution of R does not follow a regular distribution since it follows from the multiplication of X and E_{PL}, of which the latter is also a product of other random variables. The resistance R may be expanded and inserted into Equations (1), giving:

$$Z = \theta_R X[\theta_E(G_{DL} + G_{SDL}) + \theta_{E,PL}] - \theta_E(G_{DL} + G_{SDL} + C_{0Q}Q) \tag{2}$$

where $\theta_{E,\mathrm{PL}}$ is the model uncertainty applicable for calculating the load effect from the applied proof load, and Q_{PL} is the load effect following from the applied load in the test. Because of the controlled conditions during the test, the uncertainty in calculating the load effect from the proof load is expected to be smaller than for the other loads. The calculation model and method will likely be the same for both; thus, a strong correlation exists between $\theta_{E,\mathrm{PL}}$ and θ_E. For simplicity, it may be assumed that they are the same ($\theta_{E,\mathrm{PL}} = \theta_E$), effectively eliminating them from the limit state equation:

$$Z = \theta_R X(G_{DL+}G_{SDL+}Q_{PL}) - (G_{DL} + G_{SDL} + C_{0Q}Q \tag{3}$$

Although the permanent loads ($G_{\mathrm{DL}} + G_{\mathrm{SDL}}$) appear in both the resistance and the load effect, they cannot be eliminated from the equation. Yet, it can be difficult to estimate them when the original drawings and calculations are lost or the structure has been modified. It is seen that the permanent load terms lead to an increase in the resistance since $X \geq 1$ must be satisfied to survive the proof load. Conservatively, the permanent load terms may be removed:

$$Z = \theta_R X Q_{\mathrm{PL}} - C_{0Q}Q \tag{4}$$

For structures where the permanent loads are relatively small compared to the live load, Equations (4) results in similar reliability values as Equations (3). It may also be observed that with

$X = 1$, the lower bound approximation is recovered, which is discussed in De Vries et al. (2023b). The lower bound approximation forms the basis of the probabilistic background for the proof load testing method in the MBE (AASHTO, 2018), as described by Lichtenstein (1993).

2.3 *Distribution of the resistance ratio (X)*

A relation between indicator values and the resistance ratio, random variable X in Equations (2), may be deduced from the laboratory tests. Therefore, the laboratory measurements are post-processed to determine the resistance ratio for each load step. The maximum indicator value observed up to each load step is used instead of the actual indicator value for each load step. This approach mitigates the noise and erratic response in the crack-forming process. When specimens have failed the ratio is 1, reflecting that the resistance is at least equal to the current load effect but not higher (Figure 1, point 1). Once the ratios X_i from the laboratory test are obtained for each chosen indicator value, the data points may be analysed using the established knowledge of sample testing, e.g. Annex D of EN 1990 (CEN, 2019). Student's t-distribution is used to account for the typically small number of tests (Gosset, 1908). Of use here is the so-called *prediction distribution* for an assumed normally distributed population (Geisser, 1993):

$$X_{n+1} = M + TS\sqrt{1 + \frac{1}{n}} \tag{5}$$

where X_{n+1} is the next to-be-observed value, M is the sample mean, S is the sample standard deviation, n is the number of samples and T follows Student's t-distribution with $v = n - 1$ degrees of freedom. The sample mean and standard deviation, including Bessel's correction $(n - 1)$, are obtained through the well-known statistical formulas (Wasserman, 2004). Because the prediction distribution of X is used, the actual variation is more significant than solely indicated by the standard deviation.

3 APPLICATION TO A REINFORCED CONCRETE SLAB BRIDGE

3.1 *Description*

To demonstrate how the proposed method would be applied in practice, the structural reliability of a reinforced concrete slab bridge is considered. The bridge is fictional but characterises typical Dutch slab bridges without shear reinforcement. Deep beams representing strips of such a slab were tested in the laboratory to determine the shear resistance (Figure 2). Because the bridge is fictional and no actual load test was performed, a load test result must be assumed. In reality, indicator values following from actual measurements would be used.

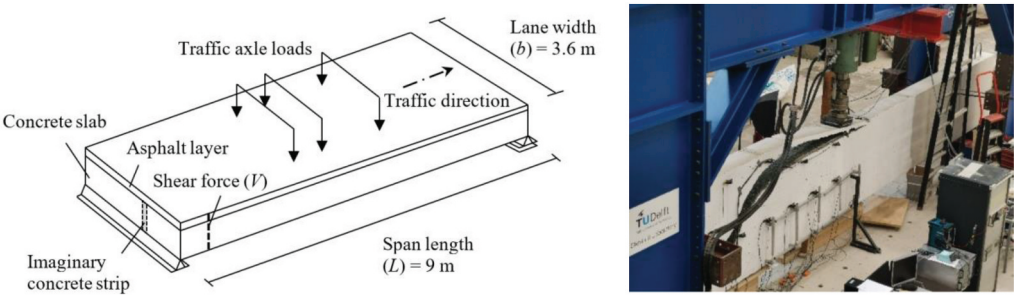

Figure 2. Reinforced concrete slab bridge considered in the case study, with (a) its schematic drawing and (b) a picture of one of the concrete strips tested to failure.

To simplify calculations only the first lane is considered, whilst in reality reinforced concrete slab bridges will typically have multiple lanes. The traffic load effect of the first lane is based on Weigh-In-Motion (WIM) measurements (FHWA, 2018) obtained from Dutch highways. The load effect in this case study is the shear force occurring at 1 m from the support ($E = V$). Loads applied at a smaller distance from the support are expected to travel directly to the support. For a span length of 9 m, the annual mean shear force is m_Q = 390 kN with a coefficient of variation V_Q = 0.035 (De Vries et al., 2023b).

The laboratory measurements used in this case study were initially designed to study the shear behaviour of reinforced concrete beams without shear reinforcement (Yang et al., 2021). The H-variants (H121, H401, H403, H404, H602) were used from the test series. These strips, or deep beams, had a height of 1.2 m and a width of 0.3 m. The simply supported beams were loaded by a single jack close to the middle of the span and resulted in shear failure close to the support. Given the assumed lane width, there are 3.6/0.3 = 12 strips within the considered slab.

3.2 *Laboratory data post-processing*

During the tests, Digital Image Correlation (DIC) was used to identify and follow the formation of cracks in the concrete (Jones & Iadicola, 2018). From the DIC results, the nominal crack width may be obtained for many locations (Gehri et al., 2020). The locations may be chosen arbitrarily, but DIC data must be available over the virtual gauge length. The gauge length that delivered the best results in this study was $0.8d$, where d is the distance from the top of the beam to the middle of the longitudinal reinforcement. For each chosen location, the nominal crack width is calculated at the reinforcement level. In order to assign greater meaning to cracks forming near the supports, a weighted crack width is introduced where the nominal crack width is multiplied by the factor Vd/M where V and M are the shear force and bending moment at the considered location, respectively. Over the entire length of the beam, the maximum nominal crack width ($w_{\max}$) and maximum *weighted* nominal crack width may be determined ($w_{\max,w}$). The corresponding resistance ratio $X = V/V_u$ for both indicators was plotted for each load step (Figure 3).

The data was further post-processed to yield the sample mean and standard deviation for each considered indicator value (Figure 4). It is observed that the standard deviation of the data is smaller with the maximum weighted nominal crack width indicator ($w_{\max,w}$), making it the best choice for further modelling. The data points with $w_{\max,w} < 0.08$ mm result in very high mean and standard deviation values. This could result from noise in the DIC measurements for very small displacements. In general, the mean and standard deviation show some erratic behaviour considering different values of the indicator $w_{\max,w}$. Therefore, an analytical model was fit to the result, which also describes the convergence towards reaching the true resistance with higher loads (Figure 4):

$$m_{V_u/V}(w_{\max,w}) = \begin{cases} 1 + 1.6\,(w_{\max,w} - 0.85)^2 & w_{\max,w} < 0.85 \\ 1 & w_{\max,w} 0.85 \end{cases} \tag{6a}$$

$$s_{V_u/V}(w_{\max,w}) = \begin{cases} 0.3 - 0.3 w_{\max,w} & w_{\max,w} < 1 \\ 0 & w_{\max,w} 1 \end{cases} \tag{6b}$$

A direct consequence of Equations (6a) and (6b), is that for $w_{\max,w} \geq 1$ mm the method provides no benefit over proof load testing using the lower bound approximation (De Vries et al., 2023b).

3.3 *Assumed load testing results*

Section 3.1 describes the bridge under consideration as hypothetical and has not been tested in real life. However, an indication of reasonable indicator values is desired. The characteristic value

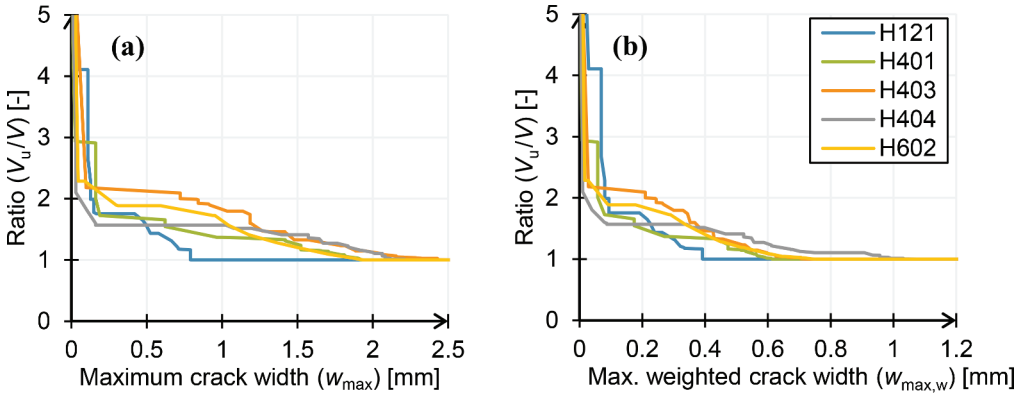

Figure 3. Shear resistance ratio versus (a) the maximum nominal crack width and (b) the maximum weighted nominal crack width.

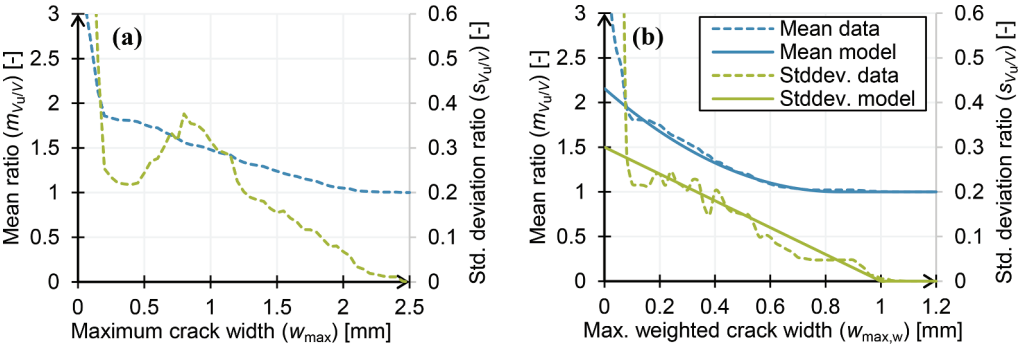

Figure 4. Mean and standard deviation of the shear resistance ratio versus (a) the maximum nominal crack width and (b) the maximum weighted nominal crack width.

of the traffic load multiplied by a factor serves as a helpful target load. Given the target loads, the laboratory test may provide reasonable indicator values (Table 1). When applied in practice, this step would not be necessary. The sensitivity to this input is described in the discussion (Section 5). It should be noted that the structure outside will already have the superimposed dead load (G_{SDL}) included in the measurements – i.e. the starting point of the measurements is different. Therefore, the values in Table 1 for the case $G_{DL} + G_{SDL}$ should be added to the values obtained during field testing to relate them to the laboratory experiments.

Table 1. Expected indicator readings given proof load.

Proof load test	Loadsacting on structure	Expected shear force [kN]	Maximum crack width, weighted by position ($w_{max,w}$) [mm]

4 RESULTS

4.1 *Probabilistic model*

In this section, the case study of Section 3 is continued with reliability calculations following the method outlined in Section 2. Given the average indicator values from Table 1, the mean and standard deviation of the resistance ratio may be obtained from Equations (6a) and (6b), see Table 2. For each proof load test, a reliability analysis is performed using the random variables specified in Table 3. The mean and coefficient of variation are based on the Probabilistic Model Code (JCSS, 2015) and *fib* Bulletin 80 (fib, 2016). A small coefficient of variation (0.02) is used for model uncertainty of the resistance because the laboratory tests are assumed to be representative.

Table 2. Mean and standard deviation of the resistance ratio for each proof load test.

Proof load test	Mean PLeffect, strip ($m_{Q,\mathrm{PL,s}}$) [kN]	Mean PLeffect, lane ($m_{Q,\mathrm{PL}}$) [kN]	Indicator value ($w_{\max,\mathrm{w}}$) [mm]	Mean ratio ($m_{V\mathrm{u}/V}$) [-]	Std. deviation ratio ($s_{V\mathrm{u}/V}$) [-]
1 (Q_k)	38.1	457.4	0.034	2.07	0.290
2 ($1.2Q_\mathrm{k}$)	45.7	548.8	0.038	2.06	0.289
3 ($1.4Q_\mathrm{k}$)	53.3	640.3	0.048	2.03	0.286
4 ($1.6Q_\mathrm{k}$)	61.0	731.8	0.096	1.91	0.271

4.2 *Reliability calculation results*

The annual reliability in the first year after the proof load test is calculated using the various limit state functions presented in Section 2 (assuming survival). In addition, the reliability is calculated using the lower bound approach that ignores permanent loads and additional resistance (i.e. $X = 1$ and $\theta_R = 1$). The calculations were performed with SORM (Hohenbichler et al., 1987), which approximately accounts for the non-linearity encountered in the limit state functions (Table 4). The results show that the calculated reliability indices are much higher compared to the lower bound approach. This reliability gain is the result of taking into account the measurements during proof load testing in the analysis (information source 2 in Figure 1). Even when the permanent loads are excluded from the limit state function, a target load of about $1.2Q_{\mathrm{k,WIM}}$ would still be sufficient to satisfy annual $\beta = 4$ requirement for CC3 (Steenbergen & Vrouwenvelder, 2010).

Table 3. Overview of random variables in the limit state function.

Var.	Description	Distribution	Mean	COV [-]
θ_R	Model uncertainty of the resistance	Lognormal	1	0.02
X	Resistance to current load effect ratio	Student's t, Equations (5)	(varies)	(varies)
G_DL	Dead load effect	Normal	356 kN	0.05
G_SDL	Superimposed dead load effect	Normal	59.3 kN	0.1
C_{0Q}	Time-invariant part of traffic load effect, including traffic trend	Lognormal	1.1	0.1
Q	Traffic load effect, annual maximum	Gumbel	390 kN	0.035
Q_PL	Load effect achieved by proof load	Normal	(varies)	0.02

Table 4. Mean and standard deviation of the resistance ratio for each proof load test.

Characteristic load effect, WIM ($Q_{k,WIM}$) [kN]	Characteristic load effect, LM1 ($Q_{k,LM1}$) [kN]	Annual reliability (β) [-]		
		Incl. permanent loads, Equations (3)	Excl. permanent loads, Equations (4)	Lower bound approach
1	0.78	3.21	3.02	0.70
1.2	0.93	4.11	4.02	2.31
1.4	1.09	5.03	5.00	3.66
1.6	1.24	5.86	5.85	4.78

5 DISCUSSION

In the laboratory data post-processing in Section 3.2, the model does not fit the data well for $w_{max,w} < 0.08$ mm. In the reliability calculations that follow, this region of minuscule cracks is used in the resistance prediction. Therefore, it may be questioned if the results can be trusted. Fortunately, as displayed in Figure 3, the data shows very high resistance ratios in this region with positive distribution skew. However, careful consideration must be made with regard to the similarity to the in-situ tested structure and the lab results. In the case study, it is assumed that the response of the bridge slab is similar to the response of the strips tested in the laboratory – presumably a conservative assumption, but it should still be validated.

An average response based on the laboratory measurements was assumed for the reliability calculations. In reality, the structure that is being tested may give a very different response and different measurement data post-processing may be necessary. When its strength is larger than expected and its condition is excellent, smaller indicator values are expected. When the assumed indicator values are divided by 10, the annual reliability indices increase by approximately 0.2. For structures that immediately display large crack widths under small loads, lower reliability is expected. When the indicator values are multiplied by 10, the reliability indices decrease by approximately 0.5 to 1. However, the reliability indices still remain higher than when calculated using the lower bound approach.

6 CONCLUSIONS

The proposed reliability updating method involves updating the resistance distribution using two sources of information: (1) the survival of the applied load in the proof load test and (2) the indicator value observed during the test, leading to an updated resistance distribution. A probabilistic model for updating the resistance distribution was presented, considering model uncertainties and permanent loads. The application of the proposed method was demonstrated through a case study of a reinforced concrete slab bridge. Laboratory data post-processing, including the consideration of weighted crack widths, provided insight into the resistance ratios considering different target loads. Reliability calculations based on the proposed method indicated a significant improvement compared to the lower bound approach, highlighting the importance of incorporating measured data.

The study addresses potential difficulties, particularly in fitting the model to data for small crack widths. It also recognizes the variability in real-world responses compared to assumed average values. Despite these considerations, the results consistently showed higher reliability indices than conservative estimates based on live loads alone. Real-world validation is recommended to enhance the robustness of the proposed approach. The next steps in the research will consider Bayesian approaches to include prior information in addition to the measurement data. Modelling choices and the application of the method with other types of resistance modes and measurements will be further reviewed.

ABSTRACT: Paper presents selected results of the diagnostic load testing of a newly-built footbridge in Novo Mesto, Slovenia. The bridge is significant as the first bridge in Slovenia being built with the stress ribbon technology. The diagnostic load testing took place in March 2023 and comprised of three-stage static load testing, dynamic testing with a light truck driving over artificial obstacles, and measurement of ambient vibrations. The consistency between the actual response of the bridge and the response of the finite element (FE) model, used in the design, was evaluated by comparing vertical displacements from the static load testing, natural frequencies and mode shapes. The comparison of the results indicates a satisfactory agreement between the measurements and the response of the FE model, confirming the appropriateness of the employed FE model.

1 INTRODUCTION

A newly built pedestrian bridge in the village of Irča Vas, near Novo Mesto, is the first bridge in Slovenia built using stress-ribbon technology. The bridge is a slender catenary-shaped structure with concrete precast segments placed over prestressed steel ribbons that function as scaffolding during bridge construction (Strasky & Pirner, 1986). Forces from the stress ribbons are transferred through well foundations and geotechnical anchors on both sides of the bridge to load-bearing soil.

In March 2023, a diagnostic load test was conducted using 18 3.9-tonne trucks, representing approximately 60% of the design load. Proof load tests in the USA should be performed using guidelines set by the Manual for Bridge Evaluation (2018). Similar approach was utilised in the case of Irča Vas bridge. To validate the designer's calculations, an extensive measurement campaign was undertaken. It is comprised of sensors installed for long-term monitoring and sensors installed for diagnostic load tests, designated as short-term measurements. The following measurements were performed: measurement of rotations using inclinometers and 3-axial MEMS accelerometers, acceleration measurements using single and 3-axial MEMS accelerometers, and deflection measurements using a total station and 3D laser scanner. Additionally, force in the geotechnical anchors was measured. This article outlines the most important results of the diagnostic load testing with a focus on short-term sensor data and compares with the calculated response from the bridge designer's finite element (FE) model.

2 BRIDGE DESCRIPTION

A new pedestrian bridge crosses the Krka river with a span of 131 m, as shown in Figure 1. The maximum longitudinal slope of the bridge is 6%, as the structure has an inbuilt radius, where its lowest point is around 8 m above the river surface.

DOI: 10.1201/9781003483755-45

Figure 1. Bridge on the day of the diagnostic load test.

The bridge deck is supported with abutments, which rest upon the well foundations. The tensile forces from prestressing tendons are carried over by geotechnical anchors and transferred in load-bearing soil (Figure 2).

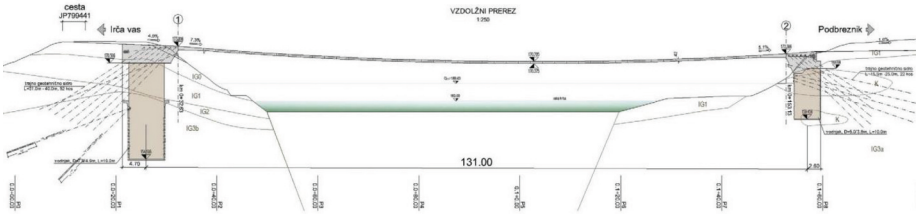

Figure 2. Longitudinal section of the bridge.

The cross-section of the bridge is shown in Figure 3. Precast concrete elements are 4.0 m wide and 2.4 m long. Element thickness varies in a transverse direction from 0.42 m at the edges to 0.18 m in the middle. The usable width of the bridge is 3.5 m. Precast elements are built offsite using C45/55 concrete. More in-depth information about the bridge geometry and building process is available in Weingerl et al. (2023).

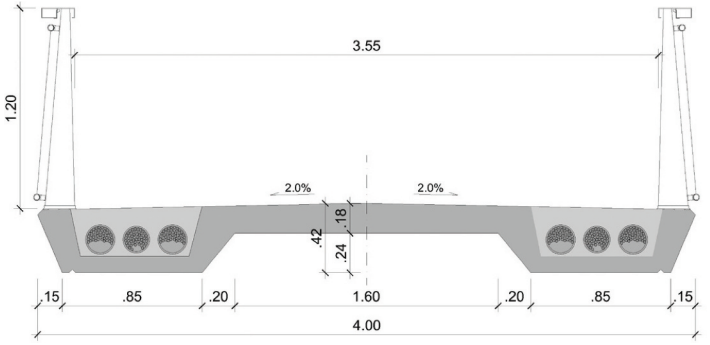

Figure 3. Cross-section of the bridge.

3 MEASUREMENTS

The bridge's diagnostic load test comprised static (trucks stationary on the bridge) and dynamic (trucks passing an artificial bump on the bridge) testing. In addition, vibrations

under ambient excitation before and after the testing campaign were captured. 6 phases were performed overall:

- Phase 0: Resting phase before loading (zero state).
- Phase 1: 9 trucks at the 2/2 of the bridge (half-load).
- Phase 2: 18 trucks across the entire bridge (full load of 70.4 tonnes overall, Figure 4).
- Phase 3: 9 trucks at the 1/2 of the bridge (half-load).
- Phase 4: Resting phase after loading (release state).
- Phase 5: Dynamic test – trucks passes artificial bump on the bridge.

Figure 4. In the static load test (Phase 2), all 18 trucks with an overall 70.4 tonnes were present on the bridge.

Axle loads and distance of statically-weighted 18 trucks are presented in Table 1.

Table 1. Axle load data for each truck used during the load test.

Truck number	Axle distance[m]	1st axle load[kg]	2nd axle load[kg]	SUM[kg]
1	4.35	1700	2200	3900
2	3.65	1600	2400	4000
3	3.65	1400	2800	4200
4	3.65	1500	2300	3800
5	3.00	1700	2200	3900
6	3.60	1600	2300	3900
7	4.35	1700	2300	4000
8	3.65	1300	2900	4200
9	3.65	1300	2900	4200
10	3.65	1400	2700	4100
11	3.65	1300	2900	4200
12	3.65	1500	1900	3400
13	3.65	1300	2700	4000
14	4.35	1700	1800	3500
15	3.65	1300	2700	4000
16	4.35	1700	1700	3400
17	3.65	1500	2300	3800
18	3.65	1500	2600	4100

During phase 0, zero state was measured with both total stations, 3D laser scanner, MEMS accelerometers (for inclinations) and inclinometers. Moreover, ambient vibrations were measured with MEMS accelerometers for a duration of approximately 20 minutes.

Phase 1 was conducted by placing the first 9 trucks on the 2nd half of the bridge, between the mid-span and end (left, according to Figure 4) abutment. Phase 2 was conducted without load relief by adding 9 additional trucks to the 1st half of the bridge, between the first abutments and the mid-span. Phase 3 of the static load test was performed by removing the 9 trucks from bridge such that trucks were only present in the 1st half of the bridge, between the right(according to the the Figure 4) abutment and the mid-span. In phase 4, the bridge was fully relieved. For Phase 1 – Phase 4 the vertical displacements of the deck and horizontal displacements of the abutments were measured with both total stations. Additionally, the inclinations of the deck were measured with MEMS accelerometers and the inclinations of the abutments with inclinometers. 3D laser scans were performed only for Phase 2 and Phase 4. Ambient vibrations using MEMS accelerometers were measured only in phase 4.

The aim of the dynamic test was to excite the structure such that modal parameters could also be determined with uniaxial accelerometers (presented in Chapter 4), which are permanently installed on the bridge, and not only with the MEMS accelerometers. During this test, a truck was driving over the four equally-distant wooden obstacles near the mid-span. In the first measurement, the truck crossed the bridge from right to left (according to Figure 4) abutment with 20 km/h. Afterwards, a truck drove in the reverse direction across the same obstacles at 10 km/h. In the last phase, the truck drove over the bridge in both directions at 10 km/h.

4 INSTRUMENTATION

The considered bridge has a built-in permanent monitoring system which is capable of continuous measurement of bridge accelerations and rotations of the abutments, as shown in Figure 5.

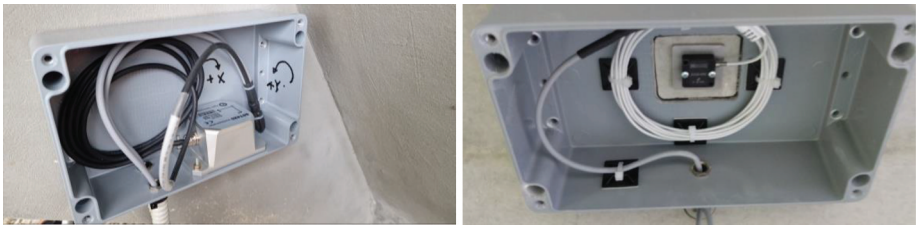

Figure 5. Sensors used for the permanent monitoring: biaxial inclinometer (left) and uniaxial accelerometer (right).

The permanent monitoring system is designed such that it allows for remote access to the measured data. Each abutment is equipped with one biaxial inclinometer (type Vigor Technology SST420), which allows for the measurement of support rotation (INCL_01 and INCL_02 in Figure 6). Uniaxial accelerometers used in permanent monitoring (type Silicon Designs 2220-002) are placed on the bottom side of the precast concrete elements of the bridge deck. They were placed before the precast elements in the construction phase due to the difficulty of access afterward. Three pairs of two accelerometers were placed at the narrower part of the bridge deck (ACC_01 – ACC_06 in Figure 6). Using those accelerometers, three cross-sections were instrumented (First quarter, middle quarter, and third quarter of the span). Due to vandalism which occurred after the construction and before the load test of the bridge, connection to accelerometer ACC_06 and inclinometer INCL_01 was lost, and it was impossible to re-establish after the end of the construction.

During the load test of the bridge, all working sensors that are part of the permanent monitoring system were used. Additionally, the bridge was temporarily equipped with 12 triaxial MEMS accelerometers (type DEWESoft IOLITEi 3xMEMS-ACC), designated with green dots in Figure 6). These accelerometers were placed in pairs every 20 m of the bridge and were used to identify modal parameters in Phase 0 and Phase 4.

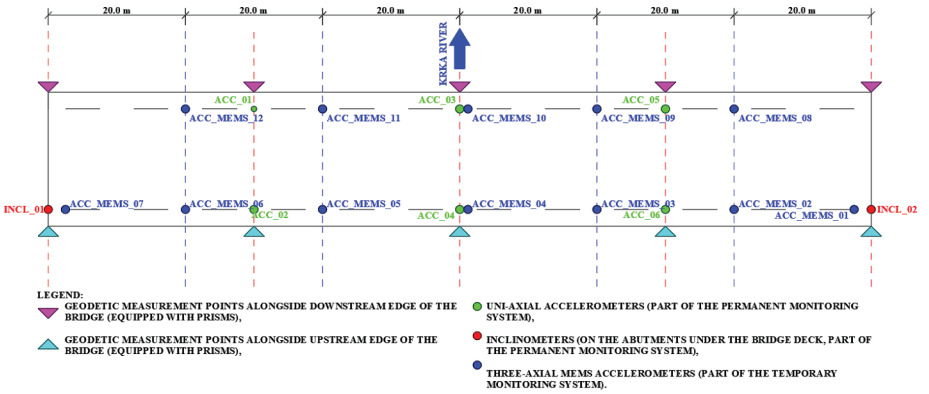

Figure 6. Sensor disposition (permanent and temporary monitoring systems).

During the static load test, vertical displacement along the upstream and downstream edge of the bridge was measured using two total stations and a laser scanner (Figure 7). Vertical displacement measurement points were placed along the upstream and downstream edges of the bridge deck at quarter, middle and three-quarters of the bridge span. Rotation of the abutments, horizontal displacements and rotations at the abutments were measured for all phases of the static load test.

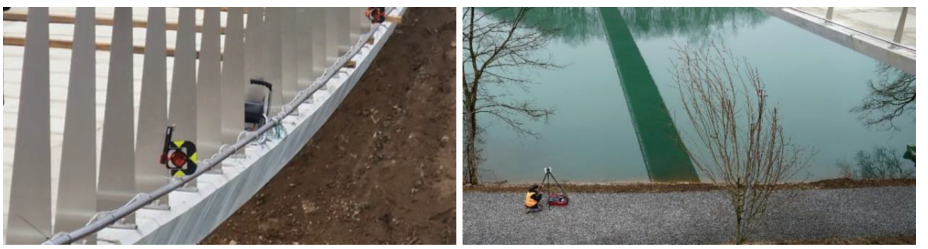

Figure 7. Geodetic measurement points along the downstream edge of the bridge deck (left) and position of the laser scanner (right).

Laser scanning was carried out with a Leica RTC360 laser scanner situated at the upstream river bank. From this location, the instrument's range managed to include about 80 m of the bridge, reaching well beyond the structure's lowest point in the middle of the bridge (60 m). Due to such limited scanning geometry, the highest scanning resolution was selected (3 mm at a distance of 10 m), resulting in roughly 3000 points per square meter at the location of the lowest bridge point. The 3D point accuracy of this scanner at a distance of 60 m is about 5 mm. One should note, however, that since only relative displacements in the vertical direction were of primary interest, this value is not completely representative.

5 MEASUREMENT RESULTS AND COMPARISON

Each of the measured parameters was calculated by the designer during the design phase of the project. A detailed FE model was created in SOFISTIK software. Before the load test phase, the designers also calculated the vertical displacement of the deck, abutment rotations and horizontal abutment displacement for each of the three phases of the static load test. Alongside the displacements, the designer calculated modal characteristics, namely the natural frequencies and mode shapes, beforehand. Below are the most important results, i.e., a comparison of the mid-span

deflection and modal characteristics measurements. More in-depth analysis exceeds the scope of this paper.

A comparison between the calculated and measured bridge deck vertical displacements for all three static load cases is shown in Table 2. The values shown represent the average displacement of the downstream and upstream edges of the bridge deck.

The scanning was carried out in three consecutive time moments, i.e. before the loading (T1 designating Phase 0), at the time of the maximum load (T2 designating Phase 2), and after unloading (T3 designating Phase 3). Two distinct point profiles (P1 and P2) were selected from these three point clouds on each side of the bridge deck, forming the basis for further bridge displacement analysis. The P1 point profile consists of points near the upstream edge of the deck, and the P2 point profile consists of points near the downstream edge of the deck. Both profiles are 5 centimetres wide. The shape of each profile in the vertical domain was modelled using polynomials since they best fitted the profile points. Figure 8 shows the deformation line of the bridge deck's downstream edge for all three static load test phases.

Table 2. A comparison between the average measured and calculated values of mid-span vertical displacement of the bridge deck.

Phase	Total station [mm]	Laser scanner* [mm]	FE model [mm]
1	65.0	/	69.5
2	129.0	127.3	145.5
3	70.1	/	64.5
4	9.9	7.6	/

* average values of profiles P1 and P2

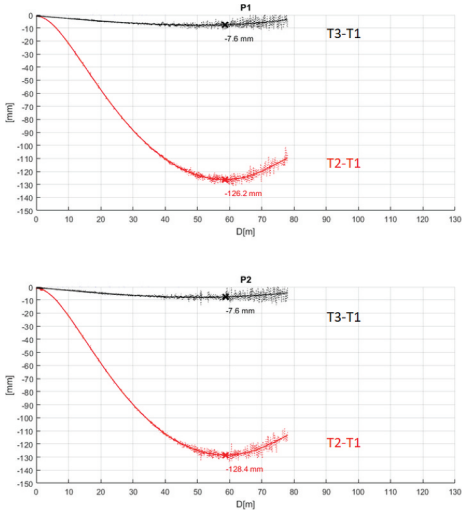

Figure 8. Measured deformation line of the downstream edge of the bridge deck for all three phases of static load test.

As shown in Table 2, the values of measured and calculated displacements match well for all three phases of the static load test. Measured displacements were smaller than calculated. Values measured by a laser scanner and total station differ by 2 mm. Figure 9 shows the point cloud measured with the laser scanner.

Table 3 shows the measured and calculated natural frequencies which correspond to the vertical mode shapes of the structure. Table 4 shows the measured and calculated mode

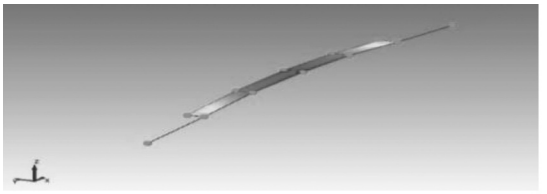

Figure 9. Point cloud measured with a laser scanner.

Table 3. First three measured and calculated natural frequencies [Hz].

Vertical mode shape	Measured – FDD	FE model
1	0.68	0.70
2	0.98	1.09
3	1.51	1.66

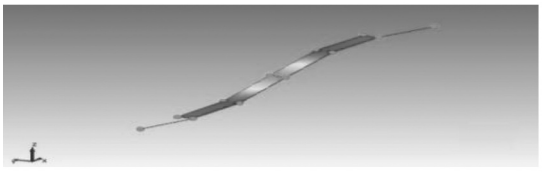

Table 4. Comparison between measured and FE model mode shapes.

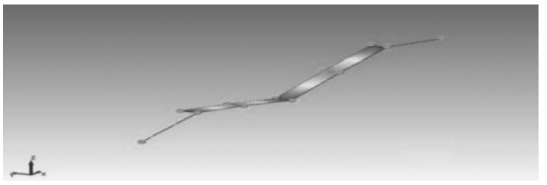
1st measured mode shape: f_1 = 0.68 Hz



1st FE model mode shape: f_2 = 0.70 Hz

2nd measured mode shape: f_2 = 0.98 Hz

2nd FE model mode shape: f_3 = 1.09 Hz

3rd measured mode shape: f_3 = 1.51 Hz

3rd FE model mode shape: f_3 = 1.66 Hz

shapes. Measured modal parameters were extracted with the Frequency Domain Decomposition (FDD) method (Brincker et al. 2000) using the ARTeMIS Modal (Structural Vibration Solutions 2023) software package for modal identification of structures.

As shown in Table 4, modal parameter identification methods give satisfactory estimates of natural frequencies. The best matching between measurements and the numerical model was recorded for the first mode shape. For the second and third mode shapes, natural frequencies were overestimated. Natural frequencies calculated using numerical models are for the first three mode shapes higher than those measured, which indicate the higher stiffness of the model. At most, measured and calculated natural frequencies differ by 11.2 % for the second mode shape.

6 CONCLUSIONS

The paper presents selected results of load testing of the newly built stress ribbon pedestrian bridge near Novo Mesto, Slovenia. The bridge is significant as the first bridge in Slovenia to be built using stress ribbon technology. Diagnostic load testing of the bridge consisted of three-phase static load testing, dynamic load testing performed with truck driving over artificial obstacles and ambient vibration measurements. Static response of the structure was recorded using two electronic total stations and a laser scanner. The dynamic response of the structure was measured using the permanent monitoring system, which includes uniaxial accelerometers and biaxial inclinometers, and a temporary monitoring system, which consists of 12 triaxial MEMS accelerometers. Furthermore, MEMS accelerometers were used to measure the response under ambient excitation before and after the load test.

Only the selected results are shown in this paper, mainly from the short-term measurements i.e. vertical displacement at the mid-span of the bridge and three vertical mode shapes and their corresponding natural frequencies. The matching between measured and calculated values of vertical displacement was satisfactory in all three phases of static load testing. Measured displacements were smaller than calculated ones. However, the order of magnitude was comparable. Additionally, satisfactory matching was also achieved between measured and calculated vertical mode shapes and their corresponding natural frequencies.

The findings of the load test confirm correct modelling and assumptions during the design of the bridge. For a better understanding of the complex static and dynamic response of the bridge, additional data analysis and calculations are required.

ABSTRACT: A road bridge in Japan's Mt. Fuji area was damaged by a large avalanche in 2021. In this study, damage evaluation was conducted on a RC beam and the foundation of the bridge. Shear cracks in the RC beam were observed with the naked eye. From reliability assessment using a Monte Carlo simulation, the equivalent impact load of the avalanche was estimated over 3-4 times the design load from weights of the superstructure and vehicles. Moreover, cracks and damages in the footing and piles were also detected from forced vibration testing using a portal vibrator and hammering impact echo inspection. Using both non-destructive testing methods, damage locations of the invisible piles under the ground were identified. The effectiveness of reliability assessment and non-destructive testing for concrete bridges damaged by accidental loads (e.g., avalanches) was indicated.

1 INTRODUCTION

Roads play important roles in rescue activities for serious natural disasters. These civil structures need to have high safety performance and remain serviceable in case of disasters. The standard specifications for concrete structures were revised (Japan Society of Civil Engineers 2022), containing safety performance verification for accidental loads, such as tsunamis, floods, landslides, rockfalls (Biagi et al. 2020, Mougin et al. 2005), impact loads of trains, airplanes (Arros & Doumbalski 2007), or ships (Consolazio et al. 2005). Studies on dynamic responses (Pham & Hao 2017), damage and failure processes, and safety design of structures for impact loads (Nataraja et al. 1999, Tachibana et al. 2010) have been investigated. However, compared to the seismic design, further data and analyses are needed to improve safety design of structures for accidental loads.

Roads are required to be in service within a short period of time after disasters. However, inspection of bridges subjected to accidental loads has a difficulty in detecting invisible cracks and damages. It is necessary to examine the effectiveness of non-destructive testing to detect invisible cracks and damages caused locally by impact loads.

In this study, reliability assessment and non-destructive testing were conducted on a road bridge to collect data for improving safety design and inspection of civil structures. The bridge was in Japan's Mt. Fuji area and was damaged by a large avalanche in March 2021, as shown in Figure 1. The reliability analyses using a Monte Carlo simulation were conducted for evaluating the relationship between load level and failure probability of the RC beam subjected to an avalanche. Moreover, forced vibration testing (Naito & Bolander 2019, Naito et al. 2020) and impact

echo inspection (Schubert et al. 2008) with elastic waves were conducted on the invisible piles from the top surface of the footing.

2 DAMAGE CONDITIONS OF THE BRIDGE

Figure 1 shows a road bridge before the avalanche. The layout of the bridge and the cross-section are shown in Figures 2 and 3. It was constructed in 1993, with a span of 20.6 m and

a width of 9.2 m. The superstructure had nine RC beams with a sectional height of 1050 mm. The RC beams were supported at both sides. Figure 4 shows a diagram of cracks on the outer beam after the avalanche. Shear cracks were observed in the beam through eye inspection. It was thought that the impact location was around the left quarter of the span, as shown in Figure 4.

In addition, cracks were observed in the left abutment (A1). The crack in the abutment was caused by a horizontal load during the avalanche. The damage conditions indicated that a large vertical load was applied to the superstructure. In addition, a large horizontal load and moment were applied to the abutment and foundation from the superstructure through bearings at both sides of the beams.

3 RELIABILITY ANALYSES ON THE RC BEAM

Failure probabilities of shear and flexural modes were calculated on the RC beam using a Monte Carlo simulation. Figure 5 shows a beam model of the bridge. For simplicity, the design load ($P = P_d$) of the beam was given as a concentrated load from weights of the superstructure and vehicles, that was applied to the center of the span (at $x = L/2$).

In the Monte Carlo simulation, normal distributions were assumed for the flexural and shear load capacities of the beam. The limit state functions of flexural and shear failures were given from the Japanese design code (Japan Society of Civil Engineers 2022). The mean of the flexural moment capacity M_u was given as $P_d L/2$, where M_u was set to twice the moment of $P_d L/4$ at the center of the span for a flexural failure safety factor of 2.0. The mean of the shear load capacity V_u was given as $1.8\ M_u \times 2/L$, where the ratio of shear to flexural capacities was set to 1.8. Coefficient of variations of the flexural and shear capacities were assumed as 10 % and 15 %, respectively. The two parameters (M_u and V_u) were changed randomly in the Monte Carlo simulation having 100,000 trials. During the 100,000 calculations, the number of flexural failures N_f and the number of shear failures N_s of the beam were counted. The failure probabilities of flexural and shear modes were obtained as $P_{f,f} = N_f/100{,}000$ and $P_{f,s} = N_s/100{,}000$, respectively.

In addition, a reliability index is obtained as $\beta = m(Z)/\sigma(Z)$, where Z is the performance function given as $Z=R–S$. β_f and β_s are the reliability indices of failure and shear modes, respectively. They were calculated from resistances R (the moment capacity M_u and the shear capacity V_u) and the subjected force S obtained from moment and shear force distributions in Figure 5.

The failure probabilities and reliability indices of flexural and shear modes calculated from the Monte Carlo simulation are shown in Table 1, when the vertical load ($P = P_d$) was applied to the center of the span (at $x = L/2$). Both failure probabilities of flexural and shear modes were low and safe. Both reliability indices of failure and shear modes were close to 5.0. These results indicated high safety performance of the beam for the design load P_d, when it was applied at $x = L/2$.

Figure 6 shows the relationship between loading location x and failure probabilities. On the x-axis in the figure, the locations $x = 0$ and $0.5L$ were at the left support and center of the span, respectively. The failure probability of shear mode increased as the loading location was closer to the left support.

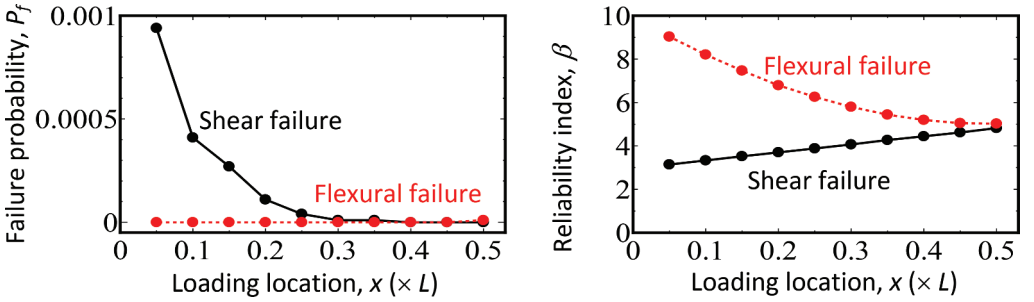

Figure 6. Failure probabilities and reliability indices with changes in loading location.

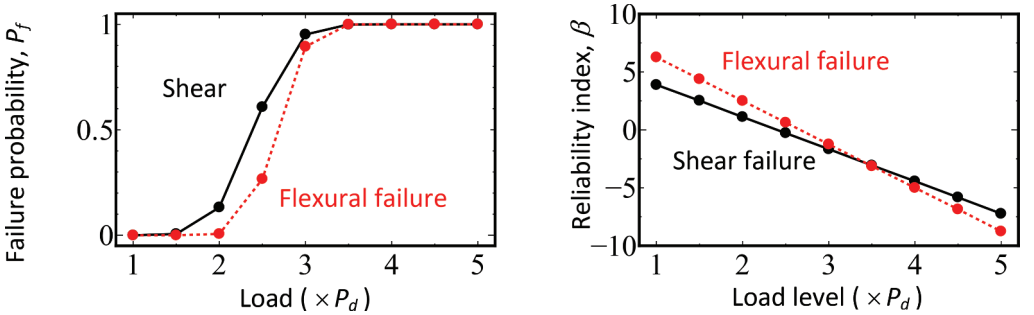

Figure 7. Failure probabilities and reliability indices with changes in load.

Referring to the reliability indices, the β_s of shear mode decreased to 3.14 (at $x = 0.05L$) from 4.82 (at $x = 0.5L$), when changing the loading location toward the support. On the other hand, the β_f of flexural mode increased to 9.03 near the support (at $x = 0.05\ L$), because the moment around the pin-support was very small. The center of the impact load of the avalanche was considered at $x = 0.25L$ from Figure 4. The failure probability $P_{f,s}$ and reliability index β_s at the location $x = 0.25\ L$ were still safe. Results indicated the load level of the avalanche was much higher than the design load P_d.

The relationship between load level and failure probabilities are shown in Figure 7, with the loading location fixed at $x = 0.25\ L$. The probabilities of flexural and shear failures converged to 1.0 when the load P was higher than $3P_d$. The safety β_s of shear mode was lower than that of flexural mode β_f. Moreover, these reliability indices were switched between 3.0 P_d and 4.0 P_d.

From the conditions set in the calculation model, the vertical load P by the avalanche was estimated over 3 to 4 times the design load P_d from weights of the superstructure and vehicles.

4 NON-DESTRUCTIVE TESTING ON THE FOUNDATION

4.1 *Forced vibration testing*

4.1.1 *Experimental program*

Cracks in the bridge abutment were observed through visual inspection, indicating large horizontal and moment had affected the abutment through bearings of the beams. Moreover, it was likely that the horizontal force had also affected the foundational footing and piles. However, it is difficult to detect damage in the footing and piles under the ground.

In this study, forced vibration testing (Naito & Bolander 2019, Naito et al. 2020) and impact echo inspection were conducted on the piles. The ground around the foundation was composed of volcaniclastic debris mixed with gravel and scoria. The foundation was a group pile structure (root piles), with 68 micropiles. The piles had a diameter of 131 mm and a length of 8.5 m. Cement milk was filled around a 51mm diameter deformed steel bar.

As shown in Figure 8, the abutment had been removed in the site test. Two non-destructive testing were conducted from the top surface of the footing to apply elastic waves into the piles. Figures 9 shows the measurement locations from the top surface of the footing, where the black marks were 20 measured piles. The measurement locations Nos. 1 to 20 were determined from the design drawings. A schematic diagram of the elastic wave testing is shown in Figure 9. The elastic waves were applied into the pile from the top surface of the footing, for obtaining reflected waves from the bottom of the pile. During these site tests, forced vibration testing and impact echo inspection were conducted.

Figure 8. The top surface of the footing.

An electric-magnetic vibrator was used in the forced vibration testing. The vibrator has a mass of 9.5 kg, frequency range of 20 to 20,000 Hz, a maximum excitation force of 49 N, and a maximum acceleration of 377 m/s^2. In the site test, white noise was applied to the piles for saving test duration. The white noise was generated at a power spectral density of 15 (m/s^2)^2 /Hz in a frequency range of 50 to 500 Hz, where the root mean square (RMS) of the acceleration waveform was 82 m/s^2. Response acceleration waveforms were measured with a piezoelectric accelerometer with a mass of 4.6 g, and a sensitivity of 10 mV/G in a frequency range of 1 to 30 kHz. The accelerometer was placed on the top surface of the footing approximately 100 mm away from the excitation location. Frequency response functions with a resolution of 1 Hz were obtained.

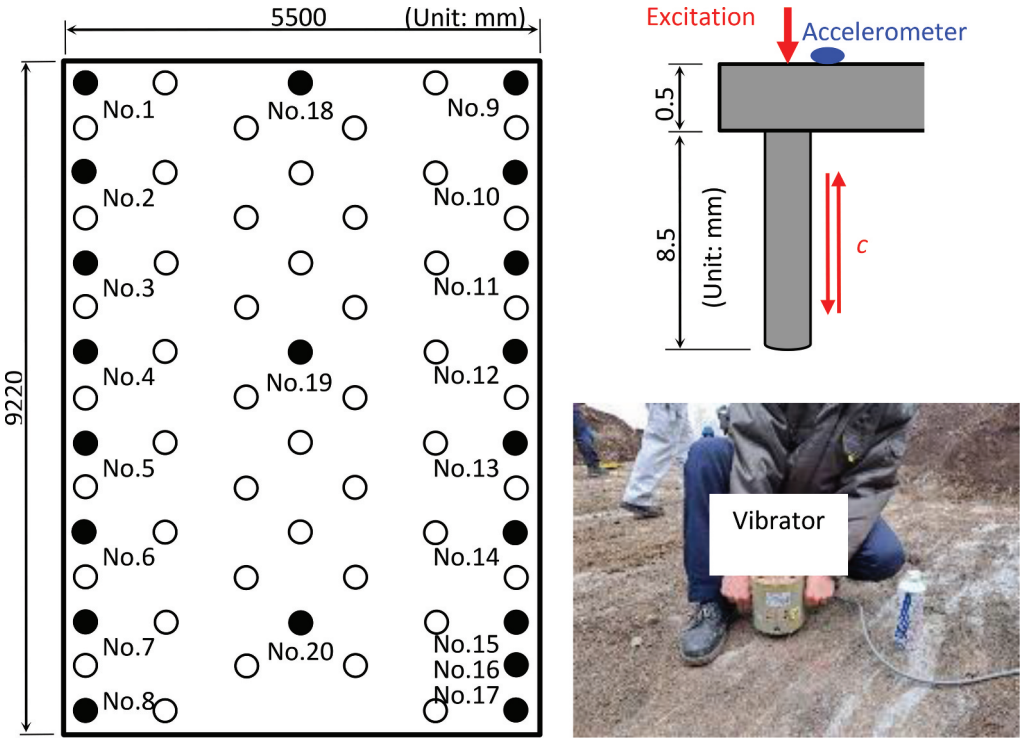

Figure 9. Measurement locations in the forced vibration tests.

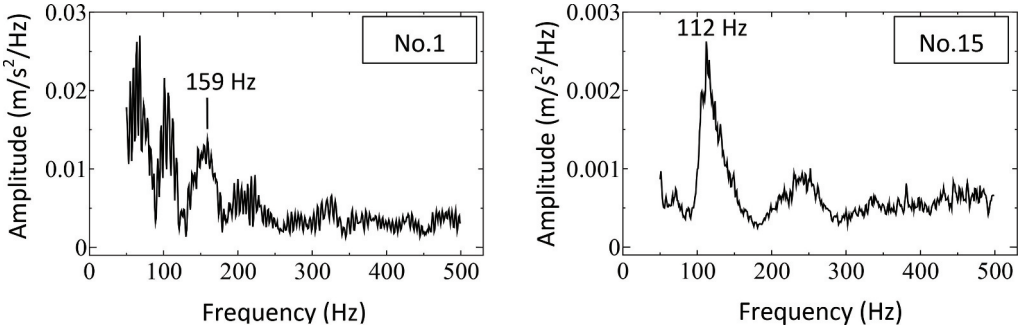

Figure 10. Frequency response functions from the forced vibration tests.

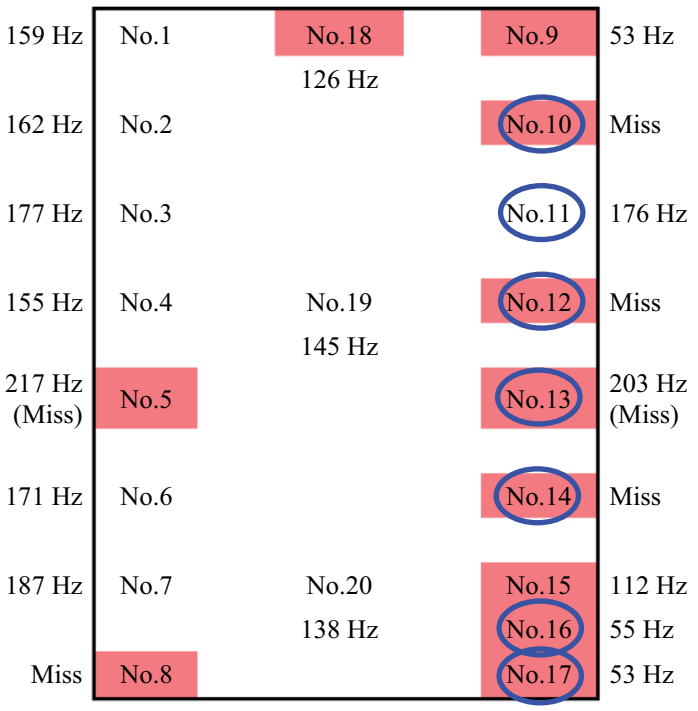

A longitudinal vibration of the pile was excited with the vibrator, as shown in Figure 9. The resonant frequency f_0 of an intact pile was obtained as $f_0 = c/(2L)$, where c is the speed of sound within the pile, and L is the vibration length. The vibration length L was given as 9.0 m, from the pile length of 8.5 m and the footing thickness of 0.5 m. The speed of sound was assumed as 3700 m/s, as well as that within concrete. In addition, a reduction factor of 0.80 was given in considering influence of the footing mass (Naito et al. 2017). The modified speed of sound c was given as $c = 0.80 \times 3700 = 3000$ m/s. The resonant frequency $f_0 = 166$ Hz was calculated. Moreover, considering a coefficient of variation $\sigma = 10$ %, resonant frequency of the intact pile was in the range of 130 to 200 Hz, from f_0 (1 +/– 2σ) in normal distribution.

However, resonant frequency (stiffness) decreases when cracks are contained within the pile. From the forced vibration testing, measured resonant frequencies were defined as frequencies corresponding to amplitude peaks in frequency response functions. The measured resonant frequencies in the range of 50 to 130 Hz were determined to be in "Damaged condition". Those in the range of 130 to 200 Hz were determined to be in "Intact condition". In addition, measurement locations were labeled as "Miss", when the measured resonant frequencies were higher than 200 Hz. This has a possibility of damage, having complex wave propagation characteristics with diffracted and reflected waves around cracks within the pile.

4.1.2 *Experimental result*

Frequency response functions of No. 1 and No. 15 are shown in Figure 10. The frequency response of No. 1 was labeled "Intact condition", since one of the amplitude peaks was observed at 159 Hz, within the intact range of 130 to 200 Hz. On the other hand, the frequency response of No. 15 had no amplitude peak in the intact range of 130 to 200 Hz. It was labeled as "Damaged condition" since the longitudinal resonant frequency (stiffness) of the pile decreased due to cracks and damages. Indeed, cracks and damage were observed around the joints of the footing and piles, after removing soil around the measurement locations Nos. 15 to 17.

Figure 11 shows the measured resonance frequencies and condition labels for Nos. 1 to 20. Conditions "Damaged" and "Miss" are colored in red. Most of Nos. 1 to 7 on the left side of the footing were labeled "Intact condition". The statistical values of the resonant frequencies from Nos. 1 to 7 except for No. 5 were: a mean of 169 Hz, and a coefficient of variation of 7.2 %. The mean value of 169 Hz showed agreement with the calculated frequency f_0 = 166 Hz.

*Red areas (from the forced vibration testing) and blue circles (from the impact echo inspection) indicate damaged piles.

Figure 11. Damage evaluation results.

On the other hand, most of the piles Nos. 9 to 17 on the right side of the footing had been labelled "Damaged condition" or "Miss", out of the intact range of 130 to 200 Hz. It was thought the piles had cracks and damage. As described above, the footing and piles of Nos. 15 to 17 were damaged, through visual inspection after soil removal.

Measured resonant frequencies from Nos. 18 to 20 on the center line of the footing were lower than those of the left side (Nos. 1 to 8). However, it was thought the piles of Nos. 18 to 20 were lightly damaged since the thickness on the center line of the footing was higher than that of the left side shown in the drawings.

4.2 *Impact echo inspection*

During the site test, impact echo inspection was also conducted on the piles. Impact loads were applied to the pile with a hand-held hammer from the top surface of the footing, as shown in Figure 12. The hammer had a mass of 1.4 kg. The accelerometer had a sensitivity of 50 mV/G ina frequency range of 0.7 to 9000 Hz.

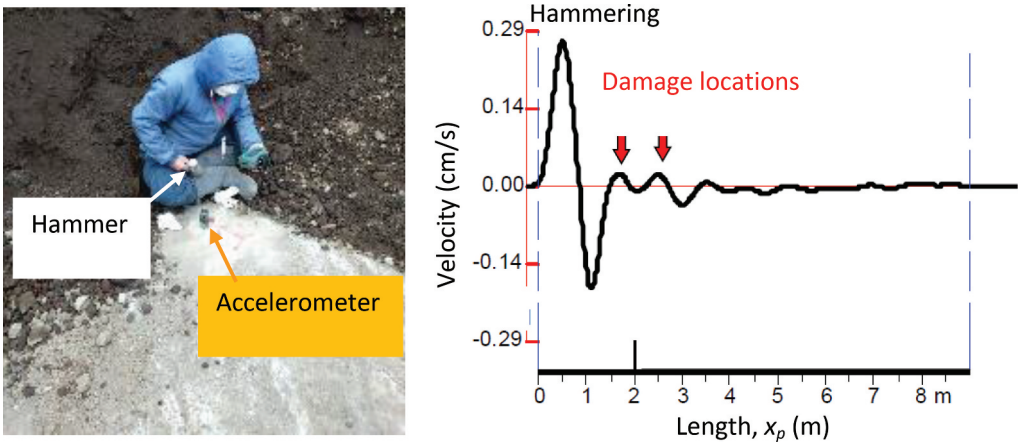

Figure 12. Impact echo inspection and measured waveform.

Figure 12 shows a schematic diagram of waveform analysis in the impact echo inspection. The time records of acceleration were integrated into velocity waveforms. The x-axis in Figure 12 was converted to a distance from the top surface of the footing in the longitudinal direction. This is given as $x_p = ct/2$, where x_p is the distance from the top surface of the footing, t is the time, and c is the speed of sound within the pile, assuming the modified value of c = 3000 m/s as in the forced vibration testing. The arrows at velocity peaks in Figure 12 indicate reflected waves from horizontal cracks within the pile.

Figure 11 shows the results of damage evaluation from the impact echo inspection. The 20 measurement locations were the same as those of the forced vibration tests. Damaged piles evaluated from the impact echo inspection were indicated with blue circles in Figure 11. Most of the piles were damaged on the right side of the footing. Comparing the results from the forced vibration tests, both non-destructive testing methods were in agreement. The effectiveness of using and comparing different testing methods for detecting damage in non-visible structures covered in soil was observed.

5 CONCLUSIONS

In this study, damage evaluation of a road bridge subjected to an avalanche was conducted, using reliability analyses and non-destructive testing. These findings were observed:

1) Shear cracks occurred in the RC beam due to a vertical load of the avalanche. From visual observation, the loading location of the center of the avalanche was thought to be around a quarter of the span.
2) A failure probability and reliability index for shear failure were evaluated using a Monte Carlo simulation. From the calculated result, the impact load of the avalanche was estimated to be over 3 to 4 times the design load from weights of the superstructure and vehicles.
3) Forced vibration testing and impact echo inspection were conducted on the foundation. The results from these two methods were in agreement. Piles on the left side of the footing were almost intact, whereas those on the right side were seriously damaged. It was thought that a large horizontal load was applied to the abutment and foundation during the avalanche.

The effectiveness of reliability assessment and non-destructive testing was shown through the examples of damage evaluation of a bridge subjected an avalanche. Further studies applying these methods on various types of accidental loads are needed to improve design and inspection processes for civil structures.

ACKNOWLEDGEMENTS

A part of this research was conducted with the support of JST FOREST Program (Grant Number JPMJFR2150, Japan), and the Japan Society for the Promotion of Science (Grant Number 22H01568). In addition, we thank the staff of the Road Maintenance Division, Yamanashi Prefecture, for providing their reports and document materials.

In-situ, lab testing and FE simulations historical steel-concrete bridge decks

A. de Boer, B. Renckens & L. Ha
Engineering Office, City of Amsterdam, The Netherlands

ABSTRACT: Before 1950 steel-concrete bridges are built without a dowel connection between the steel and concrete part of the bridge deck. The steel part of this bridge type is a common steel I-type girder. The concrete part has no bearing capacity reinforcement. The span length vary from 5-15 meter. The assessment of those structures aren't covered by the Eurocode, a dowel connection between the steel and concrete part is missing. Slip behaviour of the bonded connection between steel and concrete is unknown. In-situ cycle loading tests, ULS cycle and ULS lab tests with Eurocode TS load configurations are executed on 5 samples, constructed in 1938. They show the bonded behaviour. Solid3D FE model simulations confirm the test measurements. This process leads to a practical engineering re-examination assessment protocol based on a simple Shell2.5D FE model. The historical view of the city of Amsterdam can be saved and reduces the renovation costs.

1 INTRODUCTION

After the publication of the steel-concrete Eurocode 4 part 2[CEN 2005] and the introduction of the set of Eurocodes in the Netherlands in 2012 it wasn't allowed anymore to design steel concrete bridge decks without dowels between the steel girders and the concrete bridge decks. However the inner cities of "old" towns like Amsterdam have a large number of steel concrete bridge decks.

Figure. 1. Overview inner city of Amsterdam.

Figure. 2. Overview 3-span steel concrete bridge.

The city of Amsterdam counts more than 800 road traffic bridges, where more than 200 in the inner city, which are mostly steel concrete bridge decks. Their technical design lifetime of 80 years is already passed, so the assessment of those bridge decks could have a problem. However the bridge decks are still in operational, sometimes with restrictions to the vehicle weight, but even with these restrictions there was a need to have an additional guideline to the

DOI: 10.1201/9781003483755-47

Eurocode 4 part 2. The so called historical steel concrete bridge decks are designed on the theory of Joseph Melan[Melan1884]. These bridge decks are well known as the bridges based on the Melan System. The system contains common steel profiles embedded as reinforcement into a concrete deck. No additional reinforcement with a bearing capacity role was included in the deck, only shrinkage reinforcement was later on added at the top of the bridge deck. Later on, Wapenhans and Kind[Wapenhans1987] have published the Melan System again with some additions in a practical form for design engineers.

An additional guideline to the Eurocode means setting up experiments of these types of historical steel concrete bridges. The renovation program of the city of Amsterdam shows some bridges where the bridge deck should be removed, so this was an opportunity to setup some in-situ experiments. When the in-situ experiments show reasonable results, parts of the bridge deck could be transported to a laboratory environment, where similar or extended experiments could be done with an extended number of sensors in relation to the in-situ. Parallel to these experiments FE simulations can be done with solid 3D models to predict the real behaviour of the experiments. Later on, the solid 3D model can be simplified to a 2.5D shell model, which is more convenient for the practical engineering offices, which are involved to make the assessment re-examinations of the structures.

2 DESCRIPTION OF THE BRIDGE

The 3-span steel concrete bridge is already shown in Figure 2. The bridge counts 2 side spans and 1 main span; the span length of the side span is 5.8 meter, where the main span counts 7.55 meter.

The west side of the 3 spans can be used for experiments, while this is the first part which will be replaced in the renovation process. The basic cross section of the bridge is given in Figure 3.

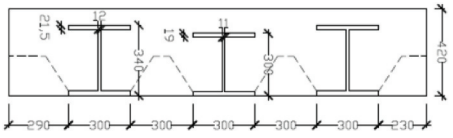

Figure 3. Basic cross section steel concrete bridge parts of the bridge deck.

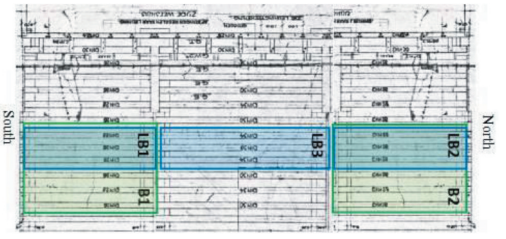

Figure 4. Top overview in-situ and lab experiment parts of the bridge deck.

Figure 3 shows 3 steel girders which are with the web and top flange full embedded in the concrete part of the bridge deck. The center to center dimension is 600 mm. Figure 3 shows also that there are 2 different steel profiles embedded, a so called DIN260 and a DIN280. The main span has a longer span, so the steel profiles are in this part a DIN300 and a DIN340. Concrete cores are taken from all 3 spans, which gives information about the concrete strength. Also some samples are taken out of the steel girders to get information about the steel quality and the steel strength and yield limit. There is shrinkage reinforcement embedded at the top of the concrete part, but this reinforcement part is neglected in Figure 3 and also in the Solid and Shell FE simulations. The abutments of the spans are given as a steel plate with a width of the bottom flange width of the steel profile and have a length of 700 mm on each side. The foundation isn't part of the experiments, it is a masonry structure on wooden piles. The restriction of the in-situ loadings is 475 kN to keep the foundation in the right condition after the experiments.

Figure 4 shows the parts of the bridge deck, which are used for the in-situ experiments (green area; B1 and B2) and the lab experiments(blue area; LB1, LB2 and LB3). The width of

the in-situ experiments counts 6 steel girders with the belonging concrete part, where the width of the lab experiments counts 3 steel girders with the belonging concrete part. As the in-situ experiments were scheduled first, the concrete of the 6 girder width part was sawn separately from the rest of the bridge deck, to get a simple supported slab environment. Only the side spans could be used for the in-situ experiments, while the transport over water in the inner city should be on going. When the in-situ experiments were finished the 3 girder width part was sawn again to make the transport of these part easier over water to the lab.

3 IN-SITU EXPERIMENTS

The in-situ experiments show a cyclic behaviour of a wheel print area load, which is located on the top of the concrete deck between the girder 3 and 4 of the 6 girder width of the side

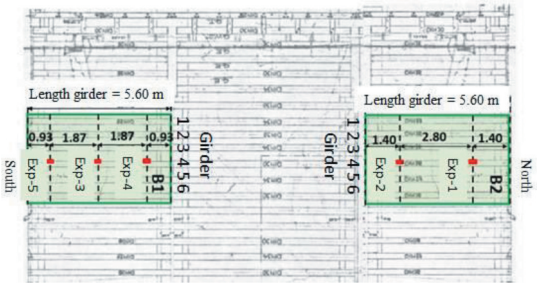

Figure 5. Wheel print load locations (red dots).

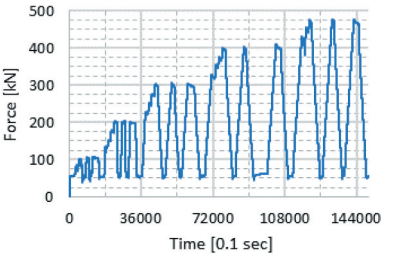

Figure 6. Cyclic loading scheme.

span. In total there were 5 locations of the wheel print, midspan, 1/4L, 3/4L, 1/6L and 5/6L. Figure 5 shows the locations of the side spans. The cyclic loading scheme is given in Figure 6.

An overview of the minimum of sensors is used at the in-situ experiments. Figure 7 shows the wheel print load sensor location in red, the strain sensors at the bottom girder flange in blue, the

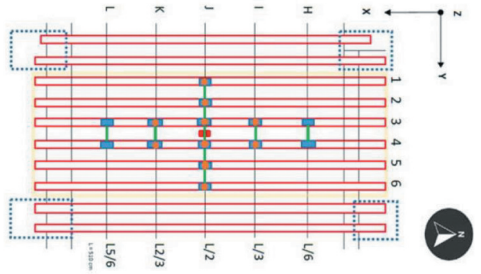

Figure 7. Sensor equipment bridge deck.

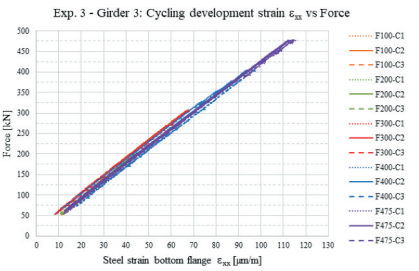

Figure 8. Strain ε $_{xx}$ cycle development.

displacement sensors of some bottom flange girders in orange and the sensors over the width to measure the displacement between the bottom flanges of the steel girders in green.

The strain εxx cycle development of girder 3 in Figure 8 shows a linear behaviour, which corresponds also with the inspections afterwards of this specific experiment, that there were no cracks seen at the bottom of the concrete bridge deck. Another important conclusion is coming from the distribution ratios of the wheel print midspan load over all 6 girders, which is given in Figure 9.

Figure 9 shows that girder 3 and 4 have almost the same distribution ratio related to the strain and the displacement in the same row with sensors at the midspan location of the wheel print load.

Further on, Figure 10 shows a possible hidden bending moment at the slab support lines. This result is neglected in the setup of the FE simulations, a simple supported span is simu-

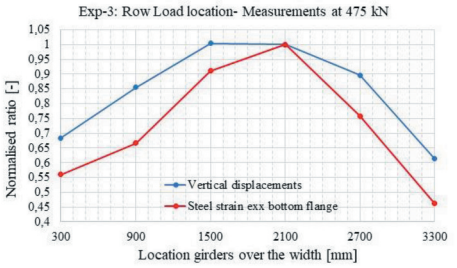

Figure 9. Distribution wheel print load.

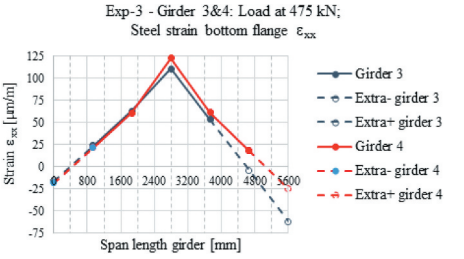

Figure 10. Hidden bending moment supports.

lated in FE. The last result of the in-situ experiments is coming from the sensors over the width of the 6 girder part. They measure a sudden jump at different load levels at different load cycles. This result is given in Figure 11.

Main result is of course, that a wheel print load capacity of 475 kN shows enough reliability related to the Eurocode, with a maximum wheel print load of 150 kN.

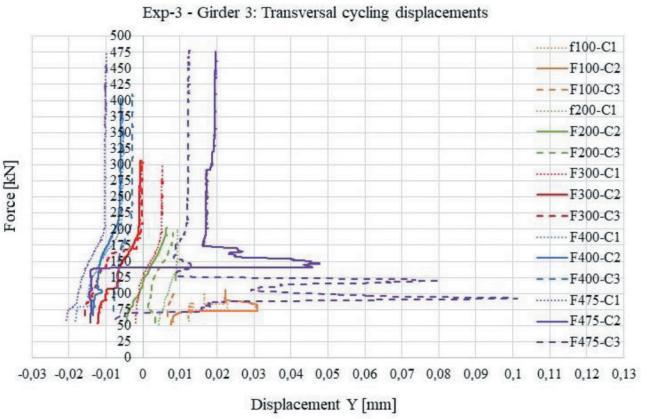

Figure 11. Transversal displacement girder 3.

Conclusion of this result given in Figure 11, shows that there is a reset of transversal displacements between the steel girder and the belonging concrete at low levels of the wheel print load at different cycles.

An interface behaviour between the steel girder and the belonging concrete should be included in the Solid FE simulations.

4 LAB EXPERIMENT WITH CYCLE LOADING

To get more information about the cycling behaviour, one of the side spans with a width of 3 steel girders with the belonging concrete gets also a cycling load scheme, but now in the laboratory, where more sensors can be installed. In total there were more than 100 sensors for

the displacements, strains, etc. The load is related to the tandem configuration of the Eurocode LM1, where both axles of the vehicle are simulated by a distributed beam over the width

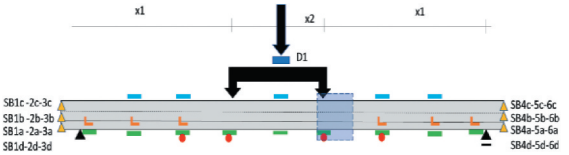

Figure 12. Side view of the lab experiment with sensor locations.

of the experiment. Also the Digital Image Correlation(DIC) method is partly installed at the concrete part underneath the location of one axle location. A side view with the sensors is given in Figure 12 and a top view with the s7ensors in Figure 12.

Figure 12 shows not only the strain sensors of the steel girders(green), vertical displacement sensors of the steel girders(red) or concrete deck(blue), but also the horizontal displacement sensors over the height of the experiment of the heads at every girder and belonging concrete.

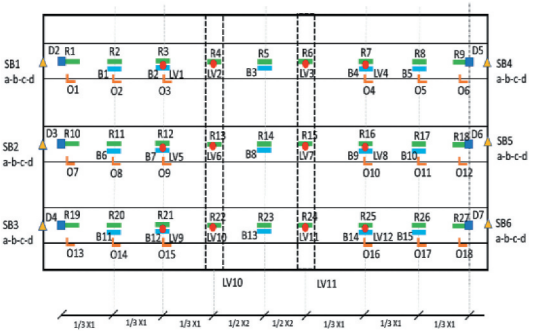

Figure 13. Top view of the lab experiment with all sensor locations.

The last mentioned sensors should measure the possible disconnecting behaviour between the steel girders and the belonging concrete. The light blue rectangle under the right load location shows the DIC area. Figure 13 shows an additional top overview of the sensor locations.

The load is attached in 2 stages, the first stage comes to a load level of 1400 kN and the second stage goes to the ULS load level. Every stage has some intermediate load levels with 3 cycles similar to the in-situ experiment. Also the breaks of the basic load level or the

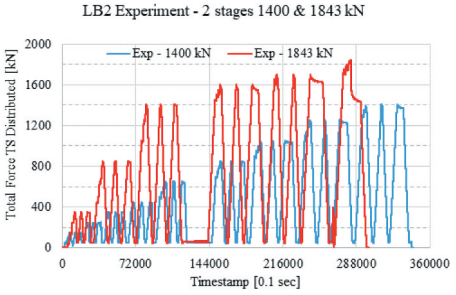

Figure 14. Loading scheme 2 stages LB2.

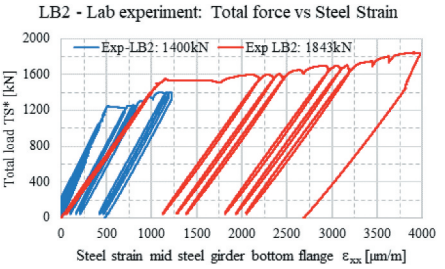

Figure 15. Strain ε_{xx} development 2 stages LB2.

intermediate load levels are similar in time duration. Figure 14 shows the load behaviour of the 2 stages, Figure 15 shows the strain of the bottom flange of the mid girder(DIN260) development of the 2 stages at the load location at the left axle.

Both stages in Figure 14 shows a break between 12.000 and 14.000 seconds, which is the lunch break in the laboratory. Also the overall duration of the experiments is very long and counts 8-10 hours. The strain development at the bottom flange beneath the left axle of the distributed load shows at the first stage a yielding behaviour at the load level of 1200 kN and at the second stage a yielding behaviour at the load level of 1500 kN. The reason is related to the hardening behaviour of the steel girder, which increases the ductility of the overall structure when overloading would be occur. The strain with a value of 500 micron at a load level of 1200 kN is in relation to the in-situ experiment much larger where the strain is 110 micron at a load level of 475 kN. Both diagrams have a linear development.

The load level of 1200 kN is 2 times the Eurocode vehicle LM1 with a load of 600 kN. Of course, there is also a Eurocode distributed vehicle load, but the span length is only 5.8 meter, so the overall distributed load counts for 160 kN, which is spread over 3 meter width or in this case at least 5 steel girders. The in-situ experiment shows already that one wheel print load will be carried by 2 steel girders, so there is sufficient bearing capacity in these type of historical bridge decks with already a technical lifetime of 80 years. Reason to follow up with ULS verifications with real wheel print load areas between the steel girders on the remaining spans. Restriction is of course the 3 girder wide spans, but still there is space to locate both wheel print locations between 2 steel girders.

5 VERIFICATION ULS EXPERIMENTS

Still there are a side span and a main span of the steel concrete bridge to verify the bearing capacity of the historical bridge decks. The assumptions from the cycle experiments are the following:

a) There is slip behaviour between the concrete part and the steel girder at a lower load level, so to be conservative the slip level is reached at a load level of 100 kN tandem axle configuration;
b) The installation of the bridge deck shows a stage with steel girders and green concrete, which implies that the steel girders are preloaded by the dead weight of steel and concrete. This means that the belonging stress by this dead weight load reached a level of 20 N/mm^2, which is ± 10% of the yield stress limit of the steel girders;

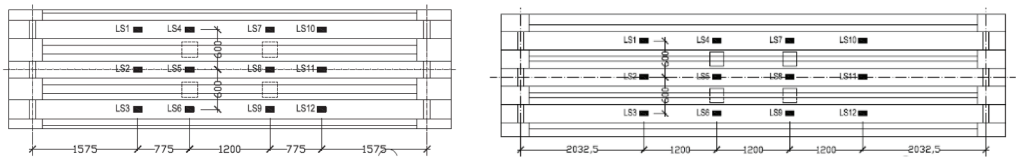

Figure 16. Topview load scheme wheel print load locations side span(left) and main span(right).

c) A restriction has to be made in case of the wheel print locations center to center distance, where the Eurocode shows a distance of 2 meter and the remaining 2 spans have a distance of 0.6 meter. This aspect shows a second conservatism. This top view of the load scheme wheel print load locations is given in Figure 16.

Both remaining spans show a similar equipment of sensors like the cycle LB2 experiment. Only the concrete decks show in this experiment no LVDT to measure the strain of the concrete but there are optic fibres installed. Also the DIC method is part of the measurements and located between a support and an axle location. The load scheme in time of both spans is shown in Figure 17 and 18. Again there is a short break around the 12.000 seconds. At that

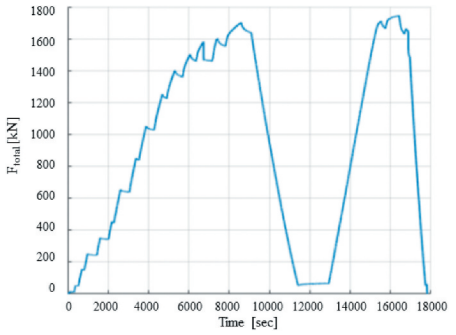

Figure 17. Load scheme side span.

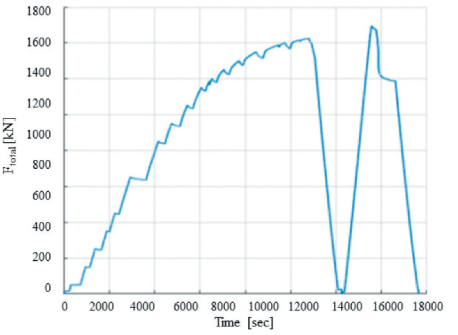

Figure 18. Load scheme main span.

moment the load was reduced to a small load level to make it possible to remove the DIC installation to avoid damage to these expensive installation.

The side span shows at the ULS load level slip behaviour between the steel girder and the concrete at one head of the experiment. Both experiments show a lot of crushing concrete at the top of the bridge deck between the axle locations. However, the ULS load level of the side span was 1744 kN and for the main span 1494 kN(1410 kN in a stable stage).

6 FINITE ELEMENT SIMULATIONS

All prediction and postdiction calculations of the experiments are based on Solid 3D element models. The basic steel girder and the belonging concrete shows the same element configuration in the cross-sectional area, which is given in Figure 19 as an extension of Figure 3, where the basic is given of a 3 girder cross section. In longitudinal direction the area between the

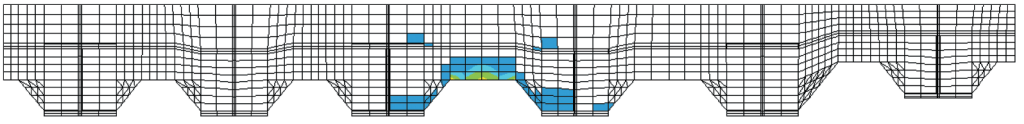

Figure 19. Cross sectional area of the 6 girder width in-situ experiment.

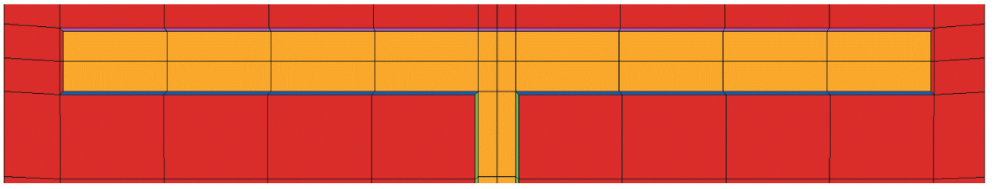

Figure 20. Interface surfaces between the steel girder and the belonging concrete.

loading lines is divided in element sizes of 100 mm. In transversal direction there are always 4 elements in the top and bottom flange of the steel girder, where the concrete between the steel girder shows maximum element sizes of 35 mm. All elements are quadratical elements. Between the steel girders surfaces and the belonging concrete surfaces with interface elements are modelled to simulate the slip behaviour. Figure 20 shows the interface surfaces, which have their own physical properties for the top and bottom of the top flange, the top of the bottom flange, the longitudinal side of the top flange and the web. The used FE program is the Dutch DIANA software [DIANAFEA 2021].

FE_{3D}	1828	1680	1330
$FE_{2.5D600}$	n/a	1410	1190
$FE_{2.5D300}$	n/a	1410	1190

The physical properties of the FE models are given in Table 1, and are related to the fib ModelCode2010[fib2012], the NLFEA Guideline of the Delft University of Technology[Hendriks2020]. Making it easier for practical engineering offices also a shell FE model based on beam grid theory is setup. Here the concrete is divided in cross beams with a width of 600 mm, based on the transversal cracks center to center distance of 600 mm of the lab tests. The FE simulations got the name $FEA_{2.5D600}$ and $FEA_{2.5D300}$. Here the center to center dimension is reduced till 300 mm. An extension of the guideline for the beam grid models is part of the re-examination process.

7 CONCLUSIONS

The following conclusions can be drawn:

a) The in-situ experiments show at least a bearing capacity distribution of the wheel print load over 2 neighboring steel girders;
b) The cycle lab experiment shows a decrease of the stiffness of the overall structure, which should be related to cracking of the concrete;

c) Bond(slip) behaviour between the steel and concrete part of the historical bridge decks is less relevant for the bearing capacity of the historical steel concrete bridge decks;
d) The linear behaviour of the steel strains till a load level of 1200 kN show a lot of confidence to allow heavy traffic with some restrictions in the inner city of Amsterdam;
e) All FE simulations, the Solid 3D model and the Shell 2.5D models, show a conservative ULS load level related to the experiments;
f) The Shell 2.5D FE simulations show also a conservative ULS load level related to the Solid 3D FE simulations, so if there is a need for a maximum bearing capacity, a 3D FE simulation is recommended;
g) The speed of the Shell 2.5D FE simulations is mostly 10 times faster than the speed of the Solid 3D FE simulations;
h) Re-examination work can be done easily, quicker & cheaper by Shell FE 2.5D simulations.

ACKNOWLEDGEMENT

The authors wish to express their gratitude and sincere appreciation to the Programme Bridges and Quay Walls of the Engineering Office of the Municipality of Amsterdam for their support of the project "Steel-Concrete Bridge Decks(Verbundträger)". Beside these thanks we like to thank also our other project team members and external partners, which were involved in the in-situ tests (TNO Research, MFPA Leipzig, Mammoet, Dekker, Bouwrisk) and the laboratory experiments (TNO Research, Delft University of Technology) for their contribution.

Practical experience with proof loading – examples from 3 bridges

J.H. Roldsgaard, J.K. Nørregaard, C. Pedersen & J. Vig
Monitoring & Analysis of Existing Structures, Transport, Ramboll DK A/S, Denmark

A. O'Connor
Trinity College Dublin, Dublin, Ireland

ABSTRACT: Practical examples of how proof loading of bridges is approached and applied by consultants with the goal of increasing the bearing capacity of existing bridges, are still limited. The present paper presents the proof loading of 3 bridge located on a route where a heavy special transport with a total weight of >500 tonnes and an axle weight of >20 tonnes. The main outcomes of the theoretical deterministic assessment before the proof loading were decided upon, determination of the proof load together with all the considerations in the planning phase including how the proof loading can be carried out will be presented. Especially the planning phase of the proof load is essential to mitigate all significant risks and ensure a successful project for both bridge owners, users and the project team. At the end some learnings from the proof loadings will be shared and the results presented.

1 INTRODUCTION

The proof loading of bridges is a crucial and highly relevant process in the field of structural engineering, serving as a comprehensive method to validate the safety and performance of a bridge structure(s). This procedure involves applying controlled and incremental loads to the bridge, often exceeding the design loads, to assess its response and behavior under extreme conditions. Proof loading provides valuable insights into the structural integrity, load-carrying capacity, and overall resilience of the bridge. By subjecting the bridge to loads beyond its expected operational conditions, potential weaknesses can be identified, effectiveness of structural components can be assessed, and it can be ensured that safety margins are appropriate. Proof loading can contribute to the optimization of bridge design/assessment and ensure that structures meet structural safety requirements. This paper presents the methodology for determination of appropriate proof loading levels for a number of bridges in Denmark. The bridges were intended to carry exceptional loads which were to be transported along their route. Traditional deterministic structural assessment failed to demonstrate adequate capacity, due in part to the absence of sufficient structural information, and as a result it was necessary to undertake proof loading to validate that the structures had sufficient structural safety to carry the loads. The paper first describes the specifics of the exceptional heavy loads to which the structures were to be subjected. This is followed by a description of the specific structures and their critical limit states for the considered loads. The process or determining, probabilistically the level of proof load to be applied, to provide for sufficient structural safety, relative to prescribed limits, is detailed along with discussion of important aspects such as the definition of stop criteria. Finally, the methodological process of carrying out the proof loading is detailed. Ultimately, the value of proof loading for validation of sufficient structural capacity it demonstrated.

DOI: 10.1201/9781003483755-48

1.1 *Heavy special transports*

The proof loading of the 3 bridges presented in the present paper has been initiated as it is wished to drive a heavy special transport from Brande to Hvide Sande (Denmark), which is from the middle of Jutland to the west coast as shown in Figure 1. The heavy special transport consists of a truck with 8 axles of 8t-10t each and a flatbed truck with >20 axles of >20t with a spacing of 1.5m and hydraulic equalization between the axles. This gives a total weight of well above 500t.

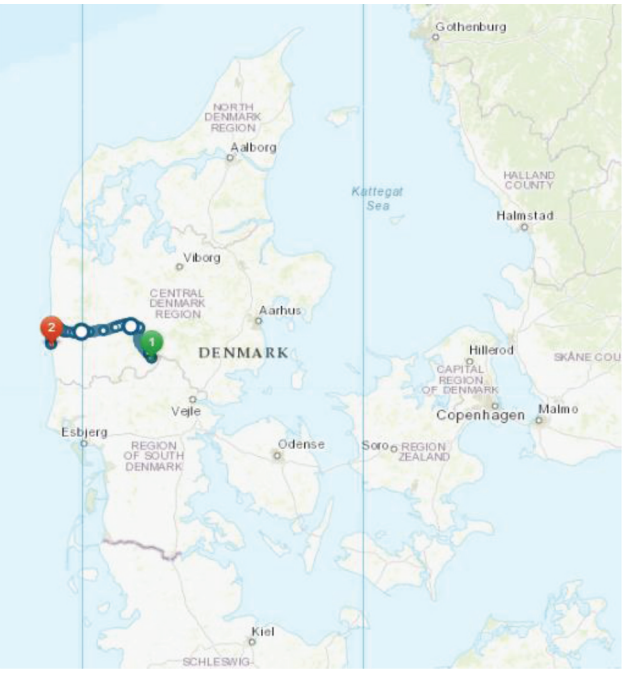

Figure 1. Route for the heavy special vehicle indicated on the map of Denmark.

2 BRIDGES SUBJECT FOR PROOF LOADING

Proof loading of the 3 bridges presented here all failed to prove adequate capacity of the sub-structure in the deterministic assessment (partial safety factor method) according to Danish Road Directorate (2017). However, for all 3 bridges the superstructures showed adequate capacity with the normal safety factor method, hence the proof loading could be tailored for the sub-structure.

For a bridge to be fit for proof loading a number of criteria should be fulfilled. The following is not a comprehensive list but some of the considerations carried out before it was decided to proof load the 3 bridges presented here.

2.1 *Rind Å - failure mechanism*

The bridge across Rind Å is a reinforced concrete beam/plate bridge with a grillage cross-section built in the 1930's. The bridge was widened in 1992 to the south with a separate pedestrian/bicycle bridge. The main span is approx. 10m and the bridge is about 9m wide carrying one lane of road traffic in each direction with a pedestrian/bicycle lane one side. Extracts of the original drawings of the bridge across Rind Å are shown in Figure 2.

All capacity checks in the ultimate limit state for the superstructure proved adequate capacity for the heavy transport to pass the bridge, however, the capacity check of the piles failed short of capacity. During the capacity assessment of the piles, it was assessed that the data

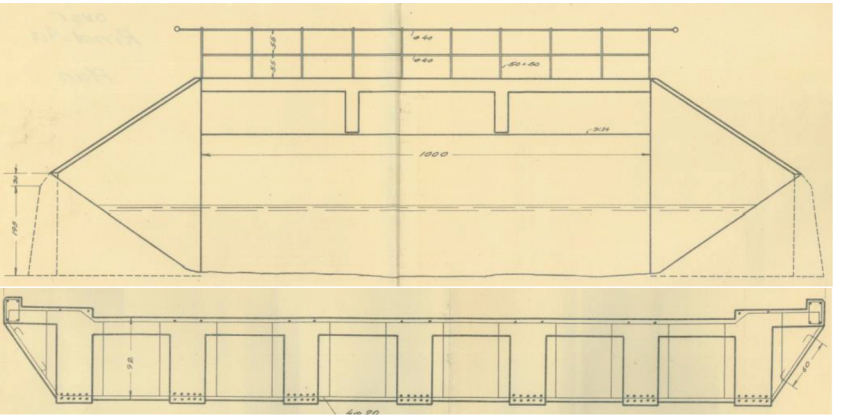

Figure 2. Original drawings of Rind Å showing the plan and cross-section.

processing of the soil samples was somehow conservative, furthermore, it was suspected that for this particular bridge the standard also was conservative. Hence, it was decided to carry out proof loading of the substructure if found possible.

An important consideration of the failure mechanism was performed before it was decided to perform proof loading of the bridge to prove the capacity of the bridge for the heavy special vehicle. From the analysis it was found that failure of one or more piles would lead to deformation/settlement of the walls supporting the bridge deck, hence a very slow a ductile failure mode, and not a sudden brittle failure.

2.2 *Vorgod Å - failure mechanism*

The bridge across Vorgod Å is a reinforced concrete 3-span beam/plate bridge with a cross-section consisting of 7 T-beams, the bridge is built in the 1950's. The main span is approx. 8m and the two side spans are approx. 7.3m with a width of about 9m wide carrying one lane of road traffic in each direction. Extracts of the original drawings of the bridge across Vorgod Å are shown in Figure 3. One thing to notice is that a mistake on the original drawing was found, it only showed 6 T-beams, but from the inspections 7 T-beams were found. A special inspection of the bridge confirmed the rest of the information from the drawings.

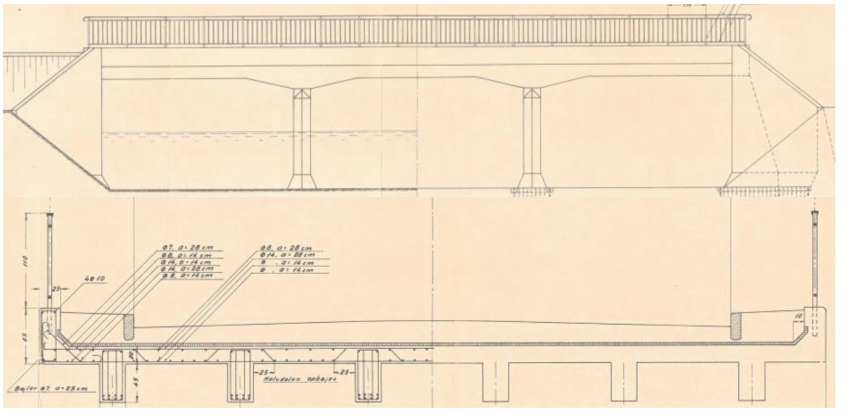

Figure 3. Original drawings of Vorgod Å showing the plan and cross-section.

All capacity checks in the ultimate limit state for the superstructure proved adequate capacity for the heavy transport to pass the bridge, however, the capacity check of the piles was

rather difficult as none of the original drawing or documentation stated the pile lengths. This bridge over Vorgod Å was key for the transport of the heavy special vehicle as it is a spanning over multiple supports and the total length is above 20m, making it very laborious and expensive to temporary replace or strengthen for the vehicle to pass and maybe even impossible without total replacement. Hence, it was decided to carry out proof loading of the substructure if found possible.

An important consideration of the failure mechanism was performed before it was decided to perform proof loading of the bridge to prove the capacity of the bridge for the heavy special vehicle. From the analysis it was found that failure of one or more piles would lead to deformation/settlement of the walls supporting the bridge deck, hence a very slow a ductile failure mode, and not a sudden brittle failure.

2.3 *Skjern Å - failure mechanism*

The bridge across Skjern Å is a reinforced concrete beam/plate bridge with a cross-section consisting of 8 T-beams, the bridge is built between 1945 and 1954, but the precise year is unknown. The main span is approx. 8m and with a width of about 9m wide carrying one lane of road traffic in each direction. Extracts of a sketch of the bridge from a military measurement in Figure 4, however, these should only serve as indicative as they often are found inaccurate for use in a detailed capacity assessment.

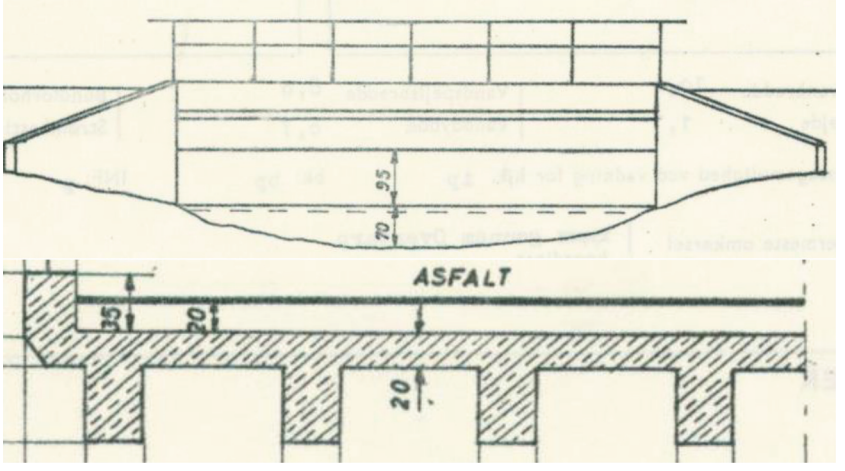

Figure 4. Sketch of Skjern Å shown plan and cross-sectional shape.

As no drawings or documentation material existed a special inspection was performed, where the geometry of the bridge deck was established together with the layout of the reinforcement by scrapping the concrete covering layer away such that the reinforcement was exposed for visual inspection and measurements. Regarding the quality such as concrete strength and yield strength of the reinforcement the typical building material for this period was assumed. The year of construction was established by archive photos and found to be between 1945-1954. Assumptions around the materials were taken conservatively, however, it was possible to show adequate capacity of the superstructure for the heavy special vehicle to pass the bridge.

About 50m away an almost similar (type, span and materials) bridge is placed, however, not longer in service as the road layout was changed during the period 1945-1954, where the bridge in question was built. The neighboring bridge was built in the 1930's and the original drawings of this bridge are available. From the drawings this bridge is direct founded, hence, as the soil test samples showed that the soil conditions for the two neighboring bridges are very similar it was assumed that the bridge in question also is built with direct foundations. However, as the assumptions around the substructure are made with high uncertainty it was

decided to proof load this bridge to show that the capacity of the substructure was adequate for the heavy special vehicle to pass.

It was assessed that the failure mechanism of the direct foundation is ductile until about a deformation of approx. 10mm, for which sudden brittle failure could happen. Hence, the loading scheme for the proof loading was made extra carefully and the stop criteria allowing only very small deformations to ensure that a sudden brittle failure would not occur.

3 PREPARATION

The level of the proof load for which the bridges should be tested is determined in accordance with Christensen et al (2023) and the next version of the guideline for reliability-based classification of existing bridges, Danish Road Directorate (2024).

The heavy special vehicle will pass the bridges with a speed equal to or lower than 10 km/h at the most favourable position on the bridge without any other traffic, hence, in accordance with Danish Road Directorate, 2017 and DS/EN 1991-2 (2003) including Danish national annex this is classified as conditional passage type 3, which means that it is assumed there is no dynamic amplification.

3.1 *Probabilistic estimation of the proof loading load*

For the 3 bridges it is the substructure and especially the uncertainty about the construction of the substructure which is uncertain. Hence, in the estimation of the proof load all the safety is put on the variable load side which essentially means that the bridges should be proof load with a load having the probability of occurrence as the safety level requires. The required safety level for existing bridge with a ductile failure mode is given in Danish Road Directorate (2017) and Danish Road Directorate (2024) as:

$$p_f = 10^{-6}$$

where p_f is the probability of failure

To determine the level of the proof load for the 3 bridges the distribution for the annual extreme vehicle weight is established according to Danish Road Directorate (2024):

$$F_p = \exp(-N_i(1 - F_W(x))$$

where N_i is the number of yearly heavy special transports and $F_W(x)$ is the distribution of the weight of the heavy vehicle.

The number of annual heavy special vehicles is conservatively assumed to 10, where the client has informed Ramboll it is less than half of this. As for the distribution of the weight of the heavy vehicle only the number of axles actually affecting the failure mode is included which for the bridges presented here is between 3-4. On this basis the uncertainty is interpolated from [guideline] and found in the order of 7-8% depending on the number of axles, where the uncertainty of the total weight of the axles decreases with increasing number of axles. The proof load factors found for the 3 bridges are shown in Table 1.

Table 1. Proof load factors and total proof load.

Bridge	Proof load factor [-]	Proof load [tons]
Rind Å	1.33	139.8
Vorgod Å	1.34	108.4
Skjern Å	1.34	108.4

3.2 *Safety of the superstructure for the proof loading load*

The capacity assessment of the superstructure is as the first step checked against the following load combination:

$$E_d = K_{FI} \cdot \left(\sum (\gamma_{Gi} \cdot G_i) + \gamma_q \cdot Q_k \right)$$

where E_d is the design load effect, $K_{FI} = 1.1$ and related to the consequence class, which for all bridges in Denmark above 6m is CC3. $\gamma_{Gi} = 1.0$ is the partial safety factor for the self-weight and the superimposed deadload and G_i is the actual load effect from self-weight or superimposed deadload. $\gamma_q = 1.20$ is the partial safety factor for the heavy special vehicle, this is to be used when the actual axle configuration and weight is known before the transport and Q_k is the load effect from the heavy special vehicle. The above load combination is to verify that the superstructure has the required safety during the actual transport according to the Eurocode with Danish national annexes [ref].

The superstructure does not only need to show adequate capacity during the actual transport with the heavy special vehicle but also during the proof loading, where more load is applied to the bridge than for the actual situation as a result of "putting" all the safety on the load side in the determination of the proof load level as described in Section 3.1. Hence, the capacity of the superstructure is shown adequate for the following load combination:

$$E_d = K_{FI} \cdot \left(\sum (\gamma_{Gi} \cdot G_i) + \gamma_{q_W} \cdot Q_{k_W} \cdot \gamma_{PF} \right)$$

where $\gamma_{q_W} = 1.15$ as the weight of the proof load vehicle is known exactly (weighed), Q_{k_W} is the load effect from the proof loading load, and γ_{PF} is the proof load factor found in Section 4.1.

3.3 *Stop criteria*

The stop criteria for the proof loading were carefully selected to ensure no failure of the bridges. In general deformation above 5mm of the supporting wall was highly undesirable, however, not a hard criterion. Whereas continuously deformation for the same load was a very hard stop criterion and if this particular situation would arise the proof loading would have been called off. The superstructures were also monitored during the proof loading even though their capacity had been shown adequate with the partial safety factor method as described in Section 3.2.

An example of the intended measuring points for Vorgod Å is shown in Figure 5.

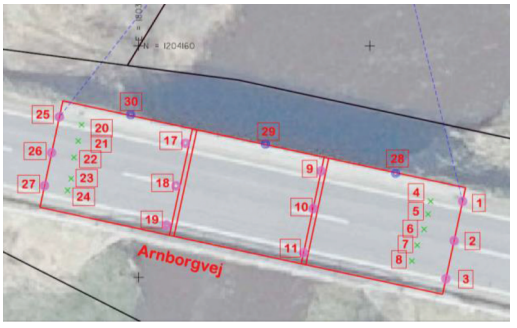

Figure 5. Example of intended measuring points for Vorgod Å.

4 EXAMPLES

For all 3 bridges more than one critical location is tested, meaning all supporting walls were subject to proof loading as well as behind the bridges for Skjern Å and Rind Å. This is to ensure that eventual difference in the foundation conditions or soil conditions critical for the capacity of the bridge is uncovered by the proof loading.

4.1 *Load stepping*

The paradigm for the load stepping was the same used for all 3 bridges. The stepwise procedure is listed below:

1) Reference measurement of the bridge without load by the surveyor. The surveyor measured approx. 10 points for the two smaller bridges and approx. 25 points for the 3-span bridge with a precision of about ±0.2mm.
2) The front end of the truck with 3x10t axles is positioned at the bridge at the marked locations on the asphalt.
3) The surveyor measures potential deformations of the bridge. This is performed again after 5 min to ensure eventual deformations do not continue.
4) The flatbed truck with 16.5t axles per 1.5m is positioned at the bridge.
5) Step 3) is repeated.
6) The load on the axles is increased by 2t.
7) Step 5) – 6) is repeated until the proof loading load is reached.
8) The bridge is onloaded and step 3) repeated before moving on to the next location.

4.2 *Rind Å*

Proof loading of Rind Å was carried out in December 2023 was a success and the capacity of both the super- and substructure of the bridge is assessed to be adequate for passing of the heavy special vehicle maintaining the required safety level. The maximum deformation for the supporting walls was approx. 2mm and 1mm for the superstructure, which both were well within the acceptable limits.

Figure 6. Photos from the proof loading of Rind Å.

Figure 7. Photos from the proof loading of Rind Å of the flatbed truck.

Figure 6 shows the flatbed truck on the bridge with the surveyor measuring the potential deformations of the bridge. Figure 7 is showing the configuration of the flatbed truck with the extra heavy steel on top to create the desired proof load and the marking of the asphalt to ensure the truck is located as assumed in the theoretical analysis.

4.3 *Vorgod Å*

The proof load of Vorgod Å was a success and the capacity of both the super- and substructure of the bridge is assessed to be adequate for passing of the heavy special vehicle maintaining the required safety level. The maximum measured deformation during loading was 2.5mm, however, the deformation after unloading was maximum 0.7mm. As the concern is permanent deformations of the substructure the type of loading during proof loading is more conservative than for the heavy special transport passing the bridge, as the proof loading lasted much longer time than it will take the heavy special transport to pass the bridge.

Figure 8. Photos during proof loading of Vorgod Å.

Figure 8 to the left shows the flatbed truck on the bridge and to the right some of the measuring points are shown with the surveyor measuring the potential deformations of the bridge. Figure 8 is showing the configuration of the flatbed truck with the extra heavy steel on top to create the desired proof load and the marking of the asphalt to ensure the truck is located as assumed in the theoretical analysis.

4.4 *Skjern Å*

The proof loading of Skjern Å was a success and the capacity of both the super- and substructure of the bridge is assessed to be adequate for passing of the heavy special vehicle maintaining the required safety level. The maximum deformation for the supporting walls was approx. 2mm and 1mm for the superstructure, which both were well within the acceptable limits. Photos from the actual proof loading of Skjern Å are shown in Figure 9. On the photo to the right, it can be seen from the compression of the tires, that the axles deliver different load to the bridge – from the left to the right it is approx. 5 – 40 – 25 – 25 tonnes. This is possible due to the hydraulic system of the flatbed truck and enables much freedom in the design of the proof loading.

5 CONCLUSIONS

This paper presented 3 practical examples of proof loading of 3 reinforced concrete bridges built between 1930-1955. The bridges all showed adequate capacity of the superstructure, but all suffered with too low capacity of the substructure or too high uncertainty of the actual foundation. Before the proof loading of the bridges was carried out careful considerations about the failure

Figure 9. Photos from the proof loading of Skjern Å.

mechanism, loading scheme, stop criteria etc. had been performed. Such that it was ensure that any potential failure would be a ductile failure with warning, allowing for decisions gates on whether to continue to the next load step or to stop.

The proof loading of all 3 bridges was a success and the capacity of both the super- and substructure of the bridge is now assessed to be adequate for passing of the heavy special vehicle maintaining the required safety level.

ABSTRACT: This study assesses the effectiveness of integrating infrared thermography (IR) and ultrasound (UT) technologies for the non-destructive testing of concrete bridges, addressing the critical need for advanced assessment methods amidst the deteriorating state of U.S. infrastructure. By combining the rapid, surface-level scanning capabilities of IR with the precise, in-depth analysis offered by UT, our research demonstrates a comprehensive approach to identifying subsurface anomalies such as delaminations, voids, and corrosion of reinforcement. The findings underscore the complementary strengths of IR and UT, highlighting their potential to significantly enhance the accuracy of infrastructure evaluations, optimize maintenance strategies, and ensure public safety. This integrated methodology proposes a balanced, efficient inspection process, advocating for further development in data collection, processing, and analysis techniques to improve the longevity and reliability of critical public works.

1 INTRODUCTION

The United States' civil infrastructure, which is fundamental to its economic success and the quality of life of its citizens, is facing severe challenges due to aging and wear. This infrastructure includes vital structures such as bridges, roads, dams, water treatment systems, and public transportation networks. These elements are essential for society's daily functioning but deteriorate over time. However, these systems are in poor condition and need urgent investment and innovation. The country's infrastructure received a dismal rating of C- from the American Society of Civil Engineers (ASCE) in their 2021 Report Card (ASCE 2021). Given that many of these structures are over 50 years old and continue to function beyond their intended lifespan, their critical state is reflected in their grade. Their deterioration puts public safety in danger and costs the country billions of dollars in missed growth and productivity. We are in a race against time because, in the absence of prompt intervention, the state of these systems is only predicted to worsen. According to ASCE projections, the country will need to invest $2.59 trillion by 2029 to close the infrastructure gap and maintain a good level of service.

Non-Destructive Testing (NDT) and Non-Destructive Evaluation (NDE) are becoming indispensable methods for addressing infrastructure deterioration. Without inflicting any harm to infrastructure elements like roads and bridges, these approaches allow for the detection of inherent flaws or vulnerabilities in them. They act as a preventative measure by

DOI: 10.1201/9781003483755-49

enabling the early identification of problems and expediting prompt repairs. But even with their drawbacks, industry standards for concrete testing continue to rely heavily on traditional techniques like visual examination and sounds. A metal rod or hammer is used to tap the concrete surface, and the sound that is created is listened to. Examining the concrete surface visually entails searching for fractures, spalling, or other indications of damage. Although easy to use, affordable, and straightforward, these methods have a number of disadvantages. They are subjective, unreliable, and only detect surface defects. They cannot reveal the internal condition of the concrete, which corrosion, delamination, voids, or other hidden flaws may compromise (Hiasa, Birgul, and Catbas 2017). Therefore, there is a need for more advanced and objective techniques that can provide a comprehensive assessment of the concrete's integrity. Infrared thermography (IR) and ultrasound (UT) can detect subsurface defects and provide quantitative data for analysis. Implementing IR and UT in maintenance routines can significantly reduce repair costs and enhance public safety. Such practices are instrumental in guiding investments and ensuring essential public works' structural integrity and longevity. With the strategic use of IR and UT, the nation can effectively manage its infrastructure assets, sustain its operation, and ensure it meets safety standards for the long term.

Infrared Thermography (IR) is a non-destructive testing method that uses thermal imaging to detect subsurface anomalies in concrete structures (Watase et al. 2015). It measures the infrared radiation emitted from the surface and converts these measurements into temperature values using the Stefan-Boltzmann law (Starnes, Carino, and Kausel 2003), which states that the radiant flux W emitted per unit area is proportional to the fourth power of the absolute temperature T of the target, modulated by the emissivity ϵ and the Stefan-Boltzmann constant σ. Mathematically, this relationship is expressed as

$$\mathrm{W} = \sigma \times \in \times \mathrm{T}^4 \tag{1}$$

In this formula, σ is the Stefan-Boltzmann constant (5.67×10-8 W/m2/K4), and W is the radiant flux emitted per unit area in watts per square meter (W/m2), ϵ denotes the unitless emissivity value of the concrete, and T stands for the absolute temperature of the target in kelvins (K). These parameters allow IR devices to generate a temperature map revealing dis-parities due to defects like cracks, voids, or delamination. Although environmental factors may influence the precision of IR, it remains an effective first step in assessing the structural integrity of concrete by identifying potential areas that warrant further, more detailed investigation.

Ultrasound, an advanced NDT (Non-Destructive Testing) technique, uses high-frequency sound waves ranging from 16 kHz to 500 MHz (Pham et al. 2009) that are inaudible to the human ear to probe beneath the surface of materials. This technology is deeply rooted in the early experiments of Lazzaro Spallanzani in 1794, who first utilized these waves to understand how bats navigate in darkness. Over the centuries, ultrasound has evolved significantly and is now indispensable in various industries, including medicine, which aids in diagnostics and engineering and ensures structural integrity. The underlying science of ultrasound in NDT is encapsulated in two fundamental equations, "Wave propagation" and "Acoustic impedance." These equations are paramount for detecting internal anomalies guiding the precise calibration and application of ultrasound equipment:

$$\mathrm{V} = \mathrm{f} \times \lambda \tag{2}$$

$$\mathrm{Z} = \rho \times \mathrm{v} \tag{3}$$

where, v = wave velocity; ρ = material density; λ = wavelength; f = frequency; Z= acoustic impedance

Mastery of these equations allows for identifying minute defects essential for maintaining the safety and functionality of critical infrastructure and medical diagnostics. Effectively using the "Wave propagation" equation (1) is crucial for selecting the appropriate frequency and transducer for the examined material. On the other hand, the "Acoustic impedance" equation

(2) is vital for evaluating the material's properties, such as density and elasticity, which affect how ultrasound waves are transmitted and reflected. This information is critical in determining the location, size, and nature of any defects present within the material. The precision with which these principles are applied directly impacts the reliability and accuracy of ultrasound inspection, making them a cornerstone of NDT practices. Through the diligent application of these scientific principles, ultrasound remains a cornerstone of non-destructive testing, enabling the discovery of defects that are not otherwise visible and ensuring the longevity and safety of various structures and systems critical to modern life.

2 METHODOLOGY

2.1 *Infrared inspection*

Two systems by ("NEXCO-West USA, Inc." n.d.) were employed for the infrared inspection: the Deck Top Scanning System (DTSS) and the Universal Surface Scanning System (U3S). The DTSS, a vehicle-mounted system including an infrared thermography camera and two line-scanning cameras, rapidly scanned the deck-top surface, Figure 1. The IR camera captures a 15-foot swath, while the line-scanning cameras cover a 13-foot swath, totaling 18 feet with overlapping areas for image stitching. The DTSS's high-speed capability (up to 70 mph) allows for quick scanning without traffic disruptions. The U3S system, adaptable for use on various platforms, scanned the bridge's underneath, girders, and bents, focusing on predefined critical areas to maximize coverage within the project's limited timeframe. Both systems operated best during temperature transitions, highlighting subsurface defects due to their distinct thermal signatures compared to sound material. Visual data, complementing IR, were collected in clear weather to identify visible deficiencies like

Figure 1. The Deck Top Scanning System (DTSS).

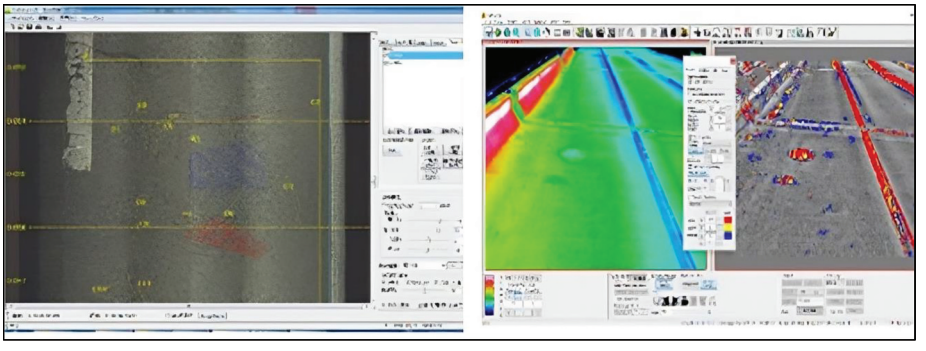

Figure 2. Software JeEditor (left) and software Ir-BAS (right).

cracks and spalls. For analysis, software such as IrBAS, JeEditor, and Kuraves integrated sensor data to create a comprehensive map of the bridge's condition (Figure 2).

2.2 *Ultrasound inspection*

Upon identifying critical spots with IR, an in-depth evaluation was conducted using Ultrasonic Testing (UT). Figure 3 shows the MIRA 1040A 3D, an ultrasonic pulse-echo tomograph, was utilized for its advanced A-DPC® sensor technology, enabling high-resolution 3D FMC/TFM imaging. This portable device can connect to a tablet wirelessly and has 32 active dry point contact transducers. The system works within a material sound velocity range from 1,000 to 4,000 m/s and is operable across a broad temperature spectrum.

Figure 3. UT setup overview.

The UT process involved scanning the areas marked by IR, using the MIRA system to generate B, C, and D scans for a detailed analysis of the concrete's internal structure. This allowed for the precise localization and characterization of flaws, as depicted in Figure 4, informed by raw and SAFT-processed data, significantly improving resolution by synthesizing signals from multiple transducers. The illustrated UT signals and their interaction with the concrete slab demonstrate the method's effectiveness. The UT's capability to focus on all directions simultaneously via SAFT provides an in-depth understanding of the defect's nature and severity, which is crucial for the structural assessment and subsequent maintenance planning.

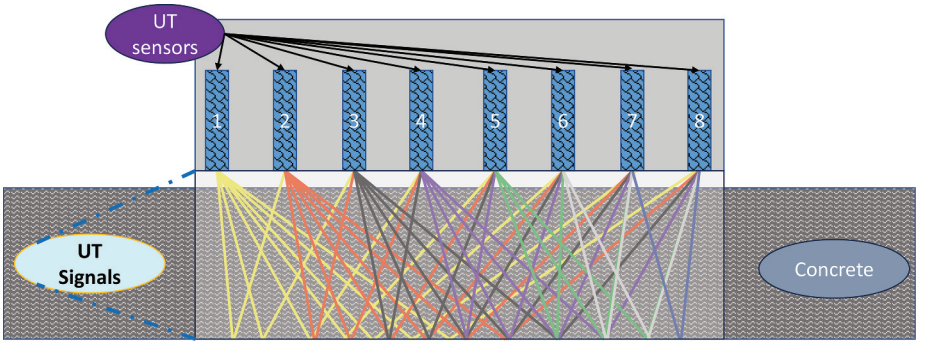

Figure 4. The work sequence of the 32 transducers.

3 RESULTS

3.1 *Bridge deck*

In Figure 5A, the green dots on the IR data for bridge deck spans 1-10 suggests potential subsurface anomalies in the concrete, identified by irregular thermal patterns, which could signify a range of structural concerns from delamination to possible voids or corrosion of reinforcement. The precise thermal signatures captured in this phase of rapid scanning are critical as they guide the subsequent in-depth analysis, highlighting areas that warrant closer inspection to ensure the bridge's safety and longevity.

Following the IR survey, targeted Ultrasonic Testing (UT) detailed scanning was performed on some areas of interest. Figures 5D and 5E show that the results correspond to spans #04 and #10, where the initial IR screening indicated potential anomalies. These UT scans give more detailed findings to the IR scans, offering a deeper look into the integrity of the concrete. The ultrasound data provides a comprehensive image of the internal features of Span #04, describing the depth, shape, and orientation of the detected irregularities. A cut of the 3D image is shown in Figure 5D. Similarly, Figure 5E showcases the ultrasound data for Span #10, providing crucial information about the size and severity of the anomalies within.

The information collected from the UT scans is valuable. It confirms the presence of anomalies and characterizes them, revealing the details of their dimensions and thus allowing for an accurate assessment of the bridge deck's condition. Moreover, these findings enable engineers to prioritize areas for repair to the sections where the structural integrity is most compromised. Therefore, the multi-dimensional insights gained from the UT scans complement the initial IR data and enhance the understanding of the bridge deck's health, laying a solid foundation for any necessary retrofit work to ensure the structure's resilience and reliability.

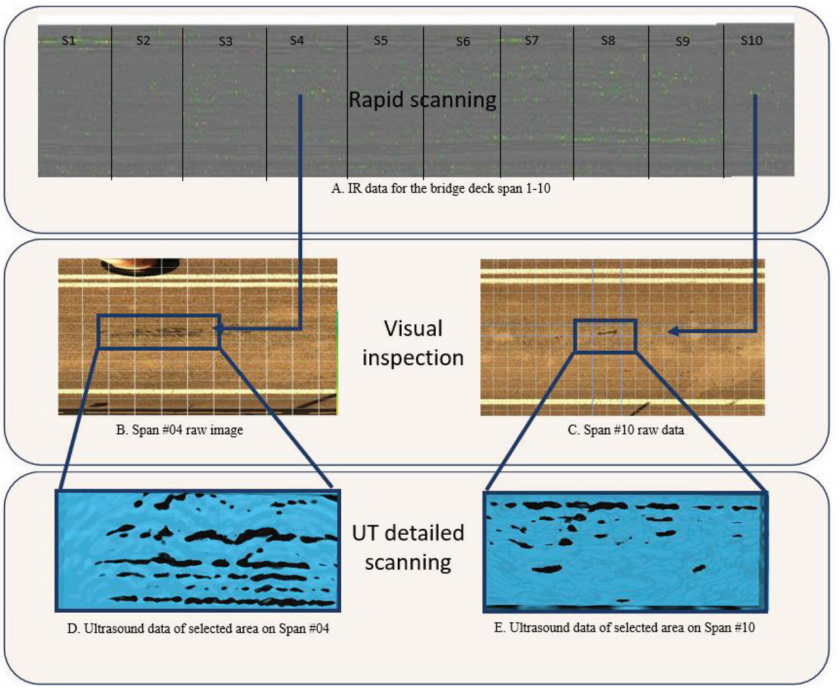

Figure 5. Bridge deck results.

3.2 *Beam*

In Figure 6a, a detailed description of the structural scan conducted on beam #1 span #1 of a bridge, employing both Infrared (IR) and Ultrasonic Testing (UT) to examine the integrity of the concrete and its internal reinforcements. The IR imagery, specifically the data from NEXCO in (A), visually captures the thermal footprint of the internal steel rebar, distinguishing it from the surrounding concrete material. The variations in green on a predominantly grey background correspond to the rebar, offering insight into its layout and condition. Such imaging is essential to ensure that the rebar is correctly positioned and intact, as any inconsistencies could impact the bridge's structural integrity. The processed IR data in (C) enhances the visual distinction of these areas, providing a more detailed and high-contrast view that makes the rebar's presence more detectable. This processing aids in detecting potential issues with coverage or anomalies in the rebar itself, which might not be apparent in standard visual inspections.

On the other side of the analysis, the UT scans in Figures 6B, 6D, and 6E offer a complementary and more in-depth look into the concrete's subsurface. UT technology utilizes high-frequency sound waves to penetrate the material and reflect information about the internal state of the concrete. The scan results, represented by vibrant blue visuals, reveal the acoustic profile of the beam's interior. Brighter areas within the blue gradient indicate differences in material density, which often signify flaws such as delamination, where the concrete may have begun to separate from the reinforcement. This separation is a critical concern for structural engineers as it can significantly reduce the load-bearing capacity of the beam. The longitudinal views provided in the UT setup overview in Figures 6D and 6E map out these potential delamination zones along the beam's span. The scans can detect subtle changes in the internal structure, such as cracks, voids, or other anomalies that could compromise the bridge's integrity. Understanding the extent and location of such defects is crucial for any structural evaluation and subsequent intervention, as it allows for a targeted approach to address these concerns, aiming to restore the beam to its optimal condition and ensure the long-term durability and safety of the bridge.

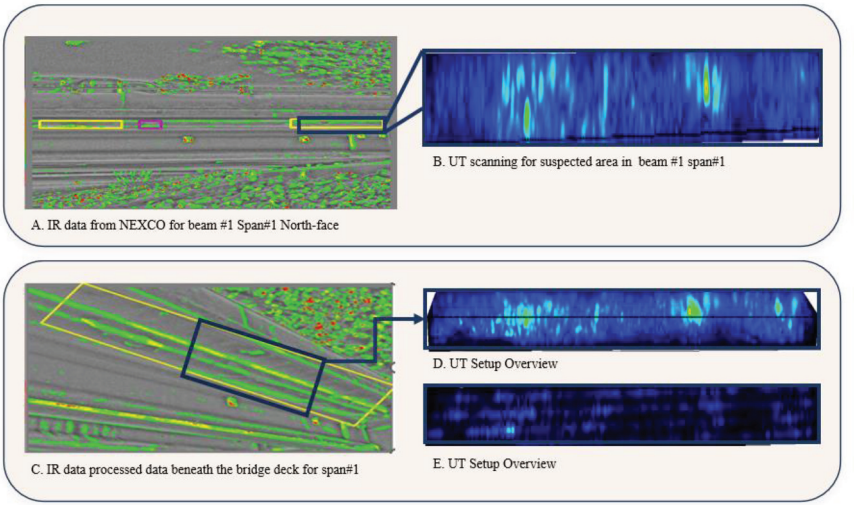

Figure 6. Beam results.

4 CONCLUSION

The inspection of the bridge deck and beam #1 span #1, as illustrated in Figures 5 and 6, highlights the process of structural assessment under the presence of complicating factors such as asphalt overlays. Figure 5A shows that asphalt overlays may prevent accurate scans of the underneath beam's condition, potentially obscuring the true state of the concrete beneath.

The IR imagery thus predominately reflects the deterioration of the asphalt, requiring additional scanning methods like Ultrasonic Testing (UT) to obtain a clear picture of the concrete's deck health.

For a more accurate understanding, targeted UT detailed scanning was employed, as represented in Figure 5D, 5E, on areas initially identified by IR as potentially deteriorated. This UT analysis provides an essential view past the asphalt, bringing to light the internal composition and anomalies within the concrete. Specifically, the UT imaging in Figure 5D delivers an in-depth look at the internal state of Span #04, while Figure 5E in Span #10, explains the extent of the detected irregularities.

Addressing the previous oversight, Figure 6 focuses on the beam itself, particularly span #1. The visual inspection and detailed UT scanning for span #1, shown in Figure 6, comprehensively evaluate the beam's subsurface condition. The UT data in Figure 6D provides a definitive acoustic profile of the interior, detecting issues such as delamination or voids that the IR method could not discern through the asphalt layer. These findings from the UT scans are pivotal for identifying precise areas of concern within the beam, areas where the structural integrity could be compromised, thereby guiding targeted and efficient rehabilitation efforts.

Although UT scanning provides detailed information about the structural element, it requires more time and effort to conduct these scans. On the other hand, IR is a rapid method to scan a structure to get the condition status of the structure. Hence, optimizing the usage of both systems is crucial to gather enough information about the structure's condition while saving time and labor efforts.

ACKNOWLEDGMENT

The author extends sincere gratitude to NEXCO for their invaluable contributions to the data collection process pertinent to this information retrieval research. Their support and collaboration have been instrumental in advancing this study.

Determining load distribution in a riveted railway bridge through controlled field testing

B. Imam, S. Biswal & M.K. Chryssanthopoulos
School of Sustainability, Civil and Environmental Engineering, University of Surrey, UK

P. Wildbore
Network Rail, The Quadrant, Elder Gate, Milton Keynes, UK

ABSTRACT: This paper summarizes results obtained from the field testing of an open deck plate-girder riveted metallic bridge removed from service in the UK and load-tested under controlled conditions. A purpose-built loading frame was constructed around the bridge for the application of the loading, which was applied in a form that represents typical passenger train axle loading; this included single and pairs of 10-ton axle loads. Testing was carried out under different axle load positions on the bridge with and without the timber deck to quantify load distribution effects on the bridge components. The response was measured via approximately 40 displacement transducers and 30 strain gauges. It was concluded that the presence of timber beams is significant both in terms of the maximum strains reached under a typical train axle load, as well as in terms of the load experienced by adjacent elements when the axle is directly over a specific cross-girder. Moreover, the effect of irregularities in the solid timber beams, e.g. in the form of unintended camber, can play a significant role in the recorded response. Minor geometric asymmetries, e.g. the location of transverse offset stiffeners on the two main girders, can introduce noticeable effects on the U-frame action, whose quantification is an important factor in bridge assessment guidelines. These observations will be utilized in updating adjustment factors for simplified fatigue assessments based on stress ranges estimated from idealized train passages over the bridge.

1 INTRODUCTION

Many metallic railway bridges in the UK (and in other countries) are characterised by an open deck construction form, with the main girders restrained laterally through a secondary system comprising cross girders (sometimes also including stringer beams running in the main girder direction). These elements are inter-connected through riveted connections (in the older bridge stock, mid-19th to mid-20th century) or welded connections (for more recently constructed bridges). The response of these bridges to live loading is dependent on the behaviour of the connections, i.e., cross-to-main girder and stringer-to-cross-girder connections, both in terms of the fatigue performance of individual members/connections as well as the overall U-frame action developed on such bridge forms. The connections are typically built-up using plates, angles and rivets with parts of them being hidden and therefore difficult to access in an inspection. Although the response of such bridges has been studied through numerical modelling (Al-Emrani & Kliger, 2003; Imam & Righiniotis, 2010) and static/fatigue component testing (Al-Emrani, 2005; Bertolesi et al., 2021), there is little information from field measurements on actual bridges, especially under controlled conditions.

The value of bridge load testing has been recognized for many years, as evidenced by early work (Bakht & Jaeger, 1990), where emphasis was placed on the shortcomings of then

DOI: 10.1201/9781003483755-50

available mathematical models; as well as the recent state-of-the-practice review (Alampalli et al., 2021) which focused on newly developed protocols and interpretation of results for various types of load testing (diagnostic, proof) undertaken for different purposes (current rating/reliability, remaining service life). Within published literature, of note to this study are investigations on testing of historical bridges, such as the wrought-iron riveted bowstring arch truss in Virginia, USA (Moen et al., 2013) and the bolted "Model 1936" Swiss military bridge (Fleming, 2022). In the former, tests were aimed at establishing the lateral stiffness provided to the arches by an innovative underslung bracing system and quantifying its influence on the global response of the bridge. The latter focused on connection stiffness parameters, which were used to calibrate a finite element model of the bridge, thus demonstrating the value that can be added to modelling through load testing, particularly in accounting for unaccounted interactions between members.

The purpose of the work described in his paper is to add to contributions on the response of historical bridges by undertaking field testing on a decommissioned 19th-century open deck riveted railway bridge with the following objectives: (1) to provide load-displacement measurements of the main bridge members (main-girders and cross-girders) that are compared with in-service monitoring measurements obtained under actual railway loading, (2) to provide evidence on the U-frame action in the bridge, and (3) to assist towards the development and calibration of a global numerical bridge model to be used for subsequent fatigue assessment calculations.

2 EXPERIMENTAL SET UP

2.1 *Structure tested*

The Yetminster bridge was taken out of service in February 2020, as part of programmed replacement aiming at asset renewal that leads to reduced maintenance requirements. The bridge was delivered to the University of Surrey (Figure 1) in order to carry out research on various aspects of the behaviour of old riveted railway under-bridges (U-frame action, connection stiffness, remaining fatigue life). The bridge was constructed approximately in the 1880/90's, with its main girders, rivets and connection angles made of wrought iron whereas the cross-girders made from early steel. Double angle riveted connections are used to connect the cross-girders with the main girders. The bridge, which has offset stiffeners with respect to the main to cross-girder connections, has been in service for approximately 130 years, sitting on masonry abutments. It carried a railway track which was fixed on top of solid timber beams (0.432×0.375×12 m) placed on top of the cross-girders, as shown in Figure 1(right). The bridge was delivered to an open land with thick concrete flooring where it was placed on four solid prestressed concrete blocks (Figure 1) sitting on an in-situ constructed concrete slab. Here it was subjected to quasi-static load testing, through controlled loads applied to the cross-girders with the displacement and strain response recorded at several points of interest. Upon completion, the bridge was cut into several large sub-assemblies which are currently undergoing static and fatigue testing.

2.2 *Loading arrangement*

The testing was carried out on the bridge, first, in the presence of the timber deck beams (Figure 1(left)), as well as after removing the timber deck beams (Figure 1(right)) to understand the load distribution on metallic members in both cases. For the application of loading, a reaction framework was constructed and was anchored into the concrete surface using 16mm threaded rods into expansion anchors, as shown in Figure 2. A total of 30 such anchors were used. Vertical loads were applied through a hydraulic jack and four load cells (LC1 to LC4). In the presence of timber beams, the vertical loads were applied onto the timber beams through loading plates. After the timber beams were removed, the loads were applied directly onto the cross-girder top flanges through loading plates. The maximum distributed pressure

force applied on the top surface of each loading plate was 50 kN, representing a typical wheel load of the passenger train type that ran on the Yetminster bridge route. The loads were applied incrementally in steps of 10 kN. A total of 25 loading scenarios were considered in the testing representing different positions of a train axle or bogie on the bridge. In this paper, a smaller number of the key loading scenarios are presented.

Figure 1. (left) Bridge with timber deck; (right) bridge with timber deck removed.

Figure 2. (left) Loading frame constructed for load application; (right) threaded anchors.

2.3 *Instrumentation*

A total of 38 linear varying displacement transducers (LVDTs) and 30 strain gauges (linear and rosettes) were used. The locations of LVDTs for measuring vertical and horizontal displacement are shown in Figure 3 and Figure 4 respectively. Strain gauges were selectively installed on the bottom flanges of cross-girders CG2, CG3 and CG4 (midspan location) and the bottom flange of the main girders. The vertical deflection measurements allowed the

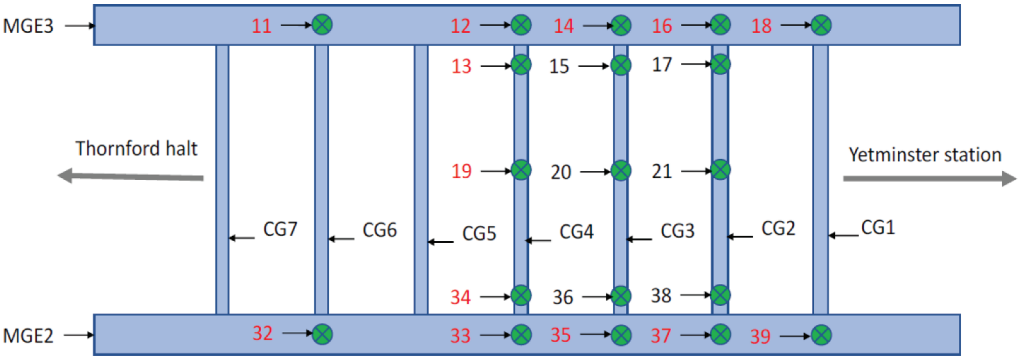

Figure 3. LVDT locations for vertical displacement measurement.

creation of longitudinal profiles for the main girders and transverse profiles for three cross-girders. The horizontal displacement measurements are aimed at longitudinal profiles of the main girder flange and selected profiles along the depth of the main girder web (U-frame action), taking into account web stiffener positions.

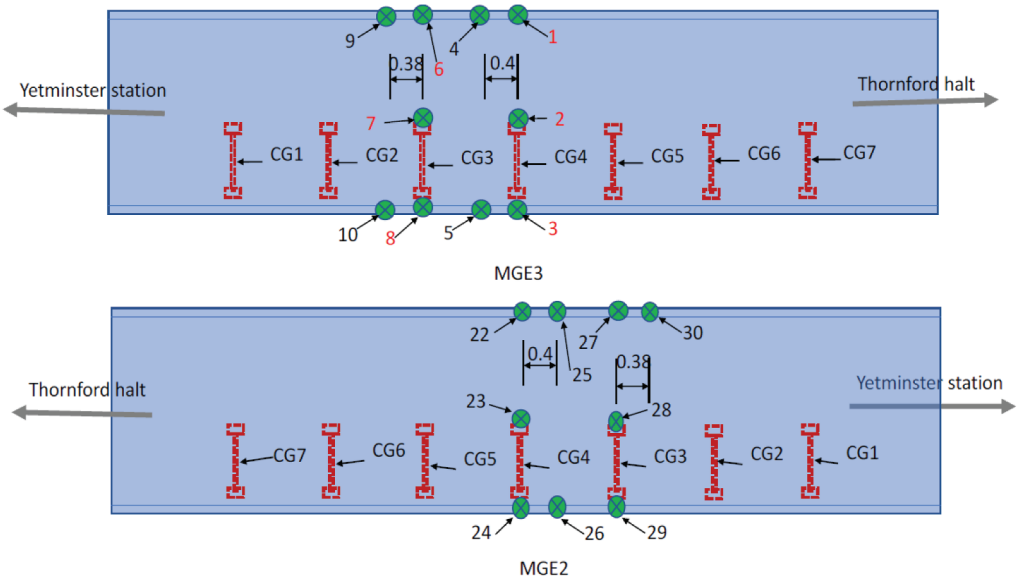

Figure 4. LVDT locations for horizontal displacement measurement (dimensions in m).

3 RESULTS AND DISCUSSION

3.1 *Load application*

Strains and displacements for two loading scenarios shown in Figure 5, with the timber deck (loading scenario A) and without the timber deck (loading scenario B) are presented herein. The load time histories of the four load cells for the two loading scenarios are shown in Figure 6. Due to stiffness variations and load application asymmetries, it can be seen that there is a variability in the actual load being applied (compared to the nominal value which should be increasing in steps of exactly 10 kN). This variability is also scenario dependent, with the case that includes timber beams producing higher variability than the one without. For load vs deformation (displacement or strain) plots involving sensors located on a plane passing through the main axis of a cross girder, the total load is taken as the sum of all the load cell measurements placed on that cross girder. For load vs deformation plots involving sensors located at all other locations, the total load is taken as the sum of all the load cell measurements present in the relevant load scenario.

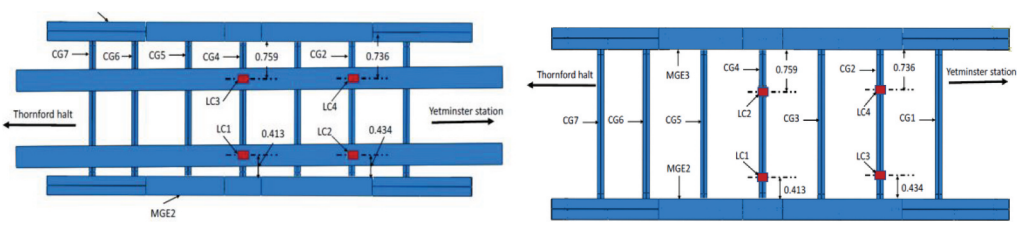

Figure 5. (left) Loading scenario A; (right) Loading scenario B (all dimensions in m).

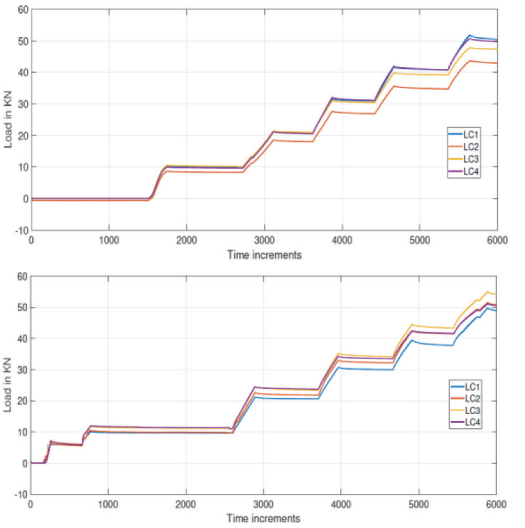

Figure 6. Load time histories for (left) scenario A, with timber deck; (right) scenario B, w/o timber deck.

3.2 *Vertical displacement measurements*

The vertical displacement measurements on the LVDTs located on the loaded cross-girders (CG4 and CG2) are shown in Figure 7. The presence of the heavy timber beams is seen to contribute to the stiffness of the structure, though the effect varies both across a single cross-girder as well as between cross-girders. On the side connected to MGE3 (LVDTs 13 and 17), the difference in stiffness between the with and without timber cases is the greatest (~50%), whereas on the side connected to MGE2 (LVDTs 34 and 38) the difference is roughly halved (22%). The smallest difference is recorded at the centre of the cross-girder, indeed it is negligible for deflections up to 1mm.

3.3 *Strain measurements*

Table 1 summarises the strain measurements obtained on the top and bottom flanges of the main girders for both with (scenario A) and without the timber deck present (scenario B), at the maximum load applied. At the MGE3 bottom flange, three strain gauges across the width of the flange were installed to measure any potential torsional effects on the member. Overall, the removal of the timber deck beams results in higher strains being recorded at the same load level, the increase ranging between 16-35% (average ~27%). This is important, especially taken in conjunction with the previous comment on stiffness, considering that numerical (e.g. grillage, FE) or simplified mechanical models do not account for the effect of timber superstructure in estimating the response; e.g. the timber deck was absent in the numerical model considered by Moen et al. (2013).

3.4 *Load distribution*

To estimate load sharing by adjacent cross girders when the load acts directly on any particular cross girder four identical scenarios with and without timber were selected (Table 2). In the absence of timber beams (cases I & VII), the indirectly loaded cross girders record a very small amount of strain (less than 10% of the corresponding value on the directly loaded girder). A similar trend can be observed for cases III & V. This could be attributed to: (i) out of plane bending of the main girders imposing rotational moments at the ends of the cross girders, and (ii) the differential displacement of the two main girders caused by the asymmetrical (offset with respect to the centre line) loading applied on the bridge. However, in the presence of timber beams (case II), the indirectly loaded cross girder CG2 experiences ten

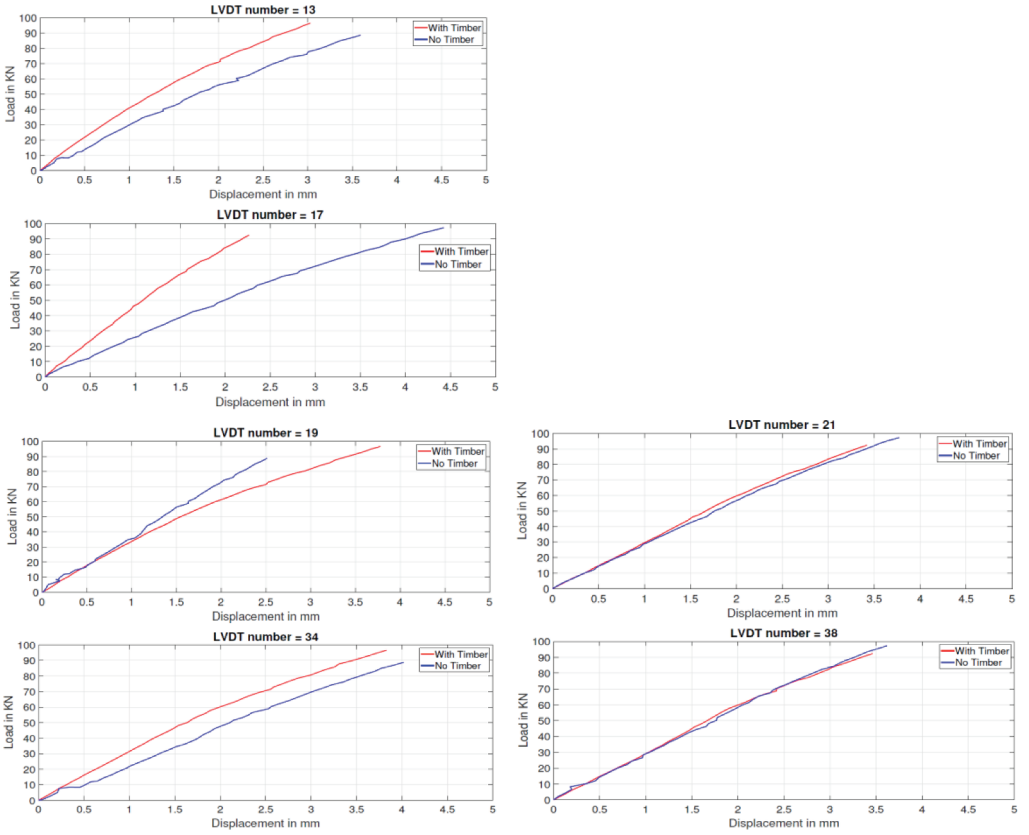

Figure 7. Vertical displacements on LDVTs located on (left) CG4 and (right) CG2.

Table 1. Longitudinal strains (in με) at top and bottom flanges of MGE2 and MGE3.

Location		With timber deck	Without timber deck
MGE3 top flange (midspan)		-59	-70
	Inside	73	39
MGE3 bottom flange (midspan)	Mid	63	92
	Outside	49	122
MGE2 top flange (midspan)		-73	-89
MGE2 bottom flange (midspan)		82	115

times more strain than the directly loaded cross girder CG4. Similarly for cases IV, VI and VIII, the load shared by the indirectly loaded cross girders varies depending on the position of applied loads on the timber beams. This can be attributed to a pre-existing camber in the timber beams, prior to testing. The maximum camber at the center of the timber beam close to MGE2 was measured to be 24 mm. Thus, for the loading scenarios with timber beams the pre-existing camber affects significantly load sharing by the adjacent indirectly loaded cross girders. As a result, load sharing estimates are subject to a degree of variability due to particularities that can only be revealed through a bridge survey.

3.5 *U-frame action*

The U-frame action was recorded at three sections, as shown in Figure 8. Sections A-A and C-C pass through the longitudinal axis of CG4 and CG3 respectively, whereas section

Table 2. Strains at bottom flanges of CG2, CG3 and CG4 corresponding to an average load of 50 kN/cell.

Case identifier	Loading type	Strain in CG2 (με)	Strain in CG3 (με)	Strain in CG4 (με)
I	Two 50 kN loads on CG4(without timber deck)	4	16	164
II	Two 50 kN loads on CG4 (with timber deck)	8	12	79
III	Two 50 kN loads on CG4 and two 50 kN loads on CG2 (without timber deck)	150	32	153
IV	Two 50 kN loads on CG4 and two 50 kN loads on CG2 (with timber deck)	115	78	42
V	Two 50 kN loads on CG3 and two 50 kN loads on CG1 (without timber deck)	22	143	5
VI	Two 50 kN loads on CG3 and two 50 kN loads on CG1 (with timber deck)	90	71	8
VII	Two 50 kN loads on CG2 (without timber deck)	153	15	2
VIII	Two 50 kN loads mid-length between CG4 and CG3 and two 50 kN loads midlength between CG2 and CG1 (with timber deck)	100	73	25

B-B passes through the web T-stiffeners at mid-length of the bridge. The displacement profiles, scaled up by a factor of 50, are shown in Figure 9 for three loading scenarios with and without timber beams. The maximum horizontal displacements for the same loading scenarios are given in Table 3.

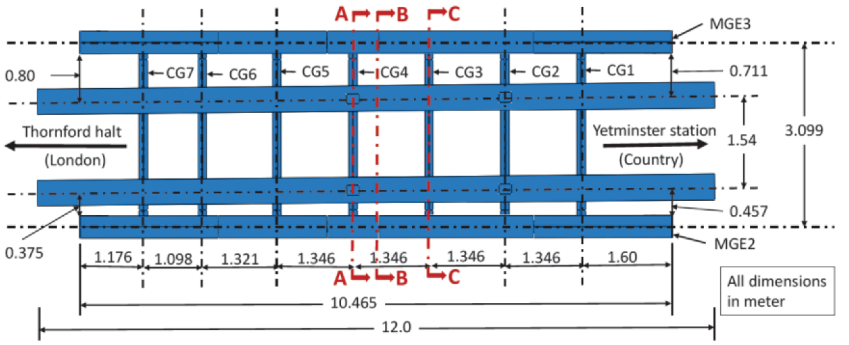

Figure 8. Top view of the bridge with details of the sections at which U-frame action was recorded.

The profiles in Figure 9 indicate that, for all cross-sections considered, sway behaviour of the bridge under vertical load is present. This can be attributed to an eccentricity in the vertical load, i.e. load which is not applied at the centre of the main girders, due to the eccentric location of the timber girders. It is also worth noting that the diagrams do not appear to conform with the usual assumption of symmetry between left and right main girders. In fact, the main girders are not identical due to the different location of transverse web stiffeners along their length. Additionally, three of the cross-girders have been stiffened in the flanges over only part of their length, which introduces a further asymmetry. As a result, it seems that the U-frame action does not introduce the same effect on the two sides of the bridge. On the other hand, the results with and without timber beams are generally consistent, with the latter showing a small magnification compared to the former in most cases. In line with conclusions reached in earlier studies (e.g. Flemming, 2022), establishing an understanding of the global behaviour of a particular bridge based on full-scale testing, provides valuable information as to whether modelling simplifications could be adopted without introducing bias and/or significant uncertainty. In addition, local effects also need to be considered (e.g. local corrosion and connection

factors, such as rivet clamping forces) in order to help explain with greater confidence observations from diagnostic tests (Alampalli, 2021) such as the ones conducted in this bridge.

4 CONCLUDING REMARKS

This paper summarised results obtained from field testing of an open deck riveted metallic railway bridge removed from service and tested under controlled conditions. Load distribution with and without the timber deck and the structure's U-frame action were assessed through a series of diagnostic tests using quasi-static loading. The main conclusions are as follows:

- Testing of real structures reveals unforeseen effects arising from unintended factors, such as imperfections and minor asymmetries, as well as deterioration and changes during service.
- Numerical models can take account of such factors especially if the performance of such models can be compared with results from diagnostic testing, as carried out herein.
- For this class of metallic riveted bridges, the effect of superstructure, such as the timber deck, was found to be quite important. Neglecting its presence in numerical models would result in conservative assessment results (in terms of strains/stresses and displacement) but this has to be carefully assessed with respect to the purpose of the analysis/assessment.
- Even relatively small asymmetries in the geometry of a bridge (i.e. the transverse offset web stiffeners on the main girders) can introduce noticeable effects on its global response.

The study re-affirms one of Bakht and Jaeger's (1990) principal conclusions, namely that "some aspects of bridge behavior, because they never enter design considerations, can escape the attention of even experienced bridge designers and analysts". It is hoped that this study has thrown a useful light on such aspects in the context of old open deck riveted metallic railway bridges.

ABSTRACT: This paper presents the assessment of a damage identification procedure applied to a multi-span prestressed concrete bridge equipped with accelerometers. In addition, the central span is equipped with LVDT sensors recording local displacements from which two structural states of the bridge are defined. Using the acceleration measurements, the corresponding modal characteristics are determined from an output-only modal identification procedure including a clustering step to compute mean values of the identified mode shapes. Damage detection and localization is performed by combining the use of damage indicators and the updating of a simplified finite element model. The damage pattern obtained in the central span is consistent with the information available from the LVDT sensors. In the side spans, the evolution between the two structural states seems to correspond to an increase in stiffness. This point requires further investigation. Improvements to the present method, including a statistical analysis, are also being considered.

1 INTRODUCTION

Vibration-Based Methods (VBMs) for Structural Health Monitoring (SHM) of bridges have been widely developed over the last 30 years (Sohn 2003, An 2019). They are promising as they potentially lead to identify damage occurrence related to structural evolution over time, such as changes in stiffness due to modifications in the connections between structural members, or degradation of material properties. Nevertheless, field applications of VBMs are not straightforward for several reasons: measurements are subject to uncertainties and noise, the number of sensors is limited, the ambient excitation due to traffic is variable and unknown. It is therefore of crucial importance to evaluate their performance in practical cases. The two first objectives of the SHM of bridges are the qualitative detection of damage and its localization. As recently recalled in the review by Karakostas & al. (Karakostas 2023) one classical approach to achieve this relies in a two steps data driven procedure consisting in the identification of natural frequencies and modal shapes in both undamaged and damaged states followed by the computation of damage indicators based on these modal data. Another possibility is to use a model-based method including a model updating. A third solution is to combine both previous approaches to build a hybrid method. This paper presents a field assessment of a Vibration-Based damage identification procedure applied to a multi-span prestressed concrete bridge subjected to thermal gradient variations. The bridge is equipped with 24 accelerometers. In addition, the central span is equipped with LVDT sensors which allow the definition of the structural states corresponding to the evolution of the bridge structure, due to the loss of prestressing of the joints causing a local loss of stiffness. The two reference states will be hereafter referred to as State S1 and State S2. In order to track the differences between these two states, a hybrid method is proposed that combines the use of damage indicators with the model updating of a simplified finite element model.

DOI: 10.1201/9781003483755-51

2 METHODOLOGY

The proposed approach is summarized on Figure 1. The acceleration signals from the sensors are filtered using a Singular Spectral Analysis procedure (Golyandina, 2020) leading to the reduction of measurement noise. The modal characteristics of the bridge are determined using an output only modal identification procedure, based on the combination of Random Decrement (RD) technique with an improved Ibrahim Time Domain (ITD) method. After a clustering step, the modal identification leads to the determination of two sets of modal characteristics:

$$\left(\tilde{\omega}_i^{S1}, \tilde{\xi}_i^{S1}, \tilde{\phi}_i^{S1}\right)_{m'} i = 1, \ldots, n; m = 1, \ldots m_{sk} \text{ in state } Sk, k = 1, 2 \quad (1)$$

After averaging, these modal data are used to calculate damage indicators enabling the detection and localization of damage. The possible location of damage is then used as an input to a finite element updating procedure using a simplified model of the bridge. Each step is briefly presented in the following sub-paragraphs. This hybrid approach has several advantages. Firstly, its spatial resolution depends mainly on the spatial resolution of the finite element model and is therefore enhanced compared to a purely data driven approach where the spatial resolution is correlated with the number of sensors. Secondly, the solution of the inverse problem of updating is simplified compared to a purely model based method as the number of parameters to update is reduced thanks to the damage indicator-based damage detection and localization.

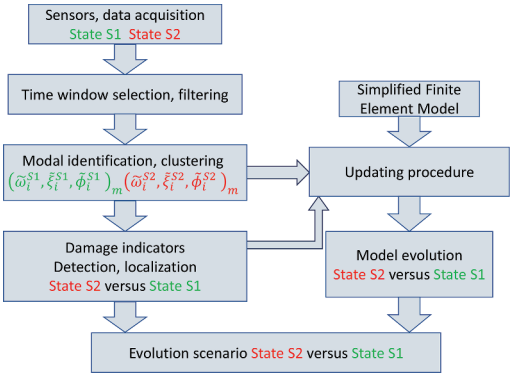

Figure 1. Methodology.

2.1 *Modal identification procedure*

The modal characteristics are determined using an output-only modal identification procedure, based on the combination of Random Decrement (RD) technique with an improved Ibrahim Time Domain (ITD) method (Ibrahim, 1977). The procedure also includes a clustering step and a statistical analysis of the obtained modal characteristics. Starting from the observation measured by the accelerometers at N locations on the bridge, the modal identification procedure leads to the determination of the identified modes $\tilde{\phi}_i \in R^N$ with $||\tilde{\phi}_i|| = 1$, pulsations $\tilde{\omega}_i$, and modal damping $\tilde{\xi}_i$, for $i = 1, \ldots, n$ where n is the number of identified modes. Compared to a finite element model giving high dimensional mass normalized modes, reduced information is therefore available.

2.2 *Damage indicators*

The considered damage indicators are based on two sets of modal characteristics identified for states S1 and S2. The objective here is limited to damage localization and the results of the damage indicators must not be interpreted in a quantitative way. The reason is that, as many authors have pointed out, the probability of false alarms is high when using damage indicators

and a reliable use of their prediction requires the definition of thresholds that are rather complicated to estimate (Alvandi 2006, Erduran 2021).

2.2.1 *Modal flexibility based index*

The Modal Flexibility method uses mass-normalized modal vectors to estimate an n-approximation F_n of the flexibility matrix F. Using only the first identified unit norm mode of reduced dimension $\tilde{\phi}_1$, the damage indicator $D_F(j)$ is defined as:

$$D_F(j) = \frac{max|\Delta F(i,j)|}{a},\ i = 1, \ldots, N \tag{2}$$

with $\Delta F = \tilde{F}_1^{S2} \tilde{F}_1^{S1} \tilde{F}_1^{Sk} = \frac{\tilde{\phi}_1^{Sk} \tilde{\phi}_1^{SkT}}{\omega_1^{Sk2}}$ and, $a = \left(\sum_{j=1}^{n} max|\Delta F(i,j)|^2 \right)^{1/2}$

2.2.2 *Modal interpolation error indicator*

The modal interpolation error, proposed by Limongelli (Limongelli, 2011), is a damage indicator based on the use of a cubic spline function interpolating the modal shapes of the structure. At the j[th] location of the structure, the accuracy of the interpolation is computed for the i[th] mode from the interpolation error E_{ji}, that is the magnitude of the difference between the identified component of the i[th] modal shape at that location $\tilde{\phi}_{ji}$ and the interpolated value $\hat{\phi}_{ji}$ of the same component.

The modal interpolation error in the state Sk at location j is defined as:

$$E_{ji}^{Sk} = \left| \tilde{\phi}_{ji}^{Sk} - \hat{\phi}_{ji}^{Sk} \right| \tag{3}$$

The damage indicator D_I is then defined as:

$$D_I(j) = \left| E_j^{S2} - E_j^{S1} \right| \tag{4}$$

where $E_j^{Sk} = \sqrt{\sum_{i=1}^{n} E_{ji}^{Sk\ 2}}$ is the interpolation error in the state Sk at the j[th] location.

Following the idea of Limongelli (Limongelli 2016), a threshold is fixed for the detection and localization of damage resulting in a binary indicator: 0 (no damage) or 1 (damage) defined by:

$$DS_P(j) = (sign(D_P(j) - \bar{D}_P - \sigma_{DP}) + 1)/2 \tag{5}$$

where $\bar{D}_P$ and σ_{DP} are respectively the mean and standard deviation of $D_P, P = F$ or I.

2.3 *Model updating*

Damage is simulated by varying the stiffness of the finite elements. The mass matrix M is considered as a constant and the following parameterization of the stiffness matrix is adopted:

$$\Delta K = K^{S2} - K^{S1} = -\sum_{p=1}^{n_d} d_p K_p \tag{6}$$

where K^{Sk} is the stiffness matrix in the state Sk, K_p is the contribution of the undamaged element p to stiffness matrix, d_p denotes the damage of element p, and n_d is the number of potentially damaged elements chosen using the damage indicators results.

It should be noted that the spatial resolution of the search for damage using the update procedure is associated with the spatial resolution of the finite element model and is therefore finer than that the one obtained from the accelerometers placed on the bridge. The originality of this procedure is that it updates the selected model parameters so that the modal differences between state S1 and S2 numerically calculated fits the experimentally identified ones.

The updating procedure consists in minimizing the following objective function:

$$J(d) = \left\| \sum_{i=1}^{n} \left[\left(\overset{\vee}{\phi}_i^{S2} - \overset{\vee}{\phi}_i^{S1} \right) - \left(\tilde{\phi}_i^{S2} - \tilde{\phi}_i^{S1} \right) \right] \right\|^2 \tag{7}$$

where $\overset{\vee}{\phi}_i^{Sk}$ are the unit norm vector obtained from the finite element model.

The model updating is performed using the CMA-ES algorithm (Hansen 2016) to find:

$$d_{S2/S1} = \text{argmin}(J(d)), d_{S2/S1} \in R^{n_d} \tag{8}$$

3 CASE STUDY: THE BRIDGE OF LONGUES

3.1 *Description and sensor equipment of the bridge of longues*

The bridge of Longues (Figure 2a) is a prestressed concrete bridge consisting of 3 spans. The total length of the structure is approximately 162m, and its width is about 12m. The structure is equipped with 24 accelerometers referenced as $a_k,\ k = 1, \ldots, 24$ (Figure 2b) placed at regular intervals of approximately 6.5m (Figure 3). The abutments are not equipped. However, 2 sensors are placed at the locations of the intermediate piers. The sensors are arranged vertically on the central web separating the 2 chambers (Figure 4). The temporal signal is acquired at a sampling frequency of 250Hz over a duration of 20s. Additionally, LVDT sensors are positioned on three different abscissae denoted L1, L2 and L3 identified as subject to decompression due to thermal gradient.

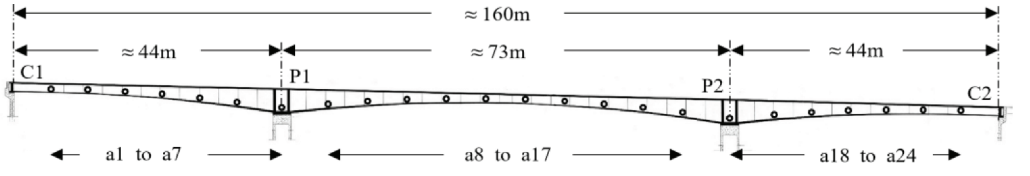

Figure 3. Overall dimensions of the bridge in longitudinal cross-section and location of accelerometers.

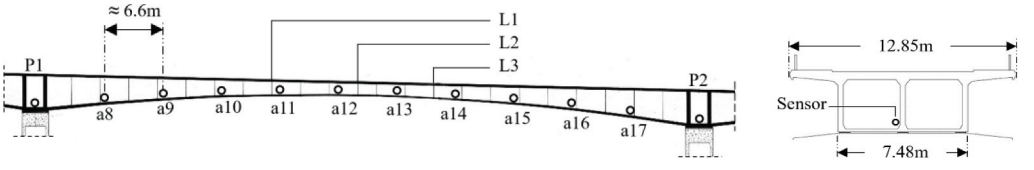

Figure 4. Location of the accelerometers on the central span (a8 to a17) and voussoir joints equipped with CEREMA's LVDT sensors (L1 to L3). Location of accelerometers on a transversal cross-section.

Recorded signals of LVDT sensors enable to identify the time windows to consider for detecting a structural modification of the bridge associated in the present case to a decompression of the intrados. Consequently, the state of the bridge on April 3, 2023 is chosen as state S1 and on April 9, 2023 as state S2. Within each of the two time-windows defined in Figure 5, two subgroups of data are selected to carry out a comparative analysis on two separate datasets corresponding to the same state of the bridge and assess the robustness of the modal identification procedure. Time windows T1.1 and T1.2 correspond to the state S1, and T2.1 and T2.2 correspond to the state S2.

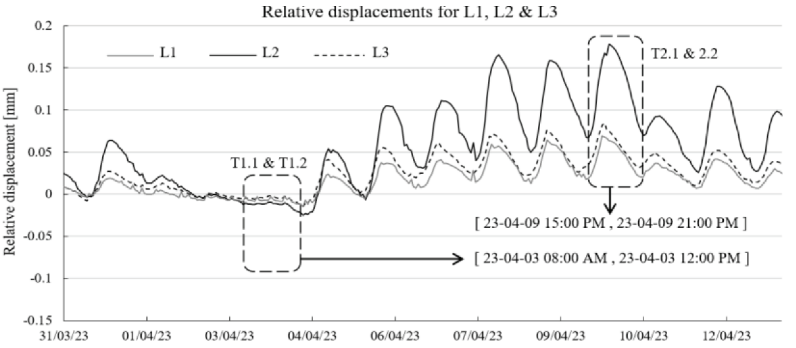

Figure 5. Selection of time windows, considering relative displacement measured by LVDT sensors L1, L2 and L3.

3.2 *Application of the damage identification procedure*

3.2.1 *Modal identification*

The modal identification procedure is applied to the data sets derived from the four temporal sub-windows T1.1 and T1.2 corresponding to the state S1, and T2.1 and T2.2 the state S2. As

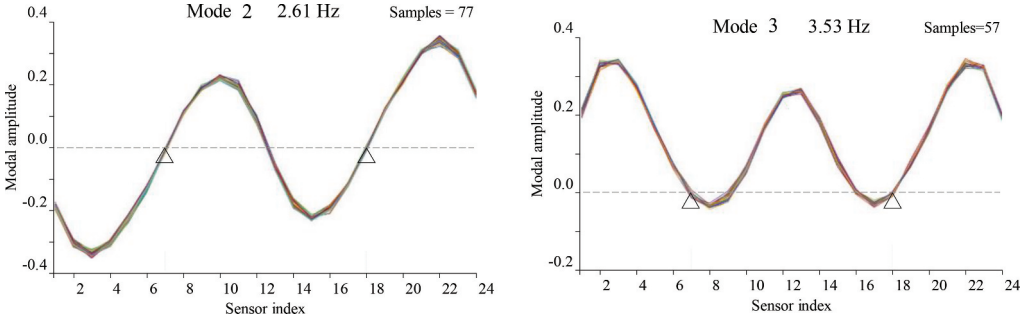

Figure 6. Illustration of two mode sets identified from the temporal sub-window T1.1.

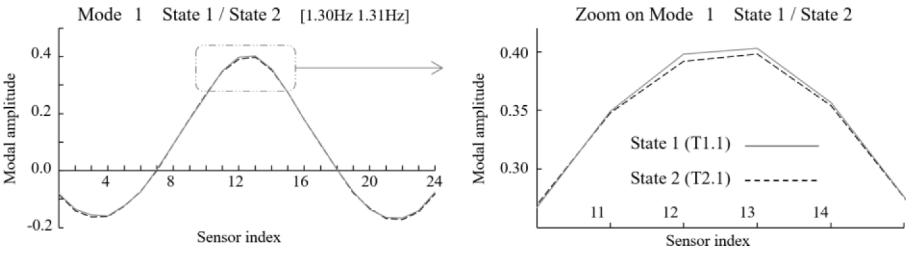

Figure 8. Comparison of mode 1 for two distinct instances of S1 and S2 (T1.1 & T2.1).

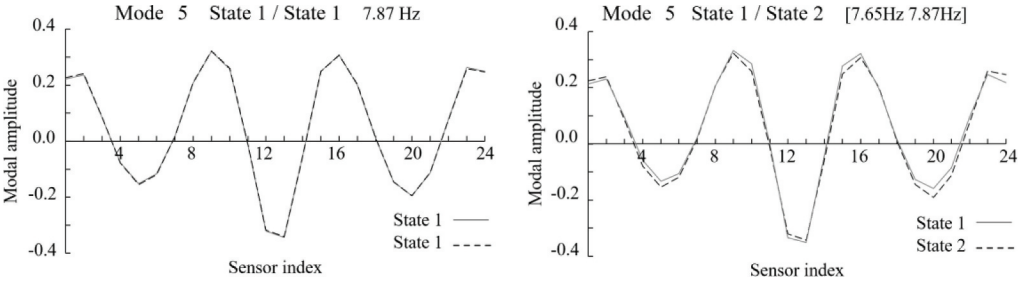

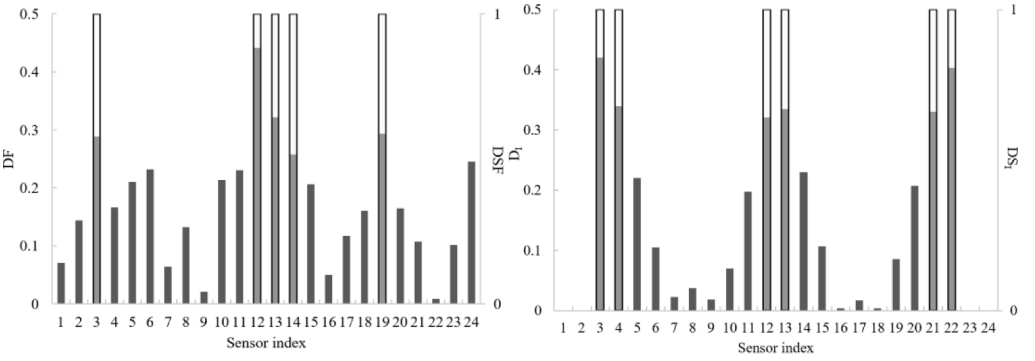

Figure 9. Superposition of mode 5 for two distinct instances of S1 (T1.1 & T1.2) and two distinct instances of S1 and S2 (T1.1 & T2.1).

an illustration, Figure 6 shows the distribution of 2 modes identified from the sub-window T1.1. Figures 7, 8 and 9 compare the average of modes 1 and 5 derived from sets of time sub-windows related to the same state (S1: T1.1 with T1.2 or S2: T2.1 with T2.2), and then to states S1 and S2. The modes obtained from the same state are very close assessing the robustness of the modal identification. The evolution of the modes between states S1 and S2 confirm the structural changes in the bridge, also detected by the LVDT sensors.

3.2.2 *Damage detection and localization*

Figures 10a and 10b show respectively the results obtained with the indicators D_F, DS_F and D_I, DS_I. Both indicators detect a modification of the bridge behavior that is in good accordance with the observations made thanks to the LVDT sensors placed in the central span. They also seem to indicate that other modifications of the bridge occur also in the left and right span. This information cannot be checked as only the central span is equipped with LVDT sensors, but a complementary analysis is possible using the updating results.

a. Flexibility: D_F and DS_F b. Interpolation (n=5): D_I and DS_I

Figure 10. Damage indicators.

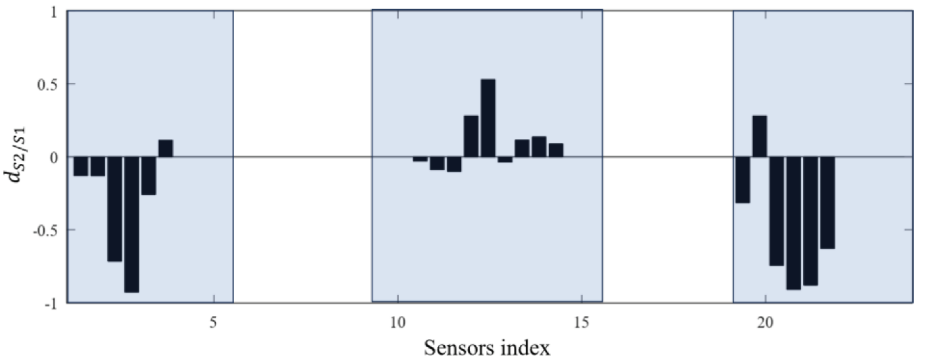
3.3 *Model updating*

3.3.1 *Model description*

The proposed model is a simplified finite element model of the bridge made of 156 Euler-Bernoulli beam elements of variable moment of inertia and cross-sectional area following the design of the bridge. The Young's modulus is homogeneous, and its value is chosen equal to that of concrete.

3.3.2 *Updating*

The potentially damaged zones and the updating results are represented in Figure 11. The obtained damage pattern in the central span is consistent with the damage indicators and measurement obtained from the LVDT sensors. In the left and right span of the bridge, the evolution between states S1 and S2 seems to correspond to an increase of stiffness. This point has to be further investigated in order to determine whether it is linked to effective modification of the bridge or not. Figure 12 present the comparison between the quantities $\overset{\vee}{\phi}_i S2 - \overset{\vee}{\phi}_i S1$ and $\tilde{\phi}_i^{S2} - \tilde{\phi}_i^{S1}$ showing a good agreement between experimental and numerical results.



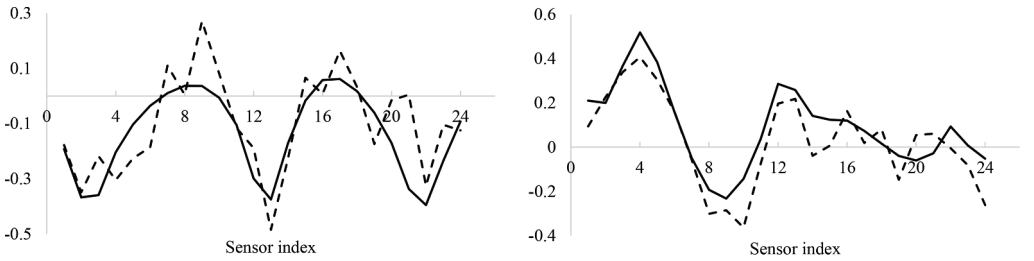


Figure 11. Updated damage between state S1 and S2.

Figure 12. Comparison of $\overset{\vee}{\phi}_i S2 - \overset{\vee}{\phi}_i S1$ ( ) and $\tilde{\phi}_i^{S2} - \tilde{\phi}_i^{S1}$(—) obtained by the model and identified from the recorded data.

4 CONCLUSION

The aim of this paper was to demonstrate the potentiality of the proposed hybrid methodology for the identification of the damage of a real bridge. The combined use of modal identification, damage indicators and simplified finite element model has enabled the detection and localization of damage on the central span that are in accordance with the information from the LVDT

sensors. Furthermore, other damage locations that were not expected have been detected by indicators and confirmed by model updating. This point has to be further investigated on the bridge by new measurements. The equipment of the bridge with complementary LVDT sensors and additional accelerometers is planned.

The advantage of the proposed strategy, compared to a classical model updating procedure, relies in the reduction of the number of model parameters to be updated on the base of the results of damage indicators. The originality of the updated procedure is that it updates the selected model parameters so that the modal differences between state S1 and S2 numerically calculated fits the experimentally identified ones.

The methodology presented in section 2 can be applied to other types of bridges as for example truss bridges. In that case, other damage indicators as for example Damage Locating Vectors (DLVs) proposed by Bernal (Bernal 2002) and an adapted simplified finite element model have to be employed. This point and other improvements to the present method, including statistical analysis, are also under consideration. This further research will enlarge the scope and improve the robustness of the proposed methodology.

ACKNOWLEDGMENT

The project CI3S received a grant from the call for projects *Ponts Connectés* funded by the French Government and led by Cerema which aims to improve bridge management by using the most recent techniques in terms of monitoring, data transfer and data processing. Moreover, the authors would like to thank Cerema for organizing this call for projects and for its scientific involvement in the follow-up of the project and for sharing the data of the LVDTs on the bridge of Longues.

Road overpasses with Gerber half-joints: Field tests and numerical models

D. De Domenico, M. Mazzeo, D. Messina & A. Recupero
Department of Engineering, University of Messina, Italy

ABSTRACT: This contribution presents a combined experimental-numerical investigation on road overpasses with Gerber half-joints. The analysis is focused on a series of existing overpasses of the A20 highway, Sicily, Italy, built more than 50 years ago and characterized by a Niagara-type Gerber deck with prestressed concrete girders and transverse diaphragms. The structural health of the overpass deck is assessed by diagnostic field tests combined with numerical simulation. First, dynamic free-vibration tests under the transit of trucks are conducted in situ to determine the bridge deck modal characteristics (frequencies and modal shapes) through a recently developed identification strategy. The experimental results are used to calibrate a finite element model, which is finally used to simulate the deflection response of the deck under static load tests. The results of this study are useful to develop field-validated digital twins of real bridge structures and for performing parametric analysis when designing repair interventions, where necessary.

1 INTRODUCTION

The Italian Road system includes around 840,000 km of highways, provincial and municipal roads (Cosenza & Losanno 2021) with more than 50,000 bridges. A large number of such bridge structures were built more than 50 years ago with concrete or prestressed concrete schemes. Because of ageing and lack of periodic inspection and maintenance, several bridges are undergoing material deterioration that, combined with structural defects related to design or construction errors or caused by the aggressive environment, may lead to catastrophic collapses (Nuti et al. 2020). The critical situation observed in Italy, with 15 bridge collapses in the last 10 years and a total of 52 fatalities and 38 injured (Palmisano et al. 2022), requires efficient methodologies to assess the health conditions of existing bridges and, if critical aspects are identified, to define the most suitable repair or intervention actions in a cost-effective manner. The structural safety of existing bridges can be comprehensively assessed through suitable experimental investigations assisted by numerical calculations. In this context, diagnostic field tests are very useful for the structural health assessment of existing bridges, as they provide rapid information on the overall response of the structure under either dynamic or static loads (Lantsoght 2023) and can be exploited to develop a field-validated numerical model of the bridge (De Domenico et al. 2022).

Among the various static schemes of decks, several existing bridges built in Italy in the 1960s and 1970s are realized with a half-joint, also called Gerber joint or dapped-end beam in the literature (Desnerck et al. 2018). This scheme has the advantage of covering a longer span (space between intermediate piers) than decks with simply supported girders and was indeed widely used for road overpasses for spans of approximately 45 m, which are typically those associated with two separate road carriageways separated by a central traffic island. Similar to the simply supported scheme, bridges with Gerber half-joints have a statically determinate scheme, which is not sensitive to differential settlements and thermal variations (that instead typically affect multi-span continuous girder bridges). Besides these advantages, there are also well-known disadvantages related to the Gerber joints, including potential brittle shear failure

DOI: 10.1201/9781003483755-52

due to the reduced height in the half-joint (Moreno-Martínez et al. 2014), defective leakage of water through the joint (Santarsiero et al. 2021) that causes concrete deterioration and reinforcement corrosion in the protruding nib (di Prisco et al. 2023), as well as difficulty of visual inspection and defect detection. The collapse of a section of the de la Concorde Overpass in Quebec, Canada in 2006, and the more recent collapse of the Annone Brianza overpass in Italy in 2016 occurred in an exceptional, sudden manner, and revealed the inherent vulnerability of these kind of structures (Mitchell et al. 2011). Consequently, it is of paramount importance to develop efficient procedures for the structural assessment of half-joint bridges by exploiting experimental data and diagnostic field tests (Spinella et al. 2022).

This contribution deals with a set of road overpasses belonging to the A20 highway in Sicily, Italy, built in the early 1970s and with a Niagara-type Gerber prestressed concrete (PC) deck. Aim of this work is to illustrate a combined experimental-numerical framework to assess the structural health conditions of these road overpasses through interconnected field tests and numerical simulation. First, a comprehensive experimental campaign is conducted for characterization of materials. A rational, well-established procedure for assessing the structural health conditions under service loads consists in the comparison between modal characteristics retrieved from in-situ tests and numerical values obtained from digital models. To this aim, we use free vibration tests, which allow a quick and cost-effective determination of dynamic structural features using a sparse network of few sensors and avoiding long-lasting monitoring campaigns. The peculiarities of the modal shapes of this kind of structures are illustrated and critically discussed against alternative continuous-girder or simply-supported deck schemes. The experimental dynamic features of the bridge deck from free vibration tests are then compared to those identified by a finite element model (FEM). The inherent material uncertainties, identified from the previous experimental campaign, are included in the numerical simulation by using three different values of the concrete elastic modulus based on the pertinent statistical distribution. Field tests also include static load tests performed on the overpass decks under heavy trucks. The FE models, previously calibrated through the dynamic test results, are then validated against the static load tests by comparison in terms of deflections.

2 ANALYZED ROAD OVERPASSES

A family of 18 road overpasses of the A20 Messina-Palermo highway (Sicily, Italy), built in the early 1970s, are analyzed in this work. The deck is realized with a Niagara-type Gerber scheme (Figure 1), with two symmetric lateral spans having length of 29.0 m, including a segment of 22.0 m from the abutment to an intermediate pier and another cantilevered segment of 6.5 m with dapped beam at the end. The dapped end of the cantilever span is the support of a complementary dapped end of a central (suspended) span of 31.0 m length: this connection is termed half joint and can be viewed as an internal hinge realizing a statically determinate scheme, with an overall length between the intermediate piers of 44.0 m. Although the entire set of 18 overpasses analyzed are characterized by the same static scheme with identical span lengths, the deck width is variable from 6.5 m to 17.0 m depending on the number of I-shaped post-tensioned prestressed concrete (PC) girders, ranging from 3 to 8, respectively, all equally spaced at 2.0 m from each other. The majority of the overpasses analyzed (12 out of 18) are composed by 5 girders and have a deck width of 10.0 m.

The girders are tapered, having a variable height ranging from 1.3 m (at the abutments) to 1.7 m (above the intermediate piers and along the cantilevered segment) and are mutually collaborating through transverse diaphragms and an overlying reinforced concrete (RC) slab 0.16 m thick. The girders are reinforced with prestressing cables, having parabolic configuration to follow the bending moment profile, and made of cold-drawn Ø7 steel wires: in the lateral spans there are 4 cables, 3 of which (anchored at the dapped end) have 32 wires and 1 (the uppermost, anchored at the abutment) have 42 wires; in the central span, there are 3 cables, all made of 32 wires, 2 of which anchored at the left dapped end and the remaining one anchored at the right dapped end. Additional ordinary reinforcement of girders consists of transverse web reinforcement Ø12/15 cm, 6Ø10 longitudinal bars both in the top flange and

central web, and 13Ø12 in the bottom flange. The dapped end, with depth 0.90 m and width 0.75 m, is reinforced with 2Ø24 hangers, 4Ø24 diagonal bars and 6Ø24 longitudinal (top and bottom) steel bars properly anchored, stirrups and longitudinal skin reinforcement Ø14/15 cm. The overlying RC slab is reinforced with 4Ø14 longitudinal bars in the central part (over the I-shaped girder flange) and 3Ø8 longitudinal bars (top and bottom) at either external side of the deck, plus Ø10/25 cm horizontal bars for the entire slab width.

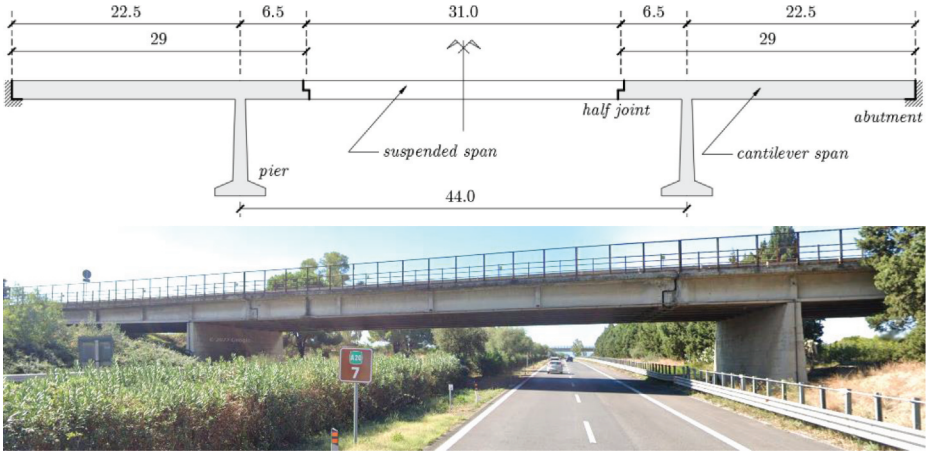

Figure 1. Longitudinal configuration (top) (measures in [m]) and photograph of a typical road overpass of the A20 Messina-Palermo highway (bottom).

An extensive in-situ test campaign has been performed, including coring, SonReb and pull-out tests for concrete strength of different structural members (foundations, abutments, piers, girders, diaphragms and slabs). Of particular relevance for the aims and scope of this paper, the concrete compressive strength data resulting from destructive and non-destructive tests have been grouped all together and processed statistically by fitting a log-normal probability density function (PDF). Indeed, the concrete strength f_c is an important parameter that affects the concrete elastic modulus E_c and, in turn, the structural response under serviceability loads explored in the dynamic and static field tests. It has been considered that two different classes of concrete were used for the realization of girders and of slabs + diaphragms, and two log-normal PDFs have been fitted accordingly (Figure 2).

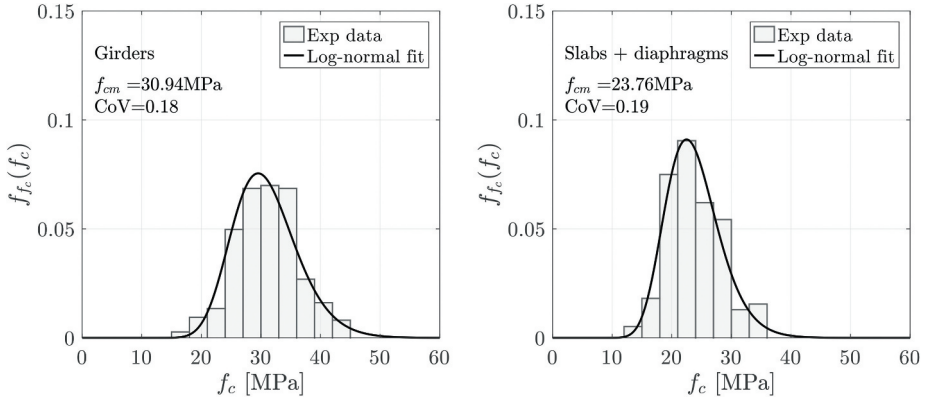

Figure 2. Statistical processing and log-normal fitting of concrete strength data for girders (left) and slabs + diaphragms (right).

3 FIELD TESTS AND NUMERICAL SIMULATION

3.1 *Dynamic load tests*

Dynamic field tests serve to identify modal characteristics of a structure, and in this work are used to assess the overall structural health conditions of the overpass deck. To this aim, free vibration tests are conducted on the analyzed overpasses and results, in terms of natural frequencies and modal shapes identified in situ, are compared to estimates obtained by a FEM assuming ideal conditions (no ongoing cracking or damage phenomenon, perfect restraints, etc.). As shown in Figure 3, a network of 8 accelerometric uniaxial sensors (labeled S1-S8) are anchored to the bridge deck to measure the vertical accelerations, of which 6 within the suspended span and the remaining 2 in the two cantilever spans. The free vibrations are triggered by the transit of a heavy truck (gross weight of 400 kN, approximately) along the deck at an average speed of 50 km/h, and the accelerometric measurements are acquired once the truck has left the overpass. The signals are sampled at a frequency of 1 kHz and are preliminarily processed through a third-order Butterworth filter by cutting off frequencies beyond the range [0.5-15] Hz.

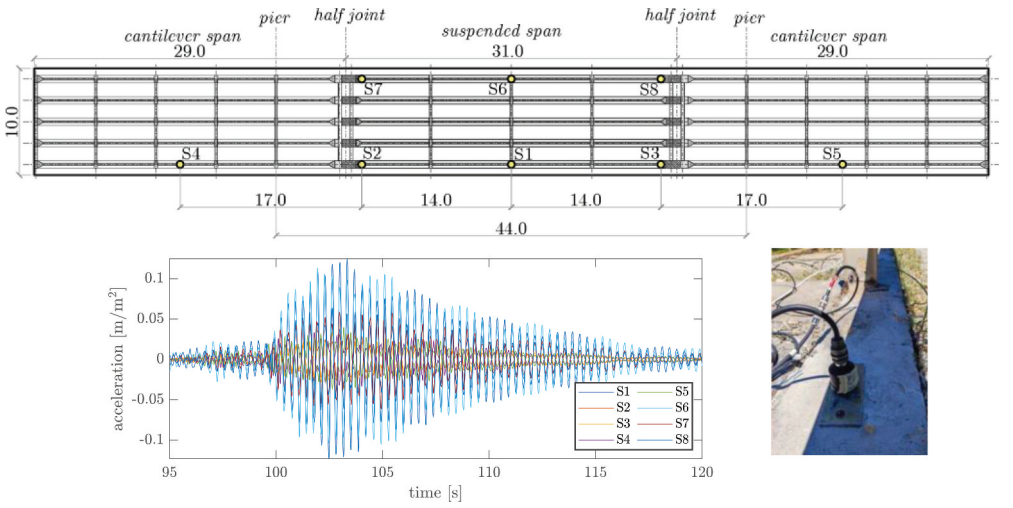

Figure 3. Arrangement of accelerometric sensors (S1-S8) on the overpass deck (top) during the dynamic load tests (measures in [m]) and representative signal array recorded during the free vibration tests (bottom).

Modal parameters of the overpass deck are identified from free-vibration-test results through the method proposed by Mazzeo et al. (2023), which exploits the Variational Mode Decomposition (VMD) to extract the intrinsic mode functions (IMFs) of the processed signals. The central frequencies of the IMFs are assumed as estimates of the natural frequencies, while the mode shapes are determined based on the phase shifts of the various synchronous sensor recordings.

Natural frequencies and modal shapes from the field tests are compared with numerical predictions by a FEM realized with the software SAP2000® (Computers and Structures Inc. 2016). In particular, different levels of accuracy are considered in the numerical simulation, by performing a parametric analysis to investigate various kinds of boundary conditions and modeling assumptions. Only a limited set of results of this parametric analysis are reported in this paper for the sake of brevity. The first model is made of 1D beam elements with six degrees of freedom per node for both girders and diaphragms, with the collaborating RC slab portion incorporated in the girder cross-section. This model underestimated the stiffness of the deck, as the numerical natural frequencies were systematically lower than those obtained from the experimental tests, Hence, a second, more refined model is set up, with 1D beam elements for girders and diaphragms, but with the RC slab being explicitly modeled with 2D shell elements, by introducing rigid links

combined with joint offsets to account for the actual difference between the slab mid-plan and the centroid of the girders, as per previous papers (De Domenico et al. 2022). The deck present Mesnager hinges at the abutments. It has been observed that clamping restraints at the abutments are the most appropriate boundary conditions to simulate the actual response of the deck, as the Mesnager hinges behave as real clamp restrains if the neighboring concrete areas is uncracked.

Figure 4 illustrates a comparison between experimental and numerical natural frequencies and mode shapes for the first three vibration modes. In particular, the first and second mode, having experimental natural frequencies of 2.82 Hz and 3.17 Hz, respectively, are related to the flexural and torsional vibration of the suspended span, respectively, while the third mode, with frequency 4.82 Hz, corresponds to a flexural behavior of the cantilever spans with the suspended span following rigidly the vertical deflections of the lateral parts with a cusp (abrupt change of rotation) at the half-joint. It can be observed that these mode shapes are quite peculiar and different from those typically observed in simply-supported bridge decks. A good agreement is observed between experimental and numerical natural frequencies and mode shapes. In particular, the accuracy of the FEM in terms in terms of frequency prediction is demonstrated by relative errors lower than 10%, while the accuracy of the FEM in terms of mode shape prediction is quantitatively demonstrated by modal assurance criterion (MAC) factors higher than 0.98 for all investigated cases. The error (interval) markers associated with the experimental bars in the histogram of Figure 4 identify the range of variation between minimum and maximum frequency from all sensors and analyzed overpasses (having the same number of girders), which are reasonably negligible, whereas the error markers associated with the numerical bars indicate the lower and upper bounds of the frequencies obtained by the FEM simulation using the 5% and 95% fractiles of the

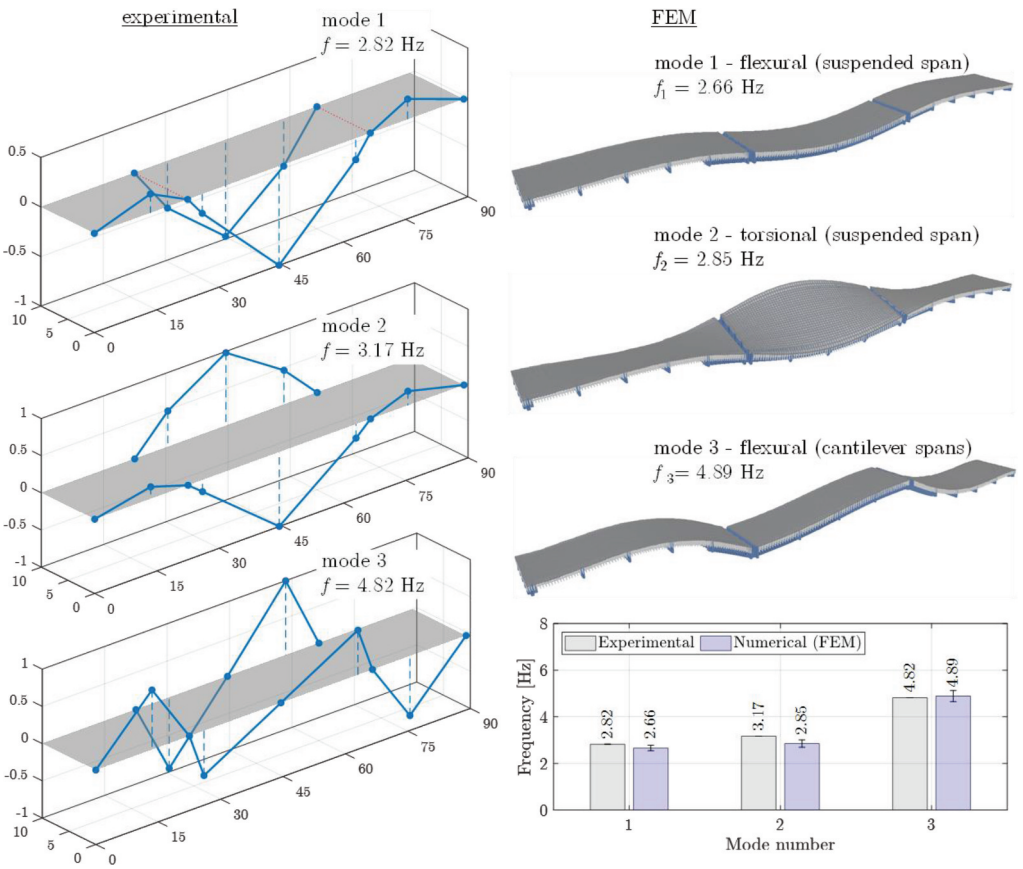

Figure 4. Comparison between experimental and numerical frequencies and mode shapes of overpass deck.

elastic modulus distribution determined by statistically processing the concrete strength data of the experimental campaign. In this simplified manner, it is possible to consider the impact of the inherent material uncertainties in the critical analysis of the numerical simulation results. Based on the obtained results, no damage spots or significant discrepancy between the FEM results (with idealized, uncracked material properties) and the experimental findings are noted, which may suggest that no damage process is taking place in the overpass deck under service conditions.

3.2 *Static load tests*

In addition to dynamic load tests, the structural health of the overpass deck under maximum serviceability load has been also assessed through static load tests. The tests are performed on 8 out of the 18 overpasses analyzed, all having 5 girders (deck width 10.0 m). The loads are applied through two trucks with four axles, whose weight and location has been designed to reproduce the same mid-span bending moment resulting from the load model 1 of the Eurocode 1-Part 2 (European Committee for Standardization 2003). The aim of these tests is to evaluate the deflection response of the deck under traffic loads that are different from those prescribed by the standards in force at the time of bridge construction; more importantly, 50 years of service life may have generated material deterioration and stiffness degradation, which can be evaluated by comparison between theoretical deflection under the assumed truck loads (e.g., via calibrated FEM) and actual experimental deflection. The location of the trucks is illustrated in Figure 5: the weight of each truck is 400 kN, and the pair of trucks are eccentrically placed so as to trigger not only flexural deflection (in the suspended span) but also torsion behavior of the deck. The deflections are measured by 7 linear variable displacement transducers (range ±50 mm, accuracy 0.01 m), denoted with letters A-G in Figure 5, fixed on aluminum rods via rigid connections and pointing towards the deck soffit.

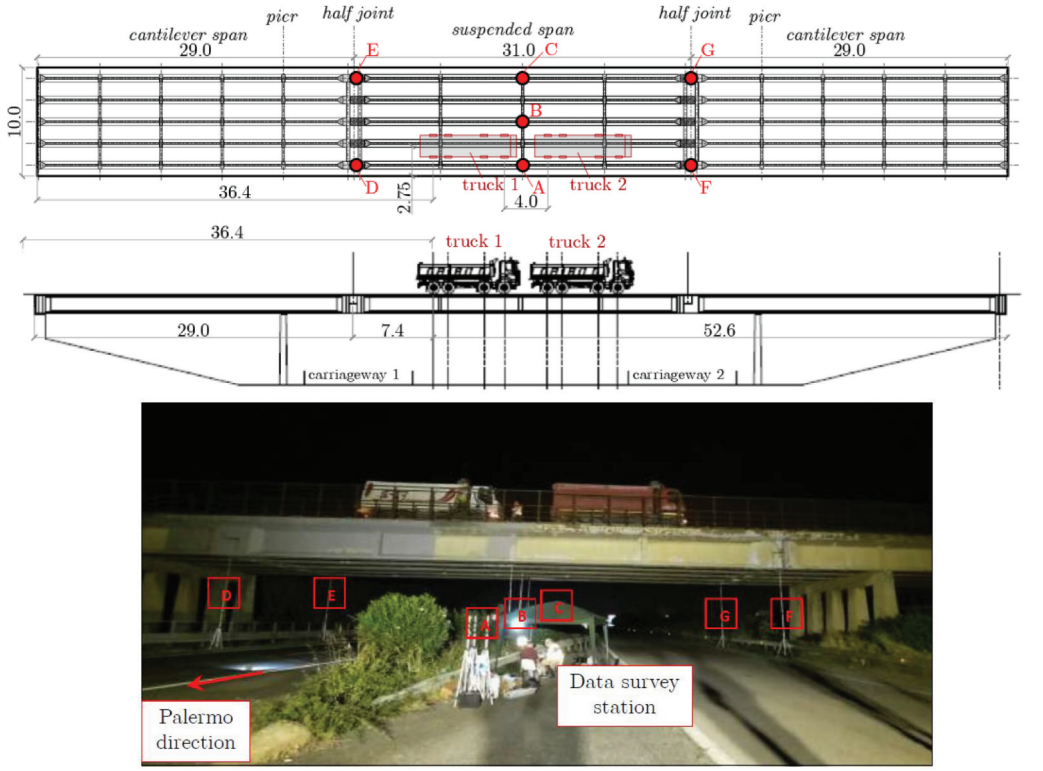

Figure 5. Arrangement of trucks and of 7 deflection sensors (A-G) on the overpass deck (top) during the static load tests (measures in [m]) and photograph taken during a representative field test (bottom).

The FEM previously calibrated against the dynamic tests is used to simulate the deflection response of the deck subjected to the truck loads, and the deflection profile is shown in the top part of Figure 6. The average experimental deflections (among the eight investigated overpasses) are reported as solid lines with circle markers in the bottom part of Figure 6, accompanied by error bars that denote the interval of variations from overpass to overpass. The quantitative value of the deflection and the corresponding interval of variation is reported as text label besides each measurement point. As reasonably expected, the maximum deflection is obtained at the mid-span in the loaded side (18.45 mm), while the maximum average deflection is 15.89 mm.

To critically analyze the experimental deflection response and to incorporate the inherent material uncertainties in the numerical simulation in a simplified way, three values of the concrete elastic modulus are used in the FEM, namely the mean value E_{cm} and the 5% and 95% fractiles of the corresponding probability distribution $E_{c,5\%}$ and $E_{c,95\%}$, respectively. The latter values can be associated with lower and upper bounds of the overpass deck stiffness, which produce the upper and lower bounds of the deflection response, respectively. By inspection of the results in Figure 6, it can be seen that the FEM is really accurate in capturing the deflection response of the deck not only along the longitudinal profile in the most loaded side (alignment of sensors D-A-F) but also along the transversal profile (alignment of sensors C-B-A). Moreover, it is clearly noted that the range of variation of the experimental findings is encompassed by the estimates of the deflection response resulting from the FEM with the lower and upper bound value of the elastic modulus. It can be concluded that the FEM results obtained in the simulation of the static load tests are consistent with those obtained during the field tests.

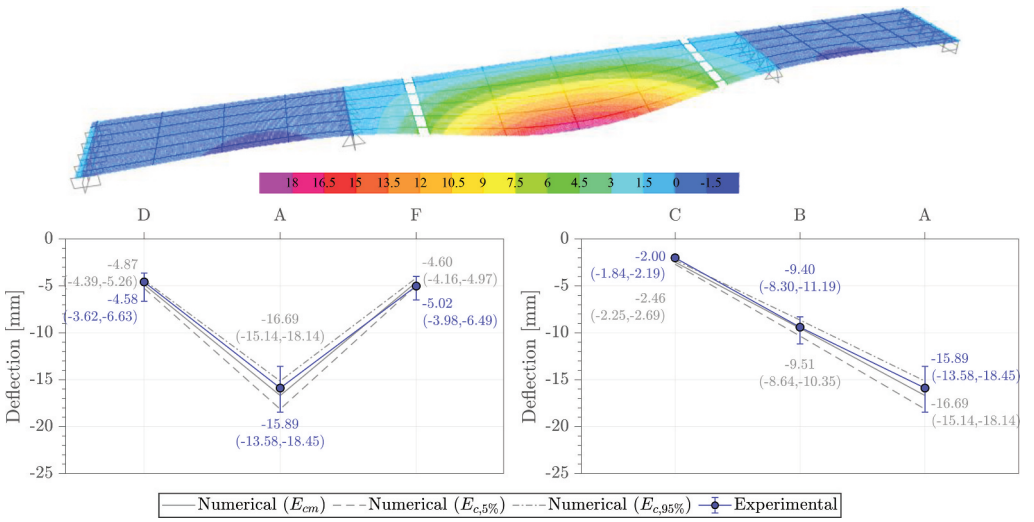

Figure 6. Deflection profile obtained by the calibrated FEM (top) and comparison between experimental and numerical deflections using three values of concrete elastic modulus (bottom).

4 CONCLUSIONS

This contribution has presented a combined experimental-numerical investigation on road overpassed located in the A20 highway Messina-Palermo (southern Italy) built around 50 years ago and whose deck is realized in prestressed concrete with a Niagara-type Gerber scheme. Starting with an extensive experimental campaign for the material characterization (only briefly described in this work, for the sake of brevity), an accurate FEM has been calibrated to simulate the results of field tests including dynamic and static load tests. Coupling information obtained from original design drawings and a parametric analysis to select the

most suitable boundary conditions and element types, a critical comparison between experimental and numerical results has led to the following conclusions: 1) the overpasses are not experiencing any evident damage or cracking process responsible for a variation of their modal parameters under service loads, as the estimates of natural frequencies and modal shapes obtained by the numerical simulation assuming ideal material properties are well aligned with the experimental findings from the dynamic field tests; 2) the overpasses remain uncracked under the maximum serviceability load prescribed by the load model 1 of the current Eurocode 1-Part 2, and the deflection response is consistent with that obtained by the numerical simulation. A simple procedure underlying a basic statistical processing of the concrete strength data for the determination of mean and relevant fractiles of the concrete elastic modulus makes it possible to incorporate the inherent material uncertainties in the critical analysis of the FEM results. The proposed method is general and is particularly useful when dealing with a family of bridges sharing similar structural scheme age and materials, to incorporate material uncertainties in the processing of diagnostic test data and to rationally exploit static and dynamic tests for an overall structural health assessment.

ACKNOWLEDGEMENTS

The authors express their gratitude to the Italian High Council of Public Works (CC.SS.LL.PP.) and the Network of University Laboratories of Seismic Engineering (RELUIS). The results of this study were achieved in the national agreement for implementing the agreement pursuant to art. 15 law 7 August 1990, No. 241 between the Superior Council of Public Works and RELUIS.

Self-healing performance of aged bacteria-based cementitious materials: An overview

Naru Kim, Seonhyeok Kim & H.K. Lee
Korea Advanced Institute of Science and Technology (KAIST), Daejeon, South Korea

ABSTRACT: The use of bacteria to impart self-healing capabilities to cementitious materials has garnered attention in addressing crack propagation issues within Submerged Floating Tunnel structures. Recent investigations into the self-healing performance of bacteria-based cementitious materials have highlighted challenges related to declining bacterial viability, attributable to adverse conditions and limited nutrients within the cementitious materials. This study presents a comprehensive overview of recent literature addressing the self-healing performance of aged bacteria-based cementitious materials, focusing on diverse bacterial strains, carrier for bacteria, and curing conditions for cementitious materials. In addition, a preliminary study examines the bacterial viability and self-healing performance of cementitious materials with different binders.

1 INTRODUCTION

The advent of Submerged Floating Tunnel (SFT) presents a possible solution for addressing challenges of waterway crossings, characterized by its consistent construction cost and weather-free operability (Zhang et al., 2010). However, the structural integrity of SFT faces potential threats due to the inherent susceptibility of cementitious materials to tensile loads and irreversible crack propagation (Kim et al., 2021), adding to the complexity on the repair work in underwater conditions (Iovane et al., 2023). Against this backdrop, the utilization of bacteria capable of self-healing in the cementitious materials emerges as a viable solution to mitigate cracks in underwater structures, addressing both environmental and economic considerations (Iovane et al., 2023). Consequently, researchers have explored the incorporation of bacteria into cementitious materials as a promising approach to recover the cracks on them (Vijay et al., 2017).

Preceded investigations into bacteria-based cementitious materials and their self-healing capabilities often overlooked the influence of curing age (Zheng and Qian, 2020). The inherently unfavorable conditions within cementitious materials, such as high alkalinity and pore sizes smaller than the bacteria, contribute to the gradual decline in bacterial viability over time (Kim et al., 2021, Zheng and Qian, 2020). Consequently, recent research has shifted focus on investigating the self-healing behaviors of aged cementitious materials and the various factors affecting them (Skevi et al., 2021).

Therefore, the present study aims to provide a comprehensive overview of recent research exploring the bacterial viability and self-healing performances of aged bacterial-based cementitious materials. Bacterial strains, carrier types, and curing conditions within these materials have been identified as key areas of interest across multiple studies. In addition, a preliminary study evaluates the impact of binder systems on bacterial viability and their subsequent self-healing performances (Kim et al., 2024).

DOI: 10.1201/9781003483755-53

2 LITERATURE REVIEW

2.1 *Bacterial strains*

The bacterial viability and self-healing performances in aged cementitious materials can be influenced by the genus species, and inherent characteristics of bacterial strains, as individual strains possess different conditions favoring $CaCO_3$ precipitation mechanism (Kim et al., 2021). For instance, ureolytic and non-ureolytic bacteria contribute to $CaCO_3$ precipitation through ureolysis and denitrification, respectively (Kim et al., 2021).

One typical non-ureolytic bacteria genus used for granting self-healing capacity on cementitious materials is *Bacillus* strain (Justo-Reinoso et al., 2021). Studies involving *Bacillus* species, including *B. pseudofirmus*, *B. cohnii*, and *B. halodurans* demonstrated varying degrees of spore viability and healing ratios after 7 days of encapsulation (Ivaškė et al., 2023). The test result showed that the bacterial spore viability decreased with time, and the spores of *B. halodurans* exhibited the highest viability exceeding 5% after 56 days (Ivaškė et al., 2023). Meanwhile, the healing ratio, defined as the ratio of covered crack width over initial crack width, was shown to be comparable among three species as 0.466 to 0.497, after 56 days of healing (Ivaškė et al., 2023). Regarding the results, Ivaškė et al. (2023) asserted that the carrier type or curing conditions may have affected more significantly than the species of bacteria on the healing performance of aged bacteria-based cementitious materials (Ivaškė et al., 2023).

Comparative studies between spore-forming (e.g., *Bacillus* strains) and non-spore forming bacteria (i.e., *Arthrobacter luteolus*, *Chryseomicrobium imtechense*, and *Corynebacterium efficiens*) in cementitious materials was performed by Shaheen et al. (Shaheen et al., 2023). The tested non-spore forming bacteria were alkaliphilic and calcifying thus having potentials to be used in self-healing cementitious materials (Shaheen et al., 2023). Spore-forming bacteria (i.e., *Bacillus* bacteria strains) exhibited slightly higher healing properties compared to the non-spore forming bacteria, in terms of crack enclosure, regain in compressive strength, permeability, and chloride resistance (Shaheen et al., 2023). Nevertheless, the non-spore forming bacteria showed significant recovery of these properties compared to bacteria-free samples, indicating the potential of both types of bacteria for healing at 90 days of curing (Shaheen et al., 2023).

2.2 *Carrier type*

The carrier type significantly influences bacterial viability within cementitious materials. Ordinary Portland cement, due to its alkalinity and dense microstructure, poses challenging conditions for bacterial survival. Specifically, the pH of ordinary Portland cement often exceeds the favorable pH range of alkaliphilic bacteria (Henze and Randall, 2018). Thus, the use of protective carrier for bacterial survival has been investigated in depth so far.

Studies by Ivaškė et al. (2023) encapsulated the self-healing bacteria within 2% sodium alginate, peptone, and meat extract. The initial bacterial viability was shown to be reduced in post-encapsulation (Ivaškė et al., 2023). However, the survival rate of bactera exceeded that of non-encapsulated bacteria (Ivaškė et al., 2023). Furthermore, the survival rate of bacteria spores in cement paste and cement mortar was also assessed, and it was revealed that the percentage of alive spore was higher in the cement paste (Ivaškė et al., 2023). It was claimed that the mortar might accompany rigid microstructure and compress the capsules with higher extent than the paste (Ivaškė et al., 2023).

The use of other encapsulating materials was explored by Wang et al. (2014), and Zheng & Qian (2020). The former study (Wang et al., 2014) tested the bacterial spores encapsulated in hydrogels. It was confirmed that the bacterial spores in hydrogel were hardly destroyed in the high alkaline cement and the bacterial viability was sustained by the encapsulation in hydrogel (Wang et al., 2014). In detail, the water stored in hydrogel was able to proceed the autogenous healing by bacterial spores, resulting in the higher healing ratio of the cement samples (Wang et al., 2014). The latter study (Zheng and Qian, 2020) delved into the cementing materials as carriers, namely potassium magnesium phosphate cement (MKPC) and sulphoaluminate

cement (SC), contributing to their low alkalinity. Consequently, the bacterial survival rate and area repair rate at 180 days of curing were greatly enhanced by the encapsulation of spores in both materials, while the use of SC achieved slightly higher survival rate and healing performance than that of MKPC (Zheng and Qian, 2020). It was asserted that the higher protective effect of SC can be due to the favorable pore characteristics for bacterial survival (Zheng and Qian, 2020).

2.3 *Curing conditions*

Curing conditions of cementitious materials significantly impact the survival and performances of bacteria. For instance, the outer temperature and salinity can offer significant impact on the survival of bacteria. Ivaškė et al. (2023) tested the temperatures of 20, 40, and 80 ˚C as curing temperatures of mortar samples with *B. pseudofirmus* bacteria for 3 days, and then cured at 20 ˚C for the rest of curing time (Ivaškė et al., 2023). The bacterial viability at 28 days of curing was observed to be approximately 10, 2, and 0%, respectively (Ivaškė et al., 2023). The results accorded with the bacterial growth rate with respect to temperature, which showed sharp decrease above 40 ˚C (Membré et al., 2005). Thus, the curing temperature of bacteria-based cementitious materials can be a crucial factor to sustain their healing performances for a long duration, regardless of the bacteria strains.

Furthermore, studies involving different temperatures (10, 20, and 30 ˚C) and salinity levels (0.5, 2, and 3.5%) for cementitious materials incorporating *Sporosarcina pasteurii* were performed (Kim et al., 2020). The growth rate and maximum optical density of bacteria were increased by the increase in temperatures from 10 to 30 ˚C (Kim et al., 2020). In addition, salinity addressed a positive relationship with bacterial growth but displayed less profound effects than temperature changes (Kim et al., 2020). These findings suggest that the selection of curing temperature and consideration of salinity levels are critical in sustaining long-term bacterial healing performances in bacterial-based cementitious materials (Kim et al., 2020, Lowe et al., 1993, Ivaškė et al., 2023).

3 A PRELIMINARY STUDY

A preliminary study was conducted to assess the bacterial viability and self-healing performances of aged bacteria-based cementitious materials using different binder types. The binder types used in the study are ordinary Portland cement and calcium sulfoaluminate cement. The bacteria strain of *S. pasteurii* was employed due to its ureolysis capabilities and high biomineralization rate (Achal et al., 2009). The assessment of these binder systems was conducted by the means of pH measurements, microscopic examination of cracks, and analysis of nutrient concentrations in cultured media containing granulated samples. Further details regarding the test methodologies and results will be thoroughly elucidated in Kim et al. (2024).

4 CONCLUDING REMARKS

The present study comprehensively reviewed literature on the bacterial viability and self-healing performance of aged bacteria-based cementitious materials. Investigations into extending bacterial lifespan within cementitious materials involved examining various factors such as bacterial strain, carrier type, and curing conditions. The bacterial viability and self-healing performances declined with increasing curing age of the cementitious materials, showing insignificant changes according to different bacterial strain (Ivaškė et al., 2023, Shaheen et al., 2023). Meanwhile, the utilization of low-alkaline carriers and maintaining temperatures within the range of 20 to 30 ˚C notably enhanced self-healing performances during later stages (Wang et al., 2014, Zheng and Qian, 2020, Kim et al., 2020). Therefore, for the successful integration of bacteria as self-healing agents in SFT, the choice of low-alkaline carriers and

careful consideration of temperature conditions will be pivotal in ensuring the longevity and efficacy of bacteria-based cementitious materials. Moreover, the results of preliminary study showed the enhancement in bacterial viability and self-healing performances in later stages of curing by the use of calcium sulfoaluminate cement instead of ordinary Portland cement as a binder.

Degradation prediction of FRP bars within concrete bridge decks in service

X.L. Zhao, Q. Zhao, I. Keitai, J.G. Dai & M.F. Kai
Department of Civil and Environmental Engineering, The Hong Kong Polytechnic University, Hong Kong, China

ABSTRACT: FRP bars are chemically anti-corrosive to chloride salts, and suitable to reinforce concrete structures in offshore and coastal regions. Some FRP bar-reinforced concrete structures have been in service for decades. As service time increases, FRP bar-reinforced concrete structures (FRPRC) will undergo degradations in different environments. The aim of this paper is to study the effects of service environments on the deterioration process of FRP bar-reinforced concrete structures. A fully coupled mesoscale physical-chemical-mechanical model was developed to simulate the ingress of moisture and carbon dioxide (CO_2) in concrete reinforced by FRP bars. The resultant effect of ingress on the mechanical deterioration of concrete was evaluated, such as carbonation depth and pH values. The predicted results were also compared and verified with field data after 15 years of service. In addition, the dominant factors from different service environments which degraded the FRP-concrete structures were discussed.

1 INTRODUCTION

The steel corrosion in concrete due to the use of deicing salts posed a severe safety risk to the bridges. As an alternative to steel reinforcement in concrete structures, fiber-reinforced polymer (FRP) bars are not sensitive to chloride salts, and they have been used to reinforce concrete in bridge decks since 1990s (Gooranorimi and Nanni 2017). Until now, many FRP-reinforced concrete structures have been in service for several decades. However, the long-term performance evaluations of these structures under natural atmospheric environments are rarely studied and reported.

To study the long-term performance of FRP bars, many accelerated experiments have been carried out by previous researchers, including exposure to wet-dry cycles, high relative humidity conditions, and immersion in water, seawater, acid and alkaline solutions (Chen et al. 2007; Wu et al. 2015; Zhao et al. 2021). However, these simulated conditions are usually much harsher than the actual service environments of FRP bars embedded in concrete. In other words, FRP bars in concrete will not degrade as fast as those exposed in these experiments. Thus, it is essential to propose an equation that can relate the accelerated data with the actual service life of FRP bars in concrete.

In this paper, the simulations of moisture ingress and CO_2 transport in concrete in the Sierrita de la Cruz Creek Bridge after 15 years of service were performed using the weather records in Amarillo, Texas, from 2000 to 2020. Firstly, the carbonation depth and pH were compared with the test data in the case study conducted by Gooranorimi and Nanni (Gooranorimi and Nanni 2017) to verify the accuracy of numerical simulations. Then, a relationship between the accelerated degradation rate in pore solution and the actual degradation rate of the relative humidity conditions in pores of concrete was proposed. Thus, the deterioration of GFRP bars embedded in concrete under a natural atmospheric environment can be evaluated by combining the chemical etching rate-based model with the moisture ingress and CO_2 transport in concrete cover.

DOI: 10.1201/9781003483755-54

2 MATERIALS AND SOFTWARE

Sierrita de la Cruz Creek Bridge was built in 2000, and it is located 40 km northwest of Amarillo, Texas (Phelan et al. 2003). The compressive strength of the concrete used in the bridge is 41.4 MPa. Two types of GFRP bars were used in the bridge. The DuCOM, an integrated coupled multi-scale platform (Maekawa et al. 2003a; b), was adopted to simulate the moisture and CO_2 ingress in concrete under the local atmospheric environment from 2000 to 2015.

3 MOISTURE INGRESS AND CO_2 TRANSPORT IN CONCRETE

The relative humidity (RH) in the pores of concrete structures varied with the atmospheric environment. The weather records from 2000 to 2015 in Amarillo, Texas, were collected. A concrete model with a size of 50 mm × 50 mm × 100 mm was built, as shown in Figure 1. Average temperatures and RHs per month from 2000 to 2015 in Amarillo, Texas, were used to carry out the moisture and CO_2 transport in the concrete bridge deck reinforced by GFRP bars. The time interval for simulation is 8 hours. The CO_2 concentration in the atmosphere was assumed to remain at 350 ppm. The RH and pH simulation results are illustrated in Figure 2 and Figure 3. The cracks due to traffic loading were not considered in the simulation.

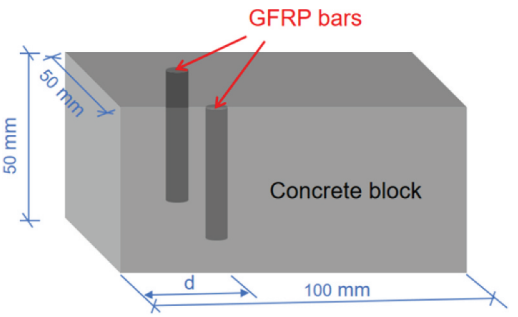

Figure 1. Size of concrete block for simulations.

From Figure 2, it can be observed that the RHs in concrete pores remained at 1.0 during the concrete casting and cement hydration period. However, the RHs in concrete pores fluctuatingly decreased to around 0.5 after 15 years of service. It is interesting to notice that the RHs of concrete pores near the surface are more likely to be affected by the atmosphere. The RH values of

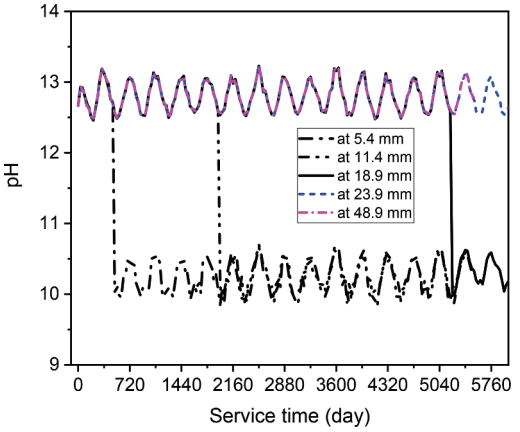

Figure 2. RH variations in concrete pores during service.

concrete pores near the concrete surface decreased much faster than those of internal pores in concrete. For instance, the RH at a depth of 5.4 mm decreased to 0.62, 0.56, and 0.64 after 30, 90 and 5400 days, respectively. By contrast, the RH values remained 0.98, 0.97, and 0.51 at a depth of 48.9 mm. In other words, the RHs near the concrete surface changed more quickly to the values approximate to those of the atmosphere than the internal parts of the concrete block, which is in accordance with the observed data.

CO_2 ingress has a significant effect on the pH values of concrete pore solution, as shown in Figure 3. The initial pH values of concrete pore solution remained around 13.0 after 28 days. As more CO_2 penetrated the concrete from the atmosphere, the pH values began to decrease, and carbonation occurred accordingly.

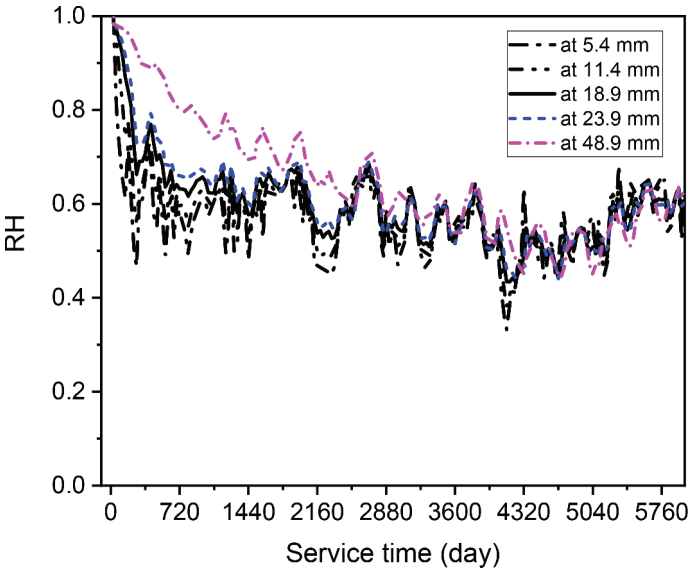

Figure 3. pH variations of concrete pore solution during service.

The pH values at five different points were compared, and their carbonation depths were evaluated after 15 years of service, as shown in Figure 4. After 540 days, the pH value at the depth of 5.4 mm decreased below 10.0. Thus, the maximum carbonation depth after 1.5 years of

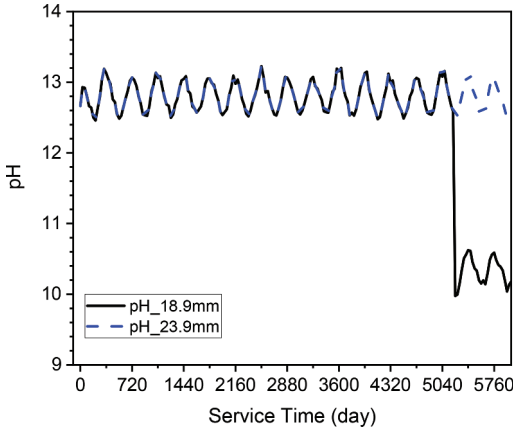

Figure 4. Carbonation evolution with service time.

service should be 5.4 mm. Similarly, the maximum carbonation depths after 2010 and 5220 days (5.8 and 14.5 years) of service reached 11.4 and 18.9 mm, respectively. According to the case study by Gooranorimi and Nanni (Gooranorimi and Nanni 2017), irregular carbonation fronts were observed in three tested samples after 15 years of service, varying between 25 and 32 mm. Considering the fact that the cracks due to traffic loads and the imperfections in construction were not considered in this simulation, the carbonation predictions are still valuable and reasonable, and these results can be referenced by engineers and maintainers for public infrastructures.

4 DEGRADATION MODEL OF FRP BARS IN SERVICE

4.1 *Gas-liquid environment shift equation*

Considering the contact probability of water molecules with FRP bars, the degradation rate of FRP bars in air at a given relative humidity (RH) can be related to that exposed in the pore solutions through Equation (1).

$$v_{RH} = v_{sol} \times \frac{\rho_{sat}}{\rho_{liq}} \times F_{gls} \times RH \tag{1}$$

where v_{RH} denotes the degradation rate in RH conditions; v_{sol} denotes the degradation rate of GFRP bars exposed in solution; ρ_{liq} is the density of the liquid solution and ρ_{sat} is the maximum vapor water content in the unit volume of air at a given temperature; F_{gls} is the reaction participation ratio considering the different states of vapor and liquid water.

4.2 *Chemical etching rate-based model*

The chemical etching rate-based model (CEM) proposed by Zhao et al. (Zhao et al. 2021, 2022) can be summarized below, as shown in Equations (2) ~ (4):

$$v_{sol} = r_{sf_m} V_m + r_{sf_f} V_f \tag{2}$$

$$R_{dg} = \int_0^t v dt \tag{3}$$

$$f_t = \frac{\left[R_0 - \left(A_1 e^{\frac{-E_{a_m}}{RT}} \times \frac{1}{N} \times V_m + A_2 e^{\frac{-E_{a_f}}{RT}} \times V_f\right) \times c[OH^-] \times t\right]^2}{{R_0}^2} f_0 \tag{4}$$

$$c[OH^-] = 10^{pH-14} \tag{5}$$

where v denotes the normal etching rate to GFRP bars exposed to pore solution. r_{sf_m} and r_{sf_f} are the reaction rates of hydrolysis of the matrix and the etching to glass fibers, respectively. V_f and V_m are molar volumes of fibers and matrix. $c[OH^-]$ denotes the concentration of hydroxyl ions. A_1 and A_2 are the pre-exponential factors of matrix and glass fiber, respectively. E_{a_m} and E_{a_f} are the active energy of matrix and glass fiber. N is the number of ester groups in the unit element of the matrix. f_t and f_0 are the residual tensile strength and initial tensile strength of GFRP bars. R_0 and R_{dg} are the bar diameter and degradation depth.

4.3 *Degradation of GFRP bars in concrete*

Based on the CEM and the proposed formula in Equation (1), the degradation of GFRP bars in concrete during service can be evaluated. The predicted degradation depths of GFRP bars are plotted against service time in Figure 5. Here, the saturated water vapor content is around 30 grams at 25ºC, while the water density is 1000 kg/m^3. The gas-liquid shift factor F_{gls} was taken as 1000 in the simulation, further research is needed to determine more accurate F_{gls}.

The degradation of GFRP bars in concrete is very minor after 15 years of service, with a degradation depth of 0.0135 and 0.0142 mm at the depth of 18.9 and 23.9 mm from the surface. It means that the tensile strength retentions of GFRP bars at the two positions are 99.7% and 99.6% after 15 years. The extracted GFRP samples showed that almost no degradation occurred. The simulation results agree well with the field data. It should be noted that carbonation is beneficial to GFRP bars in concrete because the pH values of the pore solution after carbonation will decrease (Zhao et al. 2021).

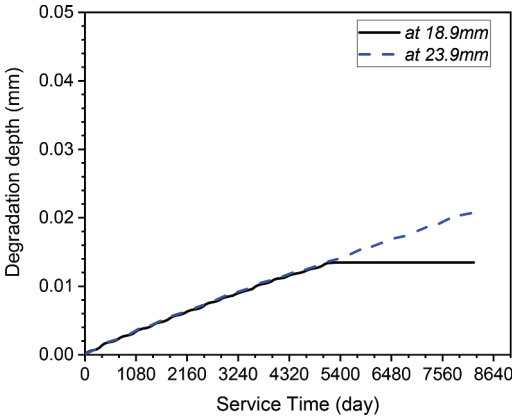

Figure 5. Degradation depth of GFRP bars during service.

5 CONCLUSION

The paper provided a degradation modeling of GFRP bars in service. Based on the chemical etching model and gas-liquid environment formula and the moisture and CO_2 ingress in concrete, the degradation of GFRP bars in the Sierrita de la Cruz Creek Bridge was evaluated during the service using local weather records from 2000 and 2015. Some conclusions can be drawn as follows.

- The distributions of moisture (RH) and pH values in concrete during service were provided using the DuCOM, and then the pH values and carbonation depth were compared and verified with field data.
- A gas-liquid environment shift equation was proposed to relate the accelerated degradation rate in solution and the normal degradation rate in air.
- The degradation of GFRP bars in concrete was predicted during the service period from 2000 to 2015. The simulation results agreed well with the test data from the extracted GFRP samples after 15 years of service.

ACKNOWLEDGEMENTS

The authors want to express our sincere appreciation to Dr. Sandra Rayne from the Climate Sciences and Services Division of NOAA's National Centers for Environmental Information for her kind guidance to help us obtain the weather records in Amarillo, Texas from 2000 to 2022.

Load-bearing capacity assessment of RC beams using corrosion crack widths

Takehiro Adachi, Mitsuyoshi Akiyama, Taiki Yamada, Satoru Nakamura & Zhejun Xu
Waseda University, Tokyo, Japan

Dan M. Frangopol
Lehigh University, Bethlehem, PA, USA

ABSTRACT: In chloride-laden environment, steel corrosion in RC members leads to their structural performance deterioration. Inspection methods using unmanned aerial vehicle (UAV) have attracted attention as an alternative method of classical visual inspection. Corrosion crack width detected by UAV could be an effective information to evaluate the structural condition. However, since the relationship between steel corrosion and crack widths is complex and uncertain due to associated parameters such as structural details, this observational information has not been used to evaluate the structural performance of in-situ concrete structures. In this study, the load-bearing capacity of deteriorated RC members is probabilistically evaluated using the observational corrosion cracks obtained by UAV, in addition to finite element analysis, stochastic field theory, and machine learning. A case study is presented to investigate the effect of the different measurement method of corrosion crack widths between UAV shooting and close-up shooting with digital camera on the load-bearing capacity.

1 INTRODUCTION

For reinforced concrete (RC) members located in a chloride-laden environment, corrosion of steel bars causes cover concrete cracking and structural performance degradation. Quantitative assessment of the structural performance of deteriorated RC structures is of great importance in maintenance. However, it is difficult to confirm the corrosion status of steel bars inside RC members directly using nondestructive detection techniques. Since corrosion-induced cracks are caused due to expansion pressure from corrosion products, they could be useful information for estimating steel weight loss inside the RC members. However, predicting the structural performance based on crack information remains challenging due to the uncertain nonlinear relationship between steel corrosion and corrosion cracks (Lim et al. 2017). Zhang et al. (2021) and Srivaranun et al. (2023) presented a probabilistic framework for estimating the load-bearing capacity of deteriorated RC members with the corrosion crack width distribution, using machine learning, stochastic simulation, nonlinear finite element analysis (Non-FEA) and Monte Carlo simulation (MCS). In their framework, the database for training machine learning models was developed numerically as a relationship between corrosion crack width and steel weight loss. In order to apply their framework of load-bearing capacity assessment to on-site corroded concrete structures, it is necessary to develop techniques for obtaining corrosion cracks.

Recently, images taken by Unmanned Aerial Vehicles (UAVs) have been utilized for crack detection of concrete structures (Ding et al. 2023). However, it is not yet widely used for structural capacity assessment. Figure 1 shows a proposed probabilistic framework for estimating the load-bearing capacity of corroded RC members using observational information of corrosion

DOI: 10.1201/9781003483755-55

cracks obtained by UAV. In addition to the application of UAVs, a database of the relationship between corrosion crack width and corrosion product thickness for training the machine learning model is developed in this study. To ensure that the numerical database can reflect the information obtained from the actual corroded RC beams, a new corrosion expansion model considering the difference in corrosive conditions is presented. After obtaining the corrosion crack distributions by remote shooting by UAV, the load-bearing capacity of deteriorated RC beams is finally estimated by utilizing the machine learning model and MCS-based FEA.

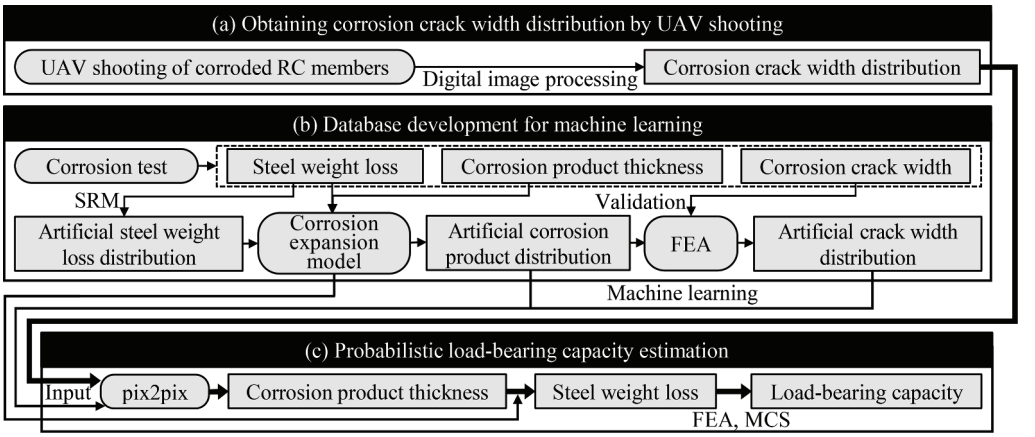

Figure 1. Probabilistic framework for estimating the load-bearing capacity of corroded RC beams using observational information on corrosion cracks obtained by UAV.

2 MEASUREMENTS OF CORROSION CRACK WIDTHS WITH UAV

2.1 *Accelerated corrosion test*

To simulate the inspection of deteriorating concrete structures using UAVs, large-scale RC beams are cast and corroded by the galvanostatic (GS) method. Table 1 shows details of the RC beam. The specimen has a cross-section of 370 mm × 450 mm and a length of 6,000 mm. Three tensile rebars, referred to as L, C, and R (left, center, and right, respectively), are arranged. In the corrosion test, the direct current (i.e., 500 $\mu A/cm^2$) is applied only to the specified corrosion region (2,800 mm ~ 3,200 mm from the left end of the RC beam, same as the pure bending region) by placing a water-absorbing sponge immersed in the 3% NaCl solution under the RC beam.

After the loading test, the steel weight loss of the tensile rebars removed from the RC beam is measured at 10 mm intervals in the longitudinal direction of the corrosion region in the RC beam using digital calipers. Figure 2 shows the steel weight loss distribution.

2.2 *Measurement of corrosion crack width with UAV and close-up shooting*

After the completion of the corrosion test, UAVs are used to take a picture of corrosion cracks on the bottom surface of the RC beam. Close-up shooting with a digital camera is also conducted to compare the measurement accuracy of the corrosion crack width. Table 2 shows the performance of the camera used in each shooting method. The UAV navigates longitudinally beneath the specimen with its camera lens pointing vertically upward. The shooting distance is approximately 0.45 m. Figure 3 shows corrosion crack width distributions and corresponding images obtained by each shooting method. The corrosion crack widths were measured with 10 mm intervals using digital image processing.

Table 1. Structural details and corrosive conditions of the large-scale RC beam.

Beam	Cover (mm)	Rebar spacing (mm)	Rebar diameter	Stirrup (mm)	Compressive strength (28 days) (MPa)	Target maximum corrosion crack width (mm)
A-1	20	95	DB19	DB10@200	41.7	0.3 ~ 0.6

Table 2. Performance of cameras.

Shooting method	UAV shooting	Close-up shooting
Sensor	1/2.3 inch	1/2.93 inch
Sensor size	6.2 mm × 4.7 mm	4.8 mm × 3.6 mm
Image resolution	3040 × 4056	3024 × 4032
Focal length*	23	28
F-number	f/2.8	f/1.8

*Focal length represents 35mm equivalent focal length.

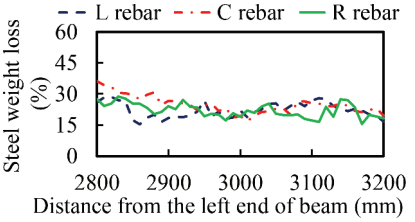

Figure 2. Steel weight loss distribution.

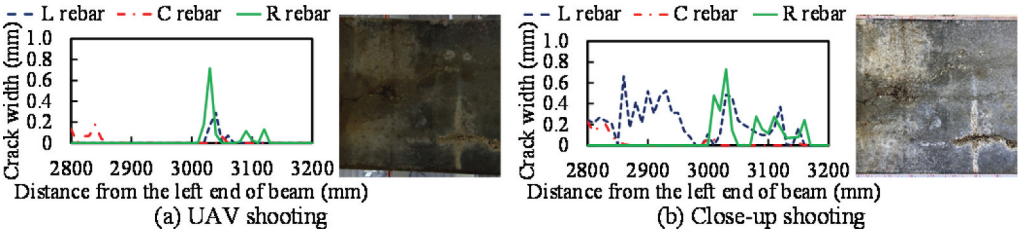

Figure 3. Corrosion crack width distribution and corrosion crack images.

2.3 *Effect of shooting method*

The effects of each shooting method on the measurement accuracy of corrosion crack width are compared. As a benchmark of the measurement, the number of pixels corresponding to corrosion cracks measured manually at certain intervals in the longitudinal direction were converted to the corrosion crack width.

Table 3 shows a comparison of the mean values of corrosion crack widths. Despite the same degree of image resolution, the corrosion crack width obtained by the UAV shooting was smaller than that obtained by the close-up shooting. Possible reasons include: 1) UAVs photographed the bottom of the specimen, which was not illuminated; and 2) the stability of UAV was disturbed by the wind reflected from the bottom of the specimen, which resulted in a blurred image. Therefore, when image processing of the crack images taken by the UAV is performed, it will be difficult to obtain the corrosion crack width from a concrete surface contaminated with rust fluid.

Table 3. Comparison between mean corrosion crack widths obtained by two shooting methods and correct value.

	Mean corrosion crack widths		
Beam	Correct value (mm)	UAV shooting (mm)	Close-up shooting (Digital image processing) (mm)
A-1	0.132	0.019	0.100

3 DEVELOPMENT OF NUMERICAL DATABASE FOR MACHINE LEARNING

3.1 *Modeling of corrosion product*

For reproducing the characteristics of corrosion-induced crack width distributions, a new model of steel corrosion product is developed in this study using the test specimens listed in Table 4 (Nakamura et al. 2022). The specimen had a cross-section of 300 mm × 160 mm and a length of 1460 mm. Three tensile rebars were arranged and exposed to the accelerated corrosion.

The corrosion expansion model is proposed considering the effect of current density. To develop a corrosion expansion model, corrosion product thickness is obtained every 5 mm in the longitudinal direction and every 30° within the cross-section using X-ray photography and digital image processing. The corrosion product thickness *Tcp* is modeled and expressed by:

Table 4. Structural details of the RC beams for developing the model of steel corrosion product.

Beam	Cover (mm)	Rebar spacing (mm)	Rebar diameter	Stirrup (mm)	Current density ($\mu A/cm^2$)	Compressive strength (28 days) (MPa)
B	20	95	DB13	DB6@100	100	45.0
C	20	57	DB13	DB6@100	500	47.8
D	20	57	DB19	DB6@100	100	45.7
E	20	95	DB13	DB6@50	100	46.6
F	20	57	DB13	DB6@100	100	44.9

$$Tcp = \alpha(\theta) \times MTcp_l \tag{1}$$

$$\alpha(\theta) = 1.884 \times \exp[-\{(\theta - 180)/91.69\}^2] + 0.1241 \tag{2}$$

$$MTcp_l = n \times (R - R') \tag{3}$$

$$n = \left\{(R + R')/R^2\right\} \times (2.873 - 2.372 \times 10^{-3} I_{corr}) \tag{4}$$

where R (mm) and R' (mm) are the rebar diameters before and after the corrosion test, respectively. α is the angle parameter representing the shape of corrosion products, which typically accumulate predominantly on the bottom of the RC beams. $MTcp_l$ (mm) is the mean value of corrosion products per cross-section. The constant n depends on the corrosive environments.

3.2 *Stochastic simulation of steel weight loss*

Based on the steel weight loss distributions inside the RC beams shown in Table 4, stochastic parameters for the spectral representation method (SRM) are derived (Srivaranun et al. 2021). In his stochastic simulation, the spatial correlation of steel weight loss distributions in the longitudinal and transverse directions are represented by the auto-spectral density function (auto-SDF) and the coherence function, respectively.

3.3 *Development of database*

Figure 4 Shows a procedure to obtain the relationship between distributions of steel weight loss and corrosion crack width. From the steel weight loss distribution simulated by SRM, corrosion product thickness is determined and provided as imposed displacement at the location of tensile rebars in the Non-FEA for obtaining the corresponding corrosion crack width.

4 PREDICTION OF CORROSION DISTRIBUTION USING MACHINE LEARNING

Using the database developed in Section 3, a machine learning model is constructed to predict the corrosion product distribution from corrosion crack width distribution. The pix2pix model is

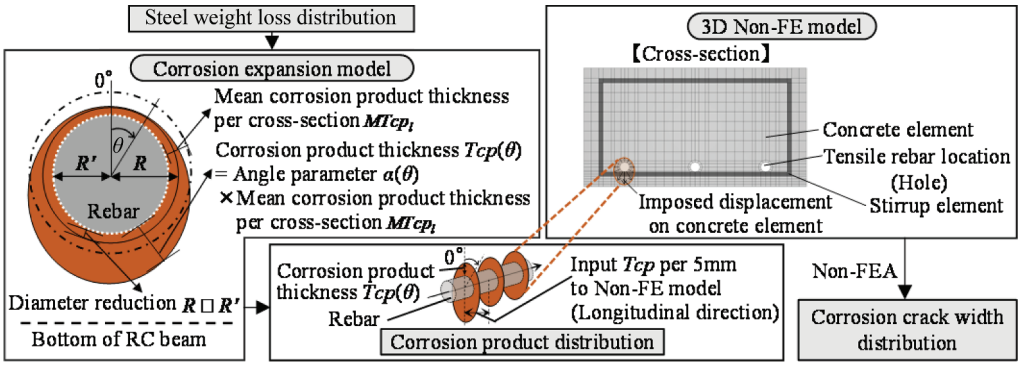

Figure 4. Application of corrosion expansion model to Non-FE model.

selected in this study to consider the two-dimensional spatial variability of the steel weight loss. To construct the pix2pix model, corrosion crack width distributions and corrosion product distributions with 41 values (10 mm interval) per rebar and the structural details (i.e., rebar diameter and rebar spacing) are linearly converted to a luminance value (0 to 255), respectively. Then, 8-bit color images with corrosion crack width distributions and structural details are given as R, G, and B channels, respectively, and the 8-bit grayscale images of the corrosion product distributions can be generated. In the estimation of corrosion product distribution from corrosion crack width distribution using pix2pix, the epoch number is set to 50 and 240 images are used for training.

The model error ε_{test} associated with pix2pix is quantified as the difference between the testing data and predicted results of steel weight loss. The details of pix2pix and corresponding model error quantification are provided in Srivaranun et al. (2023).

5 CASE STUDY: PROBABILISTIC ESTIMATION OF LOAD-BEARING CAPACITY OF CORRODED RC BEAMS USING MCS

5.1 *Corrosion crack information for load-bearing capacity assessment*

As the case study, the corrosion crack width distributions of the large-scale RC beam shown in Table 1, obtained by UAV shooting and close-up shooting, are used in the pix2pix model to predict the steel weight loss distribution. Since there is a difference in load-bearing capacity between the experimental and 3D Non-FE results, the model error ε_{FE} associated with 3D Non-FEA is quantified using the previous loading test results. ε_{FE} is assumed to follow a normal distribution. Considering the pix2pix model error ε_{test} and the Non-FE model error ε_{FE}, Monte Carlo-based Non-FEA is performed to obtain the load-bearing capacity.

5.2 *Results and discussion*

Figure 5 shows a comparison of the yield load between the experimental and computational results of the A-1 specimen. In the case of close-up shooting, the experimental yield load is located near the mean value of the estimated probability density function (PDF). With the estimation results by UAV shooting, the assessed PDF of flexure capacity was overestimated compared to the loading test result. This result suggests that the measurement accuracy of corrosion crack width has a significant impact on the estimation of the load-bearing capacity of deteriorated RC structures.

The minimum visible scale width which was obtained by using the crack scale attached to the bottom of the RC beam, depends significantly on the shooting method; the minimum visible scale width was 0.05 mm for close-up shooting and 0.20 mm for UAV shooting. In order to estimate the load-bearing capacity of deteriorated RC structures with sufficient accuracy using UAV shooting, the quality of the image is should be equivalent to that of the close-up image.

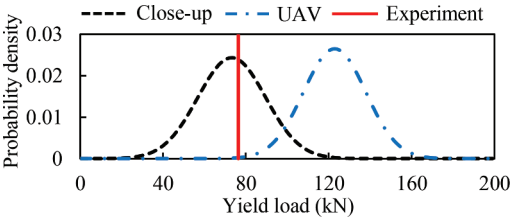

Figure 5. Experimental result and estimated probability density functions of yield load.

6 CONCLUSIONS

1. A framework, which consists of digital image processing, machine learning, stochastic field theory, nonlinear finite element analysis, and Monte Carlo simulation, was proposed to calculate the PDF of the load-bearing capacity of corroded RC members based on images of corrosion cracks taken by a UAV.
2. A database for pix2pix machine learning model to predict steel weight loss from corrosion crack width was developed using a proposed corrosion expansion model.
3. The quality of corrosion crack images required for load-bearing capacity assessment of corroded RC members was discussed. It is clarified that the images which can capture the crack width of 0.05 mm is required for the UAV inspection of the deteriorating concrete structures.

Probabilistic structural identification using time-dependent deflection of prestressed concrete bridges

Siyi Jia & Mitsuyoshi Akiyama
Waseda University, Tokyo, Japan

Dan. M. Frangopol
Lehigh University, Bethlehem, PA, USA

ABSTRACT: This paper presents a probabilistic structural identification (SI) framework using the time-dependent deflection of prestressed concrete bridges (PSCBs). The framework involves a stochastic volatile model (SVM) that considers the full ranges of the unobserved state variables affecting the time-dependent deflection of PSCBs, namely, structural rigidity, creep, shrinkage, prestress level and dead load level, along with the volatility parameters associated with the deterioration path of structural rigidity, which is modeled via the Wiener process. Exploiting the latent structure of the SVM, a cyclic Markov chain Monte Carlo sampler is proposed to draw samples from the joint posterior distribution of the unobserved state variables and volatility parameters. In an illustrative example, deflection measurements of an existing bridge are used as the target information for SI. The updated model can reveal the accumulated damage of the case bridge over the monitoring period.

1 INTRODUCTION

The time-dependent deflection of prestressed concrete bridges (PSCBs) features low-cost acquisition and contains low-entropy evidence about multiple structural states, including damage accumulation, creep and shrinkage behaviors of concrete. Structural identification (SI) using the time-dependent deflection is of practical importance for PSCBs, because it avoids the calibration of mass and damping ratio as required in vibration-based SI (Buda and Caddemi, 2007). Previous studies on SI using the time-dependent deflection of bridges have been primarily output-only analyses that focus on discerning anomalous data outside of expected bounds (Hedegaard et al., 2017; Reynders et al., 2013). However, output-only damage detection is subject to large uncertainties due to changing environmental conditions and time-dependent material behaviors such as creep and shrinkage, which can mask subtle changes in damage (Hedegaard et al., 2017). Therefore, more reliable SI conditioned on time-dependent deflection requires a model-based inverse analysis that is anchored on mechanical models. On the other hand, the uncertainties in the time-dependencies of state variables associated with time-dependent deflection are rarely considered in the previous studies. It is necessary to consider these uncertainties since the time-dependencies of state variables can vary significantly with changing environments. By modelling the stochastic time-dependencies of state variables, the inverse analysis conditioned on time-dependent deflection is converted to a stochastic volatility model (SVM), in which both the unobserved state variables and their time-dependencies are subject to inference (Jacquire et al., 1994).

This paper presents a probabilistic SI framework for an SVM conditioned on the time-dependent deflection of PSCBs. As illustrated in Figure 1, the SI considers the full ranges of the unobserved state variables affecting the time-dependent deflection of PSCBs, namely, structural rigidity, creep, shrinkage, prestress level and dead load level, along with the volatility parameters associated with the deterioration path of structural rigidity, which is modeled

DOI: 10.1201/9781003483755-56

by the Wiener process. A rate-type time-dependent finite element model (FEM) is constructed considering the effects of the state variables. In view of the latent structure of the SVM, a cyclic Markov chain Monte Carlo (CMCMC) sampler is proposed to draw samples from the joint posterior distribution of the unobserved state variables and volatility parameters. As an illustrative example, the proposed framework is applied to the SI of an existing PSCB.

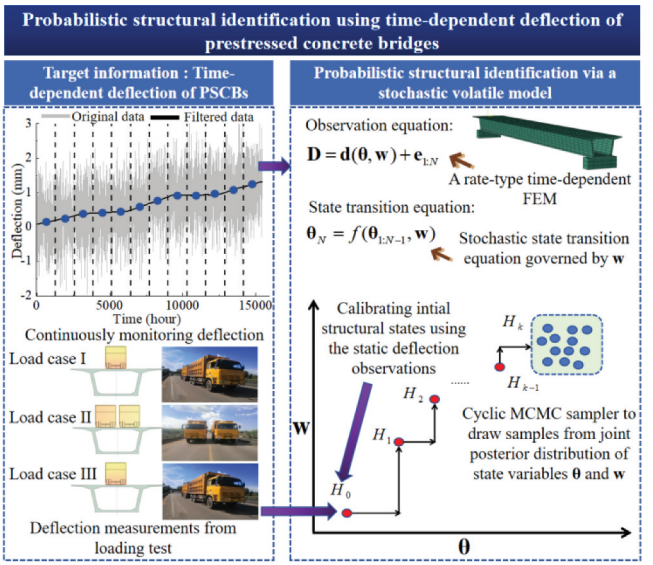

Figure 1. Flowchart of probabilistic structural identification of PSCBs.

2 METHOD

2.1 *Inference Frame of the SVM*

The SVM involves an observation equation that links the deflection measurements $\mathbf{D}_{1:N}$ from time 1 to time N with the unobserved time series of state variables $\boldsymbol{\theta}_{1:N}$:

$$\mathbf{D}_{1:N} = \mathbf{d}(\theta_{1:N}, \mathbf{w}) + \mathbf{e}_{1:N} \tag{1}$$

where $\mathbf{d}$ denotes the time-dependent deflection of the PSCB as computed using a physical model. $\mathbf{e}_{1:N}$ is the error term that follows a normal probability distribution N(0, σ). σ is the standard deviation of the model. The stochastic transition density of $\boldsymbol{\theta}$ is determined by a stochastic hyperparameter vector $\mathbf{w}$:

$$\boldsymbol{\theta}_N = f(\boldsymbol{\theta}_{1:N-1}, \mathbf{w}) \tag{2}$$

The joint posterior distribution of $\boldsymbol{\theta}_{1:N}$ and $\mathbf{w}$ conditioned on $\mathbf{D}_{1:N}$ is provided by Bayes theorem (Jacquire et al., 1994):

$$p(\boldsymbol{\theta}_{1:N}, \mathbf{w}|\mathbf{D}_{1:N}) = \frac{L(\mathbf{D}_{1:N}|\boldsymbol{\theta}_{1:N}, \mathbf{w})p(\boldsymbol{\theta}_{1:N}|\mathbf{w})p(\mathbf{w})}{\int L(\mathbf{D}_{1:N}|\boldsymbol{\theta}_{1:N}, \mathbf{w})p(\boldsymbol{\theta}_{1:N}|\mathbf{w})p(\mathbf{w})d\mathbf{w}} \tag{3}$$

where $p(\mathbf{w})$ is the prior probability density of $\mathbf{w}$. $p(\boldsymbol{\theta}_{1:N}|\mathbf{w})$ is the prior distribution of $\boldsymbol{\theta}$ given a deterioration path defined by $\mathbf{w}$. L denotes the likelihood function, which can be formulated as a Gaussian density of the error term $\mathbf{e}$.

2.2 *State variables and their time-dependencies*

Time-dependent deflection of PSCBs is initiated by the dead loads that are not offset by the prestress, which are magnified by the creep effects of concrete. Shrinkage and damage accumulation also contribute to the time-dependent deflection. Accordingly, $\boldsymbol{\theta} = (\theta_{cr}, \theta_{sh}, \theta_q, \theta_{ps}, \theta_e)^T$ in which θ_{cr} and θ_{sh} represent the ratios between the actual creep compliance J and shrinkage strain ε_{sh}, with respect to those computed from prescribed by the B3 model, denoted as J_0 and $\varepsilon_{sh,0}$, respectively (Bažant and Baweja, 1995):

$$J = \theta_{cr} J_0, \varepsilon_{sh} = \theta_{sh} \varepsilon_{sh,0} \tag{4}$$

Similarly, θ_q, θ_{ps} denote the ratios between actual dead load p_q and prestress p_{ps} of PSCBs, with respect to their designed values $p_{q,0}$ and $p_{ps,0}$, respectively:

$$p_q = \theta_q p_{q,0}, p_{ps} = \theta_{ps} p_{ps0} \tag{5}$$

θ_e represents the reduction in structural rigidity, which is characterized in terms of the reduction of the global stiffness matrix $\mathbf{k}_e$ (Cheung and Beck, 2009):

$$\mathbf{k}_e = \theta_e \mathbf{k}_e{}^0 \tag{6}$$

where $\mathbf{k}_e{}^\circ$ is the nominal global stiffness matrix calculated based on the design values of material elasticity and structural geometry.

For aging PSCBs, the statistics of $\boldsymbol{\theta}$ need to be re-calibrated because they can largely deviate from their prior distributions. Specifically, $\boldsymbol{\theta}_0 = (\theta_{cr,0}, \theta_{sh,0}, \theta_{q,0}, \theta_{ps,0}, \theta_{e,0})^T$ is calibrated using the static deflection measurement $\mathbf{D}_0$ before the continuous monitoring:

$$p_0(\boldsymbol{\theta}_0) = \frac{L(D_0|\boldsymbol{\theta}_0) p(\boldsymbol{\theta}_0)}{\int L(D_0|\boldsymbol{\theta}_0) p(\boldsymbol{\theta}_0) d\boldsymbol{\theta}_0} = c_0{}^{-1} L(D_0|\boldsymbol{\theta}_0) p(\boldsymbol{\theta}_0) \tag{7}$$

The calibrated statistics of θ_{cr}, θ_{sh}, θ_q and θ_{ps} are assumed to remain time-invariant, while the time-dependency of $\boldsymbol{\theta}_e$ should be considered and calibrated by the continuously monitoring deflection data, due to the accumulation of structural damage. In this paper, the decrement in structural rigidity over a time increment Δt, $\Delta\theta_e(t) = \theta_e(t+\Delta t) - \theta_e(t)$, is assumed to be independent of $\theta_e(t)$ and modeled as a Gaussian variable:

$$\Delta\theta_e(t) \sim \mathrm{N}(\beta \Delta\Lambda(t), \alpha^2 \Delta\Lambda(t)) \tag{8}$$

where β and α denote the mean and standard deviation, respectively, of each increment. $\Delta\Lambda(t) = \Lambda(t+\Delta t) - \Lambda(t)$ is the increment in a monotonically increasing function of time $\Lambda(t) = t^q$ (Peng et al., 2014), where q is the exponential factor.

2.3 *Rate-type time-dependent FEM*

A step-by-step time-dependent FEM is constructed to compute $\mathbf{d}$ in Equation (1), which reduces the time-dependent computation to a sequence of elastic analyses based on the creep increment in each time step (Jia et al., 2023). To remove the dependencies among creep increments and the history stress in previous time steps, a rate-type formulation is adopted, in which the creep compliance J at time τ is approximated by an m-order Dirichlet series

$$J(\tau, t') = \sum_{l=1}^{m} a_l(t') [1 - e^{-\kappa_l(\tau - t')}] \tag{9}$$

where $\boldsymbol{\kappa}_l$ is the exponent associated with the l-th Dirichlet basis. t' is the age of loading. The undetermined parameters a are calibrated based on the observed creep/shrinkage curve. The time-dependent FEM is processed in ABAQUS using users' subroutines USDFLD and

EXPAN, which convert the creep and shrinkage increments at each time-step into the thermal strain applied to the concrete. Detailed formulations of the time-dependent FEM can be found in Jia et al. (2023).

A Kriging surrogate model of the time-dependent FEM is built to improve the computation efficiency for the samplers, in which $\mathbf{d}$ is modeled as a Gauss process determined by input $\boldsymbol{\theta}$, centered on the best linear unbiased estimate $\mu_d(\boldsymbol{\theta})$, with variance $\sigma^2{}_d(\boldsymbol{\theta})$ (Santner et al., 2003)

$$\mathbf{d}(\boldsymbol{\theta}) \sim \mathrm{N}(\mu_d(\boldsymbol{\theta}), \sigma^2{}_d(\boldsymbol{\theta})) \tag{10}$$

2.4 *Samplers for the posterior distribution*

The analytical solution for the joint posterior distribution $p(\mathbf{w}, \boldsymbol{\theta}_{1:N} | \mathbf{D}_{1:N})$ in Equation (3) is generally intractable. Alternatively, a sampler is constructed to draw samples from $p(\mathbf{w}, \boldsymbol{\theta}_{1:N} | \mathbf{D}_{1:N})$, and the samples are used to approximate the statistics of the distribution. Considering that the conditional distributions between $\boldsymbol{\theta}_{1:N}$ and $\mathbf{w}$ are readily available, a CMCMC sampler is designed as a Gibbs-type sampler that alternatively draws samples from $\boldsymbol{\theta}_{1:N}$ and $\mathbf{w}$ in the augmented state space $(\boldsymbol{\theta}_{1:N}, \mathbf{w}) \in H$ (Jacquire et al., 1994).

As illustrated in Figure 2, the CMCMC sampler starts at the point H_0 $(\boldsymbol{\theta}_0, \mathbf{w}_0)$, which is obtained by the Bayesian inference in Equation (7). Each step of the Markov chain involves alternating sampling from the two conditional densities $p(\boldsymbol{\theta}_{1:N}|\mathbf{w}, \mathbf{D}_{1:N})$ and $p(\mathbf{w}|\boldsymbol{\theta}_{1:N}, \mathbf{D}_{1:N})$, which are derived through Bayesian inference conditioned on the deflection measurements $\mathbf{D}_{1:N}$:

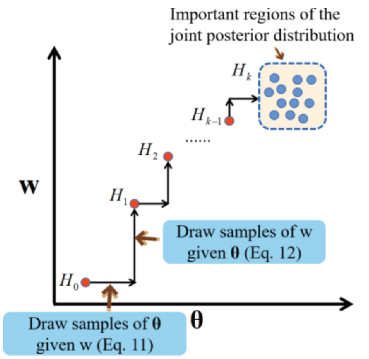

Figure 2. Flowchart of the CMCMC sampler.

$$p(\boldsymbol{\theta}_{1:N}|\mathbf{w}, \mathbf{D}_{1:N}) \propto L(\mathbf{D}_{1:N}|\mathbf{w}, \boldsymbol{\theta}_{1:N}) p(\boldsymbol{\theta}_{1:N}|\mathbf{w}) \tag{11}$$

$$p(\mathbf{w}|\boldsymbol{\theta}_{1:N}, \mathbf{D}_{1:N}) \propto L(\mathbf{D}_{1:N}|\mathbf{w}, \boldsymbol{\theta}_{1:N}) p(\mathbf{w}|\boldsymbol{\theta}_{1:N}) \tag{12}$$

where $p(\boldsymbol{\theta}_{1:N}|\mathbf{w})$ refers to the prior distribution of $\boldsymbol{\theta}_{1:N}$ under a certain degradation path that is specified by $\mathbf{w}$. $p(\mathbf{w}|\boldsymbol{\theta}_{1:N})$ is readily available from the Bayesian treatment of linear models with specified samples of $\boldsymbol{\theta}_{1:N}$ (Jacquire et al., 1994). The drawn samples gradually populate the important regions in posterior distribution $p(\mathbf{w}|\boldsymbol{\theta}_{1:N}, \mathbf{D}_{1:N})$ after a sufficient number of iterations.

3 NUMERICAL APPLICATION

3.1 *Case description*

The bridge analyzed herein is a posttensioned single box-girder PSCB built in 1985. Figure 3 presents the geometry and monitoring scheme of the bridge.

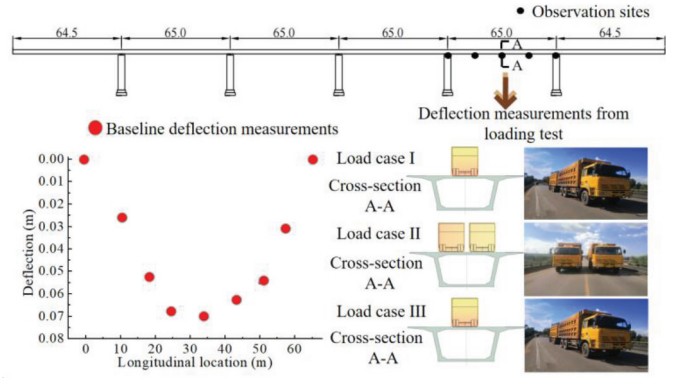

Figure 3. Geometry and monitoring scheme of the case bridge (unit: m).

3.2 *Inference results before the continuous monitoring*

As formulated in Equation (7), $\boldsymbol{\theta}_0 = (\theta_{cr,0}, \theta_{sh,0}, \theta_{q,0}, \theta_{ps,0}, \theta_{e,0})^T$ is calibrated by the Bayesian inference conditioned on deflection measurements $\mathbf{D}_0$ before the continuous monitoring. As shown in Figure 3, $\mathbf{D}_0$ includes heterogeneous deflection measurements obtained from a static loading test and baseline static deflection measured by the electronic level, which were used to update $\boldsymbol{\theta}_0$ in a sequential manner. The marginal posterior distributions of the components of $\boldsymbol{\theta}_0$ approximately follow Gaussian distributions, with their means and standardized deviations (STDEV) provided by Figures 4 a), b), c), d) and e). The posterior average of $\theta_{e,0}$ shows noticeable reduction from the undamaged state (θ_e =1), which suggests the damage accumulation in case bridge. The updated statistics of $\theta_{cr,0}$ and $\theta_{sh,0}$ suggest that the standard model (θ_{cr} ~ N(1, 0.23), θ_{sh} ~ N(1, 0.34)) (Bažant and Baweja, 1995) overestimates the development of creep and shrinkage for the case bridge, and the uncertainties associated with θ_{cr} and θ_{sh} can be significantly reduced after updating.

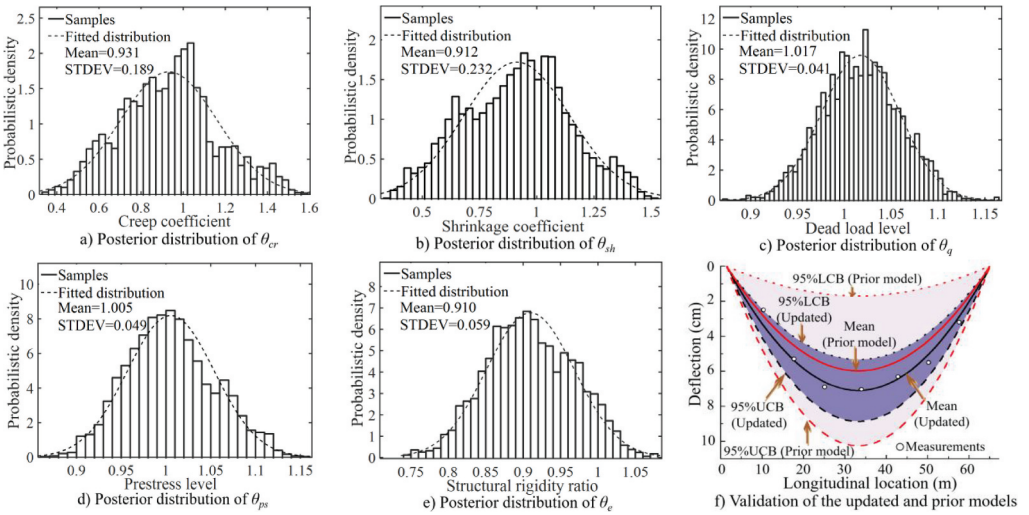

Figure 4. Inference results before the continuous monitoring.

Figure 4 (f) shows the deflection outputs of the updated and prior models, in which the average and the 95% upper confidence bounds (UCBs) and lower confidence bounds (LCBs) of deflection are presented. It can be observed that the average deflection output from the model with the updated parameters can fit the deflection measurements better than the prior standard

model. Additionally, the variance of the predictions is greatly reduced after the update, while the updated 95%-confidence interval can still capture most of the deflection measurements.

3.3 *Inference results based on the continuous monitoring deflection*

Continuous monitoring of the case bridge started in 2018 and lasted for two years. Angle-measuring inclinometers were used to collect the static and dynamic deflection of the bridge at 1/4-span, mid-span and 3/4-span of the bridge. A multiresolution discontinuous wavelet transformation (DWT) analysis was conducted on the original deflection signal to filter out the influence of temperature variation (Mallat, 1999). As presented in Figures 5 a), b) and c), the low-pass components with characterized period (T > 3072 h) were retained and averaged every two-month intervals. The averages were used as the target information in further Bayesian inference of $\boldsymbol{\theta}_e$.

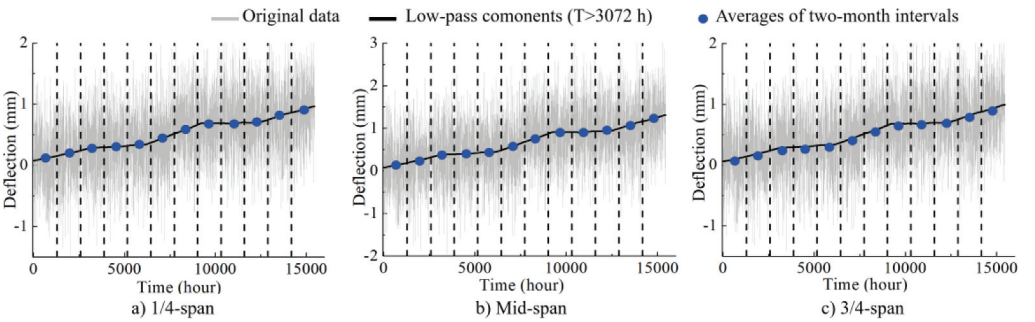

Figure 5. Wavelet analysis of the continuously monitoring deflection.

Figure 6 (a) presents the marginal posterior distributions of $\boldsymbol{\theta}_e$ that are derived using the CMCMC sampler, in which $\boldsymbol{\theta}_e$ is averaged in each two-month interval. All components of $\boldsymbol{\theta}_e$ approximately follow a Gaussian distribution, and the mean values of the samples exhibit a clear deterioration path over time. During the two-year monitoring period, the average level of structural rigidity dropped from 0.91 to 0.905. The reduced structural rigidity is a phenomenological representation of the damage accumulated during the monitoring period.

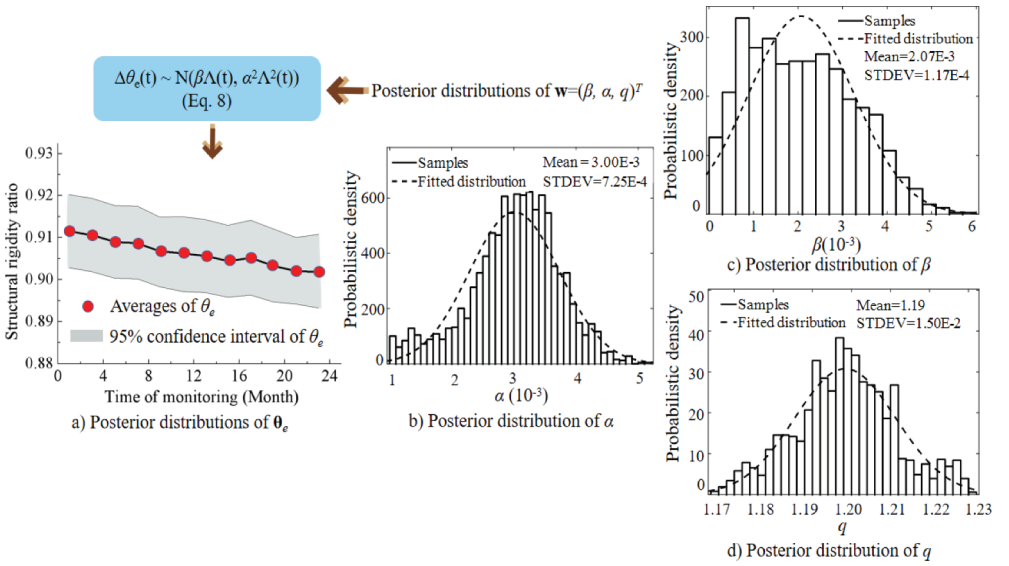

Figure 6. Inference results based on the continuous monitoring deflection.

The CMCMC sampler was also used to update $\mathbf{w}=(\beta, \alpha, q)^T$ that governs the deterioration path of $\boldsymbol{\theta}_e$ using the Wiener process formulated in Equation (8). As presented in Figures 6 b) and c), the posterior distributions of β and α are truncated Gaussian distributions since the values of these parameters must be nonnegative to ensure a nondecreasing deterioration path. As shown in Figure 6 d), the posterior distribution of q approximately follows a Gaussian distribution centered on the average of 1.198, which produces a nearly linear degradation path for this PSCB, which has been in service for 36 years.

4 CONCLUSIONS

The proposed probabilistic SI framework can identify the state variables associated with the time-dependent deflection of PSCBs, along with their time-dependencies. Specifically, damage-insensitive factors (i.e., creep, shrinkage, dead load, and prestress) can be calibrated based on static measurements before the start of continuous monitoring, whereas the damage-sensitive state variable (i.e., structural rigidity), together with its degradation path as specified by the Wiener process, can be updated based on continuously monitored deflection data.

Qatar University, Doha, Qatar

ABSTRACT: The safe operation of steel structures, such as bridges, is of paramount importance to mitigate potential issues. Consequently, the continuous and thorough monitoring of their operational conditions is imperative to uphold their safety and reliability. However, the inexorable process of corrosion, catalyzed by environmental conditions, leads to the inevitable deterioration of structural integrity over time. This research endeavors to predict the extent of corrosion in the primary cables of bridges through the application of advanced methodologies based on machine learning techniques. The execution of the proposed model necessitates the utilization of an extensive database encompassing diverse characteristics pertaining to the environmental properties of the surrounding region. The performance of the proposed models is rigorously assessed using a comprehensive suite of statistical and graphical metrics. The findings of this investigation underscore the effectiveness of the recommended solutions, surpassing previously established methodologies in addressing this pressing issue. The demonstrated success of the proposed model augurs favorably for its potential utility in furthering research into the dependability assessment of suspension bridge main cables.

1 INTRODUCTION

Suspension bridges rely on main cables made of high-strength carbon steel with a zinc protection layer (Barton Scott et al., 2000) to carry traffic loads and maintain structural stability. These cables are susceptible to corrosion, which depends on manufacturing and environmental factors (Chavel & Leshko, 2012). Current inspection methods involve removing the external cover to assess internal wire condition, but this provides limited information due to practical constraints and budget limitations (Mayrbaurl & Camo, 2004). Accurate prediction of the annual corrosion rate in these cables is crucial for ensuring safety, determining remaining useful life, and optimizing maintenance and replacement efforts while minimizing costs (Ben Seghier, Corriea, et al., 2021).

Corrosion growth on steel structures poses a formidable challenge, with substantial cost implications (El Amine Ben Seghier et al., 2018; Hussein Farh et al., 2023). Bridge cables, in particular, endure harsh environmental conditions, experiencing fluctuating temperatures and varied weather patterns over their lifespan (Kim et al., 2002). Numerous studies have delved into the critical environmental factors affecting metal corrosion in bridge cables, highlighting temperature (T), pH levels, humidity duration, contaminant and ion concentrations, and extended wetness periods as the key determinants (Saha, 2012). Bettie et al. (Betti & Yanev, 1999) discovered that pH values below 4 can result in water infiltration into internal cables in New York City suspension bridges, while Eiselstein and Caligiuri (Eiselstein & Caligiuri, 1987) emphasized the significance of water contaminant accumulation within the cables. Stahl

DOI: 10.1201/9781003483755-57

(Stahl & Gagnon, 1995) pointed out that issues could also be linked to imperfections in protective coatings or cable manufacturing. Further investigations (Deeble Sloane Matthew et al., 2013; Suzumura & Nakamura, 2004) have as well demonstrated the pivotal role of humidity and temperature fluctuations during the day in corrosion rates acceleration within main cables under ambient conditions. Collectively, these findings underscore the detrimental impact of environmental factors on bridge cable corrosion rates, emphasizing the need of appropriate advanced models for predicting corrosion rates using available environmental data from inspection reports.

The power-law model (Romanoff, 1957), is commonly used to predict corrosion rates in steel structures, including carbon steel wires. It relies on time and constant variables derived from simple fitting methods based on experimental data. However, its efficiency is limited, especially in terms of its applicability and precision to a larger database, resulting in inaccurate corrosion rate estimations in various scenarios (Kamrunnahar & Urquidi-Macdonald, 2010). Recently, the research community has turned its attention to machine learning techniques, recognizing their potential to effectively capture the intricate relationships through the implementation of complex anomaly detection algorithms (Jiménez Rios et al., 2023). Karanci and Betti (Karanci & Betti, 2018a) were pioneers in this area, implementing artificial intelligence (AI) models to model the annual corrosion rate in suspension bridge main cables. They compared linear regression, artificial neural networks (ANN), and support vector regression (SVR) to tackle the problem, but their approaches yielded less-than-ideal results, attributed to the complexity of the database and the limited generalization capabilities of the AI models. Ben Seghier et al. (Ben Seghier, Corriea, et al., 2021) optimized the single machine learning (ML) model control parameters using more advanced AI-models such as hybrid-ML techniques with meta-heuristic algorithms (i.e. marine predators algorithm (MPA)). When compared to single-ML models, their results were more accurate. This highlights the pressing need for more advanced AI models to enhance the predictive accuracy of such complex problems.

The primary objective of this research is to introduce a new predictive model designed to estimate the annual corrosion rate by analyzing environmental conditions from a global dataset. To address this challenge, we assess the performance of different ensemble learning models, namely, decision tree (DT), random forest (RF), adaptive boosting (ADB), and extreme gradient boosting (XGB). Furthermore, these models' performance is compared against four conventional regression techniques, i.e. multiple linear regression (MLR), ridge regression (RR), lasso regression (LR), and elastic net regression (ER). Various evaluation criteria are applied to assess the performance of ensemble and regression models in term of efficiency and accuracy.

2 METHODOLOGY

2.1 *Database description*

In this paper, we delve into an in-depth analysis of the intricate patterns of corrosion rate in suspension bridge main cables, which exhibit nonlinear behaviors contingent upon the environmental factors at play. To accomplish this, we draw upon a comprehensive database meticulously compiled by Karanci and Betti (Karanci & Betti, 2018a, 2018b). The database encompasses over 250 testing sites distributed across 33 countries (e.g. USA, Germany, Norway, Mexico, …, etc). Within this extensive collection, an uncover 309 distinct measurements are used, which shed light on the annual corrosion rate of carbon steel specimens, each subjected to diverse atmospheric conditions over the course of a year. The tests consisted on exposing carbon steel specimens to different atmospheric circumstances.

This study considers the impact of six crucial environmental factors, which serve as input variables. Specifically, these factors encompass temperature (T, °C), relative humidity (RH,%), the duration of moisture on the metal's surface (TOW, %), annual precipitation (P, mm), rainwater pH (pH), and chloride ion concentration (Cl^-, mg/L). These variables collectively represent the surrounding environmental conditions. The primary focus of this investigation centers on the annual corrosion rate (mm/year), which is regarded as the principal output parameter and is observed in the main cable wires. Table 1 presents a statistical summary of the database,

including the mean (X_{Mean}), standard deviation (X_{STD}), the minimum value (X_{Min}) and the maximum value (X_{Max}). Figure 1 shows the Pearson correlation matrix of the studied parameters. It can be seen that there is moderate to low correlation between the input variables and the target output, indicating that all the utilized variables are suitable to be included in the models' development.

Table 1. Dataset description of the input and output variables.

Type	Variables	X_{Mean}	X_{STD}	X_{Min}	X_{Max}
Inputs	Temperature, °C	15.30	8.75	-3.10	29.82
	RH, %	0.46	0.18	0.00	0.98
	TOW, %	68.70	14.10	33.30	91.10
	Precipitation, mm	882.43	486.83	13.00	3677.00
	pH	4.99	0.87	3.45	7.37
	Cl^-, mg/L	12.35	27.17	0.01	192.73
Outputs	Corrosion rate, μm	38.53	43.76	3.30	376.70

Figure 1. Pearson correlation matrix of the input and output variables.

2.2 *Regression models*

Four conventional regression techniques were implemented in this study as follows:

- Multiple linear regression (MLR): a statistical technique used in data analysis and modeling to examine the relationship between a dependent variable (or response variable) and two or more independent variables (or predictor variables).

- Ridge regression (RR): also known as L2 regularization, it is a linear regression technique used in statistics and machine learning to address the problem of multicollinearity and overfitting in MLR.
- Lasso regression (LR): an abbreviation for "Least Absolute Shrinkage and Selection Operator" regression, which is a linear regression technique used in statistics and machine learning for variable selection and regularization.
- Elastic net regression (ER): it is a linear regression technique that combines both Lasso (L1 regularization) and Ridge (L2 regularization) regression methods to address the limitations of each individual approach.

2.3 *Ensemble learning models*

Ensemble Learning (EL) models are machine learning (ML) techniques that combine the predictions of multiple individual models (base models or learners) to improve overall predictive performance, generalization, and robustness. The idea behind ensemble learning is that by aggregating the predictions of multiple models, the ensemble can often produce more accurate and reliable results than any single model on its own. One base model and three ensemble learning models were employed in this work, as follows:

- Decision tree (DT) –Base model-: used for both classification and regression tasks. It is a versatile and interpretable model that can be represented graphically as a tree structure.
- Random forest (RF) –EL-model-: a technique that combines the predictive strength of multiple DT to produce more accurate and robust results.
- Adaptive boosting (ADB) -EL-model-: a technique that designed to improve the performance of weak learners (classifiers that perform slightly better than random guessing) by combining them into a strong ensemble model.
- Extreme gradient boosting (XGB) -EL-model-: an extension of the gradient boosting machine (GBM) algorithm, designed to be highly optimized, scalable, and capable of delivering excellent predictive performance.

Besides, a k-fold cross-validation was used to prevent over-fitting of all EL-models and regression approaches. The data were divided into 70% for building the predictive models, while 30% were attributed for the validation of the developed predictive models. The performance of all models was measured based on comparative statistical indicators as described in the following (Ben Seghier, Gao, et al., 2021; Ben Seghier, Kechtegar, et al., 2021):

1. Root mean square error (RMSE):

$$RMSE = \frac{1}{n}\sum_{i=1}^{n}\left(C_{rate,i}^{Act} - C_{rate,i}^{Pre}\right)^2 \tag{1}$$

2. Mean absolute error (MAE):

$$MAE = \frac{1}{n}\sum_{i=1}^{n}\left|C_{rate,i}^{Act} - C_{rate,i}^{Pre}\right| \tag{2}$$

3. Coefficient of determination (R^2):

$$R^2 = 1 - \frac{\sum_{i=1}^{n}\left(C_{rate,i}^{Act} - C_{rate,i}^{Pre}\right)^2}{\sum_{i=1}^{n}\left(C_{rate}^{Avg} - C_{rate,i}^{Pre}\right)^2} \tag{3}$$

4. Confidence interval (CI):

$$CI = WI \times NSE \tag{4}$$

$$WI = 1 - \frac{\sum_{i=1}^{n}\left(C_{rate,i}^{Act} - C_{rate,i}^{Pre}\right)^2}{\sum_{i=1}^{n}\left(\left|C_{rate,i}^{Pre} - C_{rate}^{Avg}\right| + \left|C_{rate,i}^{Act} - C_{rate}^{Avg}\right|\right)^2} \quad (5)$$

$$NSE = 1 - \frac{\sum_{i=1}^{n}\left(C_{rate,i}^{Act} - C_{rate,i}^{Pre}\right)^2}{\sum_{i=1}^{n}\left(C_{rate,i}^{Act} - C_{rate}^{Avg}\right)^2} \quad (6)$$

5. U95:

$$U95 = 1.96 \times \sqrt{Standard\ deviation^2 - RMSE^2} \quad (7)$$

Where $C_{rate,i}^{Act}$, $C_{rate,i}^{Pre}$ and C_{rate}^{Avg} are the actual, predicted, and average values of the i-th annual corrosion rate from the test result measurements. The lower the RMSE, MAE, and U95 values, the higher the projected values by the utilized model, and the higher the CI and R^2 values, the higher the model accuracy.

3 RESULTS AND DISCUSSION

3.1 *Predictive regression models*

The performance evaluation of the four regression models implemented in this study is presented in Table 2. It can be seen from the obtained results that the best performing regression model among the utilized ones is the ER. This latter yielded the lowest RMSE, MAE and U95 values flowed by LR, while the MLR yielded the lowest performance during both phases, training, and testing. In addition, the highest obtained R^2 value is 0.825 and 0.742 by the EL during the training and testing sets respectively. The overall results show low adaptation to the complexity of the used database, indicating the drawbacks of the used regression models.

Table 2. Performance evaluation of the four regression models.

Phase	Models	RMSE	MAE	R^2	CI	U95
Training	MLR	22.991	16.331	0.758	0.530	46.134
	RR	23.528	15.707	0.780	0.479	47.107
	LR	21.910	15.236	0.803	0.516	43.899
	ER	**19.859**	**14.328**	**0.825**	**0.576**	**39.673**
Testing	MLR	29.421	16.391	0.543	0.239	58.225
	RR	20.442	14.480	0.679	0.457	40.545
	LR	18.834	13.427	0.727	0.481	37.743
	ER	**18.245**	**13.310**	**0.742**	**0.501**	**36.565**

* Bold numbers represent the best results.

Furthermore, Figure 2 presents the scatter plots of the different employed regression models. Besides from the relatively low prediction capacity of the regression models explored in this paper, another important drawback worth highlighting is the fact that such models could result into negative values of annual corrosion rate (see dots plotted below the horizontal axis, close to the origin), which does not hold any physical meaning. Thus, the applicability of such models can result on misleading values of the annual corrosion rate.

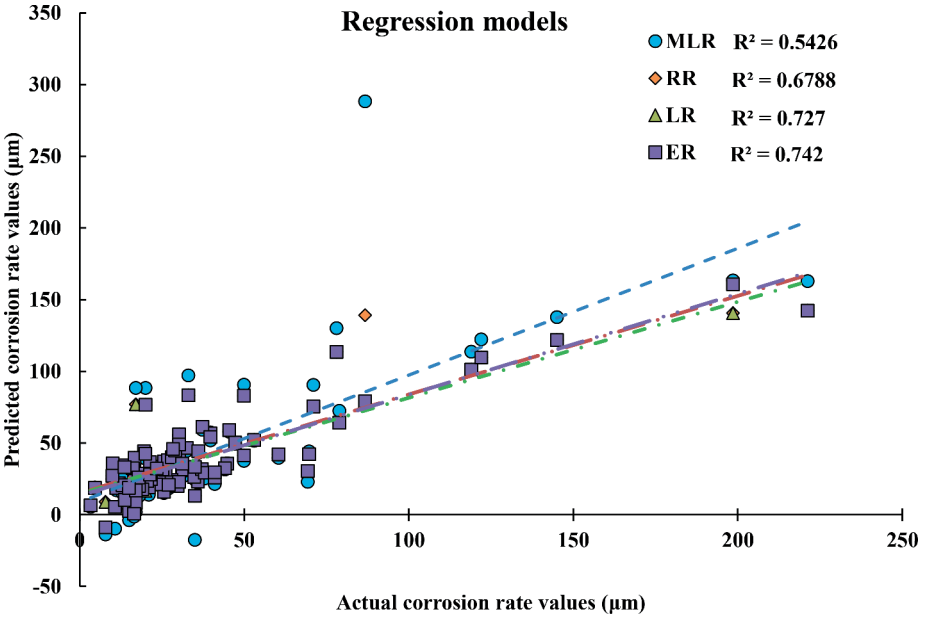

Figure 2. Scatter plots of the regression models.

3.2 *Predictive ensemble learning models*

The performance evaluation of the single based models (i.e. DT) and the three ensemble learning models (i.e. RF, ADB and XGB) implemented in this study are presented in Table 3. According to the results, the DT model showed perfect results during the training phase, whereas the model yielded the lowest results during the testing phase, indicating an overfitting and inaccurate results obtained by this technique a single base model. The DT results are obtained as follow: RMSE = 37.999 µm/year, MAE=16.997 µm/year and CI=-0.117, which is the lowest among all other ensemble learning models. The best performing ensemble learning algorithm is the XGB, where this observation is based on all the utilized statistical indicators, including the obtained R^2 value (0.999 and 0.941 for the training and testing sets respectively). These results highlight the suitability of ensemble learning models to be implemented in annual corrosion prediction tasks.

Table 3. Performance evaluation of the three ensemble learning models.

Phase	Models	RMSE	MAE	R^2	CI	U95
Training	DT**	0.000	0.000	1.000	0.750	0.000
	RF	9.579	5.245	0.970	0.684	19.770
	XGB	**1.604**	**1.145**	**0.999**	**0.746**	**4.010**
	ADB	11.030	8.492	0.954	0.694	20.897
Testing	DT	37.999	16.997	0.380	-0.117	74.978
	RF	14.876	10.966	0.863	0.549	29.784
	XGB	**8.858**	**6.733**	**0.941**	**0.678**	**18.315**
	ADB	14.562	12.173	0.887	0.582	25.936

* Bold numbers represent the best results.
** DT shows perfect results due to the overfitting problem.

Similar to the previous section, Figure 3 presents the scatter plots of the base single model (i.e. DT) and the different ensemble learning models using the testing phase results. Besides from the higher performance already commented, it can be observed that under no

circumstances, ensemble learning models provide negative values of annual corrosion rate, thus respecting the physical meaning of the task at hand. In addition, the performance of the models can be ranked as follows: XGB>ADB>RF>DT.

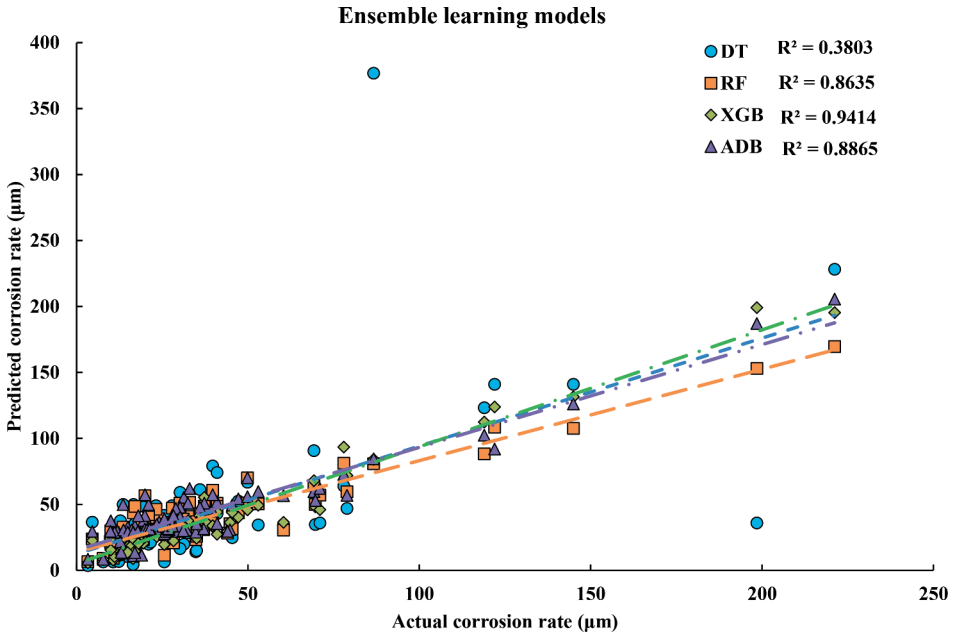

Figure 3. Scatter plots of the ensemble learning models.

4 CONCLUSION

The prediction of the annual corrosion rate in suspension bridge main cables presents a complex and nonlinear issue characterized by chaotic patterns and stochastic tendencies. In this paper, we have assessed the performance of different ensemble learning models, namely, decision tree (DT), random forest (RF), adaptive boosting (ADB), and extreme gradient boosting (XGB), to predict annual corrosion rates using a comprehensive database composed of 309 measurements of annual corrosion rate of carbon steel specimens as a function of diverse atmospheric conditions over the course of a year, distributed across 33 countries. Furthermore, these models' performance was compared against four conventional regression techniques, i.e. multiple linear regression (MLR), ridge regression (RR), lasso regression (LR), and elastic net regression (ER).

In general, except for the DT model, the ensemble learning models presented a better performance than the conventional regression models. XGB was the best performing ensemble learning algorithm with R^2 values reaching 0.999 and 0.941 for the training and testing sets, respectively. Moreover, all ensemble learning models respected the physical meaning of the predicted outcome parameter and none of them resulted in negative estimated values.

Modeling the deterioration of road bridges at the provincial level in Lao PDR

H. Silimanotham, A. Amir & M. Henry
Shibaura Institute of Technology, Tokyo, Japan

ABSTRACT: Deterioration is one of the key concerns in assessing bridge performance and is necessary to understand how bridges degrade with age for optimal maintenance budget allocation. The rate of deterioration varies across bridge types, with Laos predominantly featuring aging concrete slab bridges, concrete girder bridges, and steel truss bridges. It is imperative to ascertain the deterioration rate of these bridge types for effectively determine maintenance costs. This paper analyzes available inspection data from the Ministry of Public Works and Transport (MPWT), employing linear regression analysis to find the trend of deterioration rates of different types of bridges with time. Focusing on concrete slab, girder, and steel truss bridges in the 18 provinces of Laos, the study forecasts the deterioration rates over bridges' service life. The results can inform various bridge management tasks, including maintenance planning and asset evaluation, contributing to more effective decision-making for the preservation and safety of Laos' bridge infrastructure.

1 INTRODUCTION

Efficient road transport is the backbone of a country's economy, and bridges constitute a crucial and costly component of the road network that necessitates a timely and effective management plan. This plan should involve allocating the available budget to specific structures (bridges) based on their condition and the prescribed maintenance and rehabilitation requirements (Amir et al., 2023). Several factors contribute to the deterioration of these bridges such as axle load, aging, and environmental factors. Many bridge management departments around the world have been developing and improving a variety of bridge management systems (BMS) for decades to provide timely and effective bridge maintenance, repair, and rehabilitation (MR&R) by collecting and analyzing technical-condition data and performance evaluations on a continuous basis (DeStefano and Grivas, 1998, Archila, 1999, Calvert et al., 2020, Madanat et al., 1997, Medina and Gonzalez, 2022, Nurmuhametov et al., 2021).

Laos has over 3,500 bridges constructed within its road network, which is classified into national, provincial, district, urban, rural, and specific roads (JICA, 2021). According to the Ministry of Public Works and Transport (MPWT), annually only 1 percent of the road annual budget goes to the maintenance of these bridges, which also covers site inspection and surveying. Since Laos lacks a maintenance management strategy, decision-making regarding which bridges should be maintained is usually based on coordination meetings between authorities without considering and evaluating technical factors. It is because of this that maintenance budgets are usually spent only on urgent cases, and that routine and periodic maintenance is generally neglected. Furthermore, there is a lack of a data-driven maintenance strategy that incorporates bridge deterioration modeling for budget optimization, necessitating the need to analyze the historical data of these bridges. This analysis is crucial for developing models that can be integrated into maintenance planning to address such issues effectively.

In recent years, bridge deterioration modeling has been developed by many researchers for predicting the bridge condition with time. Various deterministic deterioration modeling studies were conducted using both the national and state bridge inventories. Transportation Research Center of the U.S. Department of Transportation (DOT) used linear regression to correlate bridge condition

DOI: 10.1201/9781003483755-58

ratings with other bridge characteristics recorded in the NBI database (Busa et al., 1985). Similarly, the Wisconsin Department of Transportation and the New York State Department of Transportation used an improved piecewise linear regression (Fitzpatrick et al., 1981, Hyman and Hugles, 1983) and developed a bridge deterioration model using two methods: 1) rates of change and 2) average condition ratings of all bridges in New York City Metropolitan area (Yanev and Chen, 1993). Similarly, In Laos, the infrastructure primarily comprises old bridges. Therefore, there is a need to develop a strategy for assessing the rate of deterioration of these bridges with time.

The Lao PDR is one of the timber-exporting countries in Southeast Asia, and a significant portion of timber exports to China and Vietnam is through the Northern and Southern Road networks of Laos. However, due to heavy transport, both these roads and bridges undergo deterioration with time. Most of the bridges in these areas fall into three types that's include concrete slab, concrete girder, and steel truss. Recognizing that bridge type can be a crucial factor influencing deterioration rate, this research focused on utilizing existing data from the Ministry of Public Works and Transport (MPWT) to develop and compare the rate of deterioration across different bridge types by utilizing the statistical approach such as the linear regression method.

2 METHODOLOGY

2.1 *Data preparation*

This research uses the bridges database of the year 2018 obtained from the MPWT which includes bridge inspection and bridge characteristics data. In the bridge database, there are six classifications of road as national, provincial, district, urban, rural, and specific road. However, approximately 24% of the total number of bridges (3,580 bridges) in Laos are located on national roads. Moreover, the collected data from the MPWT was incomplete and lacked characteristics and information about the years of construction for the entire road classification network. Consequently, the research narrowed its focus to compare the rates of deterioration of different types of bridges classified under one road category, specifically, national roads in different areas such as the Northern (8 provinces), Central (6 provinces), and Southern area (4 provinces). The areas' descriptions are mentioned in Table 1. The classification of Northern, Central, and Southern areas is based on their respective geographical locations. The Northern region is predominantly mountainous, the Central region consists of flat areas, and the Southern region encompasses both mountainous and flat terrain. Most of the timber transportation to the neighboring countries of Laos is carried out on the Northern and Southern areas road network.

Table 1. The regions of Laos.

Northern area	Central area	Southern area
Phongsaly province	Vientiane capital	Saravan province
Houaphane province	Vientiane province	Xekong province
Xiengkhouang province	Xaisomboun province	Champasak province
Louang Prabang province	Bolikhamxai province	Attapeu province
Xaiyabouly province	Khammouan province	
Oudomxai province	Savannakhet province	
Bokeo province		
Louangnamtha province		

The national road network has around 844 bridges with 3 main bridge types that included concrete slab, concrete girder, and steel truss. Due to data limitations, complete information was available for only 735 bridges in the three different areas. Among these, there are 190 bridges of concrete slab, 452 bridges of concrete girder, and 93 bridges with steel truss, as shown in Figure 1. The analysis was done based on the bridge service period (age) and bridge conditions. The bridge conditions were classified into 5 categories in the data obtained, with 0 showing "no damage" to the 4 representing the "severe damage" of the bridge as shown in Table 2.

Table 2. Condition ratings.

Code	Bridge Condition
0	No damage, element as new
1	Insignificant damage, no repair needed
2	Minor damage, repair when convenient
3	Damage, repair soon
4	Severe damage, repair immediately

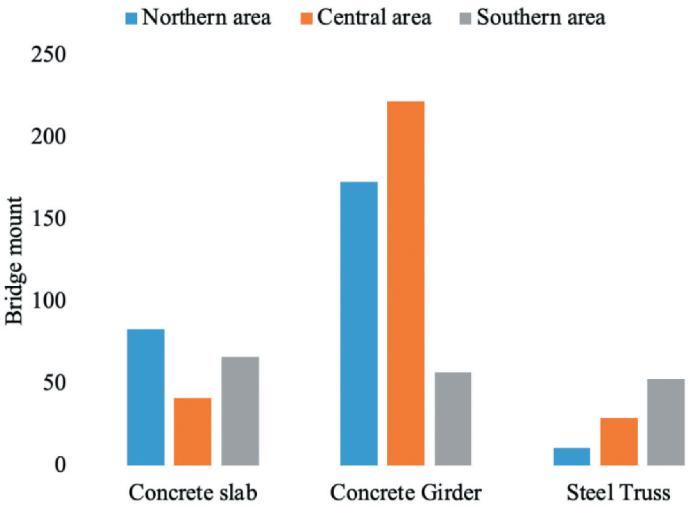

Figure 1. Number of three bridge types on the national road.

2.2 *Methodology*

The data consisted of 735 bridges. During the pre-processing of data, it was found that several bridges have the same service life (age), hence average bridge condition was calculated for different years of service life (age). The linear regression was performed by taking the average bridge condition as the dependent variable and the service life (age) as the independent variable for estimating the trends of deterioration rate with time by the equation below:

Linear regression:

$$Y = a + bX \tag{1}$$

Where,
Y represents the dependent variable (average bridge condition),
a is the intercept,
b is the slope, and
X signifies the independent variable (bridge service period or age).

In equation 1, the slope b offers insights into the rate of deterioration. A positive b implies a positive relationship between the variables which means that as the independent variable increases (e.g., as the bridge ages), the dependent variable also increases (e.g., indicating deterioration in bridge condition). Similarly, when comparing the rate of deterioration in different areas using linear regression, a higher slope for a particular area suggests more rapid deterioration in the average bridge condition as the bridge service period or age increases in that specific area.

3 RESULTS AND DISCUSSIONS

3.1 *Regression modeling of deterioration by bridge type and region*

3.1.1 *Concrete slab bridges*

The results of the linear regression are shown in Figures 2, 3, and 4, which illustrate the deterioration rate of concrete slab bridges over bridge service life in different areas. These figures represent the relationship between the bridge's average condition and bridge service period. It was observed from the analysis that there is a higher rate of deterioration for concrete bridges in the Northern area as compared to the Central and Southern areas (Figure 2). This increased rate of deterioration is evident through the larger slope value (0.0485) in the Northern area. In contrast, the deterioration slope values are 0.0278 in the Central area and 0.009 in the Southern area, as illustrated in Figures 3 and 4, respectively.

Furthermore, the values associated with these linear regression analyses provide information about how well the model fits for each area's data. For the Northern and Southern areas, the R^2 values were 0.7432 and 0.5126, indicating that 74.3% and 51.2% of the variability, respectively, is explained by the regression analysis. However, the R^2 value for the Central region was the lowest (0.1529), signifying only 15% variability explained. This lower R^2 value may be attributed to the limited amount of available data for the Central region. Despite this limitation, the model can still be utilized for finding the trend of bridge deterioration rates in the Central area (Lu et al. 2016).

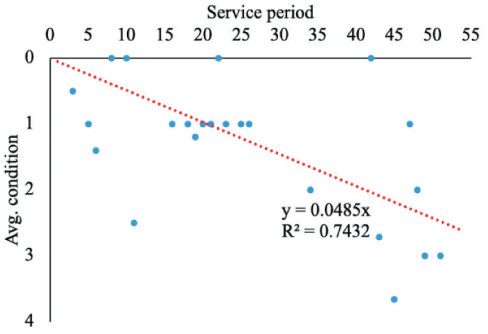

Figure 2. The deterioration rate of concrete slab bridges in Northern area.

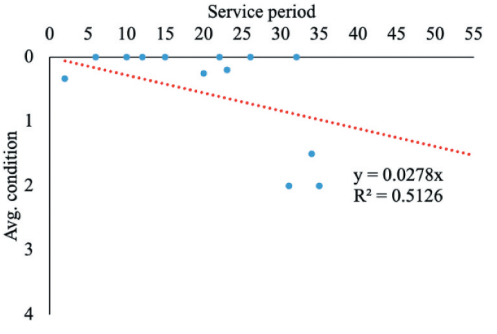

Figure 3. The deterioration rate of concrete slab bridges in Central area.

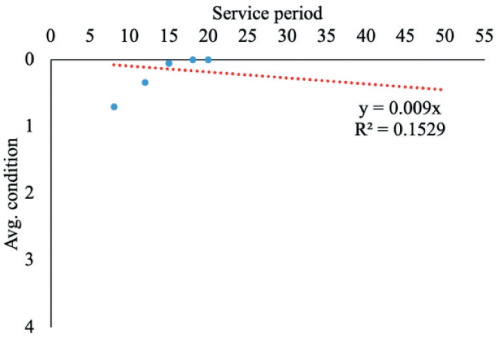

Figure 4. The deterioration rate of the concrete slab bridges in the Southern area.

3.1.2 *Concrete girder bridges*

Figures 5, 6, and 7 show the deterioration rate of concrete girder bridges in the Northern, Central, and South areas. It has been observed from the analysis that the rates of deterioration of concrete girder bridges in the Southern and Northern areas were almost similar (y= 0.0377

and 0.0358) and higher than the concrete girder bridges in the Center area (y=0.0225). Similarly, the R^2 values obtained for these models were 0.5965, 0.4312, and 0.584 indicating 59.6%, 43.1%, and 58.4% of variability explained for the Northern, Southern, and Central areas bridges data respectively.

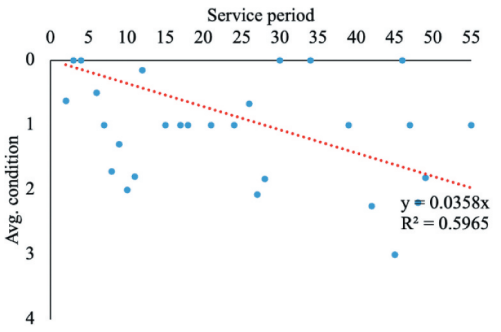

Figure 5. The deterioration rate of concrete girder bridges in Northern area.

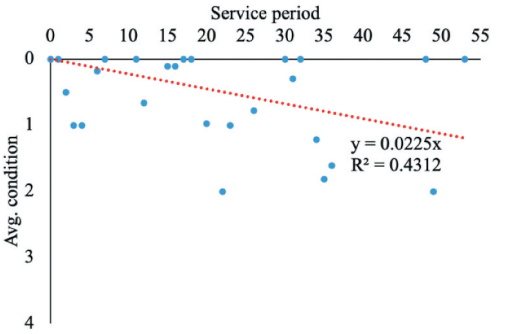

Figure 6. The deterioration rate of concrete girder bridges in Central area.

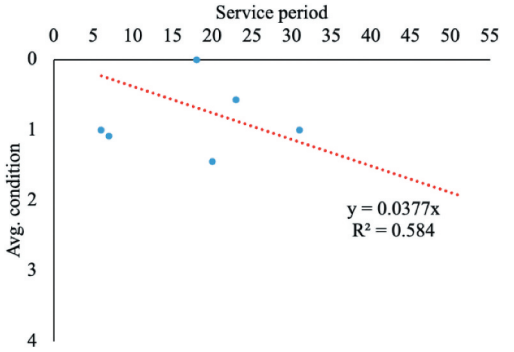

Figure 7. The deterioration rate of concrete girder bridges in Southern area.

3.1.3 *Steel truss bridges*

The results of the linear regression model for steel truss bridges are shown in Figures 8, 9, and 10, illustrating the deterioration rating of concrete slabs in different areas by examining the relationship between bridge average condition and bridge service period. It was observed that the rate of deterioration of steel truss bridges in the Northern areas is higher, as evident by the elevated slope value (y=0.0578, Figure 7), while steel bridges in the Central areas exhibit the slowest rate of deterioration (y=0.0315, Figure 9). The R^2 values obtained from the analysis showed the lowest value for the Central area with 0.2215 indicating the 22% variability explained by the bridge data of central areas.

3.2 *Comparison of the bridge deterioration rates between different areas*

Figure 11 shows the comparison of deterioration rates of three types of bridges such as concrete slab, concrete girder, and steel truss in the Northern, Center, and Southern areas. The comparison of bridge deterioration rates among different areas reveals distinct patterns. It was observed that the Northern areas exhibit higher rates of deterioration across all three bridge types. It may be due to the heavy axle loading in this region. However, for concrete

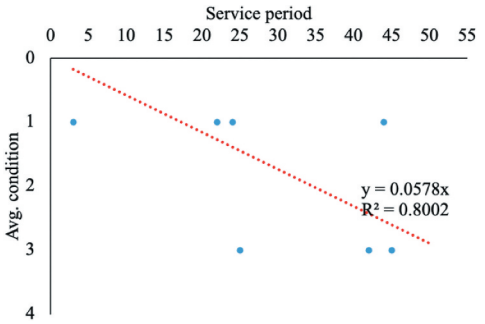

Figure 8. The deterioration rate of steel truss bridges in Northern area.

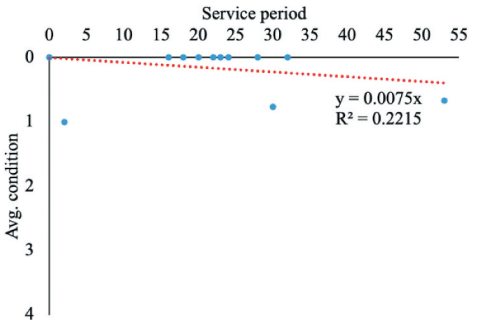

Figure 9. The deterioration rate of steel truss bridges in Central area.

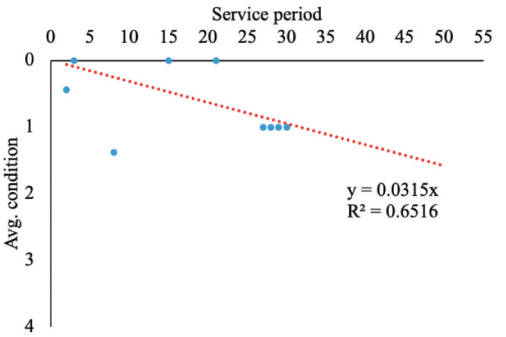

Figure 10. The deterioration rate of steel truss bridges in the Southern area.

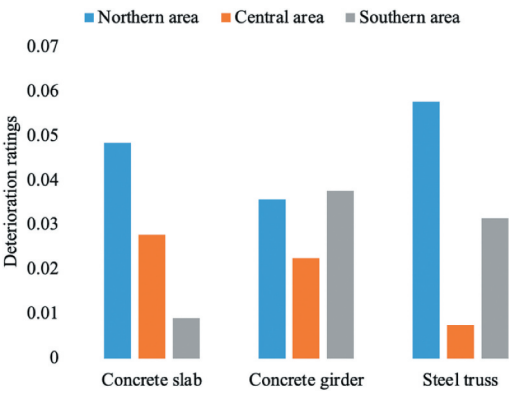

Figure 11. Bridge deterioration rating in three areas.

girder bridges, the rates are almost equal in both Northern and Southern areas. Conversely, the Central area, characterized by predominantly flat terrain, showed low rates of bridge deterioration for all three bridge types. In light of these findings, it is evident that geographical variations, specifically the type of traffic usage can influence the rates of bridge deterioration for three bridge types in different terrains. It could be attributed to the presence of heavy axle traffic in the Northern and Southern areas, given that a substantial portion of the road network is utilized for transporting timber with heavy axle loads.

4 CONCLUSIONS

This research aimed to evaluate and compare the trends of bridge deterioration based on available data from the Ministry of Public Works and Transport (MPWT) in the national road network of Laos. Linear regression methods were applied to three types of bridges, namely concrete slab, concrete girder, and steel truss, to estimate deterioration rates for effective maintenance planning. The results were thoroughly analyzed and compared, revealing different rates of deterioration among the three bridge types in different geographical areas.

It was observed that the Northern area exhibited a higher bridge deterioration rate compared to the Central and Southern regions. This discrepancy suggests a higher frequency of required bridge maintenance in the Northern areas, which can be attributed to the prevalent heavy axle traffic associated with timber transportation. Conversely, the analysis for the Central area showed the slowest bridge deterioration rates, reducing overall maintenance frequency is suggested. The findings emphasize the substantial influence of geographical variations on bridge deterioration rates. The future research can be extended by incorporating additional factors into the bridge data for finding more robust factors affecting the rate of deterioration.

ACKNOWLEDGEMENT

The Authors would like to extend their gratitude to Japan International Cooperation Agency (JICA) for their support through the Road Asset Management Program, to Shibaura Institute of Technology (SIT), Tokyo for providing the environment for the research, and to Ministry of Public Works and Transport (MPWT) in Lao PDR, for sharing the data and information needed.

ABSTRACT: In this paper, an investigation on the shear capacity of naturally corroded prestressed concrete (PC) beams without transversal reinforcement is presented. At first, to estimate the corrosion level, a visual inspection was carried out to detect concrete spalling and cracking, together with chloride concentration, as well as potential, resistivity, and corrosion rate measurements. Moreover, in the damaged areas, measurements of cross-section and weight loss for reinforcement were carried out. Then, the beam was repaired, and full-scale tests were conducted. To evaluate the effectiveness of the repairing system for shear capacity, full-scale tests were conducted by applying a concentrated load close to the ends of the beam - where the strands were subjected to corrosion - and close to the central part of the beam - where strands were uncorroded. The experimental results highlight that, since the repairing system is not able to restore prestress, the shear capacity is strongly reduced also after reparation.

1 INTRODUCTION

Reinforcement corrosion is one of the main causes of deterioration for reinforced concrete structures, which results in significant damages and intervention costs all over the world (Soutsos 2010; Hansson 2011; Menga et al. 2022). This detrimental effect can strongly reduce the bearing capacity of reinforced concrete elements, due to the decrease in the cross-sectional area of reinforcements and the reduced bond stiffening action between reinforcement and concrete. Hence, corrosion can pose severe risks to safety of reinforced concrete structures, being also responsible for the modification of collapse mechanisms from ductile to brittle (Ravasini et al. 2023). In the most critical cases, corrosion can provoke the failure of the structure, even under dead loading (Belletti et al. 2019; Soltani et al. 2019).

In the case of prestressed concrete (PC) elements, the risk of failure becomes higher than in ordinary reinforced members due to the intrinsic higher susceptibility of this kind of prestressed members to corrosion phenomena. Indeed, the bond decay in PC structures causes the de-tensioning and the loss of prestressing force that anticipate brittle failures, often related to shear resistance. However, the scientific literature lacks of experimental tests on shear resistance of naturally corroded PC beams, while it is more focused on ordinary reinforced concrete beams, often artificially corroded (Li et al. 2011; Vecchi et al. 2020; Vereecken et al. 2021). Few experimental test results on naturally corroded beams (Recupero and Spinella 2019) can be found in the literature, and none of them, except the ones by the authors (Belletti et al. 2020; Vecchi et al. 2020), focus on PC beams without transversal reinforcement.

In this paper, the shear behaviour of a PC beam without transverse reinforcement subjected to natural corrosion, induced by chloride exposition of strands is analysed. The tested beam

DOI: 10.1201/9781003483755-59

comes from a group of beams that were part of a thermal power plant located on the Spanish Mediterranean coast and were exposed to wetting and drying cycles with marine water. The environmental aggressivity and the deficiencies in the strand's protection at the ends of the PC beams, caused a fast propagation of corrosion in strands and, for some of them, shear failures.

The visible damage induced by volume expansion and consequent reduction of the cross-sectional area, was longitudinal splitting cracking and cover spalling. The detected damage caused a decay of the bond resistance between concrete and strands that negatively influences flexural and shear capacity of the PC beams (Vecchi et al. 2021; Franceschini et al. 2022).

The paper deals with verifying the effectiveness of patch repairing and other interventions aimed at re-activating the pull-out resistance of strands on the shear capacity of PC beams. The methodology adopted in this research simulates engineering practices for in situ inspections and repairing planning, when no detailed information on the corrosion morphology along the length of the strands is available. Firstly, non-destructive methods were adopted to assess the level of corrosion, such as crack mapping, chloride concentration, potential, resistivity, and corrosion rate measurements. Secondly, based on the in-situ measurement outcomes, a patch repair was applied to deteriorated zones located at both ends of the beam together with specific interventions to reactivate the pull-out resistance of strands along the transmission length. Finally, the shear capacity of the PC beam was experimentally investigated by performing three-point bending tests in three different positions of the beam: at the ends of the beam - where the strands were corroded and then the beam was repaired - and in the central zone - where the strands were uncorroded and then the beam was unrepaired.

2 CORROSION MEASUREMENTS AND REPAIRING SYSTEM

2.1 *Geometry and mechanical properties of the investigated PC beam*

The beam under investigation had a cross-section (b x h) of 150 x 300 mm and a length of 5.21 m. The prestressed beam was characterized by a lower reinforcement formed by two seven-wire strands. The outer wires' diameter is 4.26 mm and the inner one is 4.38 mm, resulting in a total nominal diameter equal to 12.9 mm. The upper reinforcement consisted of two bars with a diameter of 5 mm, whereas the beam did not contain transversal reinforcement. The concrete cover is 50 mm on each side of the beam. The assessment of residual prestress was not experimentally measured but the prestressing stress at the time of testing can be estimated to be equal to 1095 MPa, by considering long-term effects for an age equal to 13 years old and by using the formulations proposed in the literature (fib 2013). The same Standard Code was used also to evaluate the transmission length, which results equal to 365 mm, approximately 30 times the strands' diameter. The mechanical properties, which are summarized in Table 1, were assumed according to the findings on companion beams previously investigated (Belletti et al. 2020; Vecchi et al. 2020).

Table 1. Assumed mechanical properties of concrete, bottom and top reinforcement.

Concrete			Bottom reinforcement			Top reinforcement		
f_c [MPa]	f_{ct} [MPa]	E_c [GPa]	E_p [GPa]	f_{pu} [MPa]	ε_{pu} [%]	E_s [GPa]	f_{sy} [MPa]	ε_{su} [%]
45.4	3.36	35.6	195	1901.75	5	195	435	18

2.2 *Damage mapping*

As the first step, before testing, a visual inspection was conducted to evaluate any type of damage observed on the surface of the beams caused by corrosion. The beam was photographed to find signs of cracks, rust stains, and spalling of concrete cover. Figure 1 shows the most important damages found during the inspection of the beam. With this data, as shown in Figure 2, a damage map was created, which reports also crack opening widths. Significant

damage was found in the concrete cover near the left end of the beam, together with splitting longitudinal cracks along the surface in correspondence with the strands. Moreover, on the top of the right side of the beam in correspondence with the top reinforcement, a longitudinal crack with a maximum width of 0.7 mm was recognized.

Figure 1. Representative damages found during visual inspection.

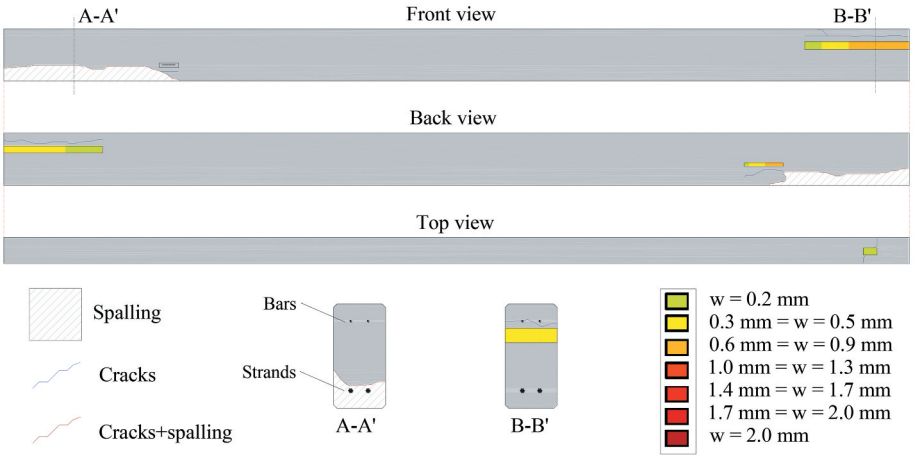

Figure 2. Damage and crack width mapping.

2.3 *Non-destructive electrochemical tests for corrosion assessment*

To assess the corrosion and degradation state of the reinforcement within the beams, various non-destructive tests using electrochemical methods were conducted. These tests include corrosion potential, resistivity, and corrosion rate measurements.

Table 2. Corrosion risk based on potential (ECORR measurements) and resistivity.

Risk of corrosion	Potential - CuSO4 (sat. Cooper sulfate)	Resistivity
Negligible	Ecorr > - 274 mV	> 100 kΩcm
Moderate	- 274 mV > Ecorr > - 424 mV	50 – 100 kΩcm
High	Ecorr < - 424 mV	10 – 50 kΩcm

Corrosion potential mapping was conducted on the lateral surfaces of the beam at 18 points, each 0.30 m apart. Two measurements, at the two sides, placed at the level of strands, were carried out by using the portable GECOR10 corrosimeter. It is important to note that the reference electrode for this equipment is $Cu/CuSO_4$, and the threshold value according to the UNE 112083 Standard for active corrosion (with an assumed risk of corrosion of 50%) is -274 mV, as shown in Table 2. Then, at the same points and by using the same system, resistivity mapping was created.

This measurement provides indirect information about the porosity of the medium and its level of saturation. It is worth noting that lower resistivity values indicate an increased probability of corrosion, as shown in Table 2. The results of the corrosion potential and resistivity mapping of the beams can be observed in Figure 3 and indicate that there is a considerable risk of corrosion near the ends of the beams, confirming the findings of visual inspections.

The corrosion rate was measured at 3 positions on the lateral faces of the beams by means of the portable GECOR10 corrosimeter, with two measurements at the ends and one at the centre of the beam. A corrosion rate (Icorr) of 0.1 μA/cm² or higher indicates active corrosion. The results reported in Figure 4 indicate that the probability of corrosion is higher near the ends of the beam; as previously highlighted.

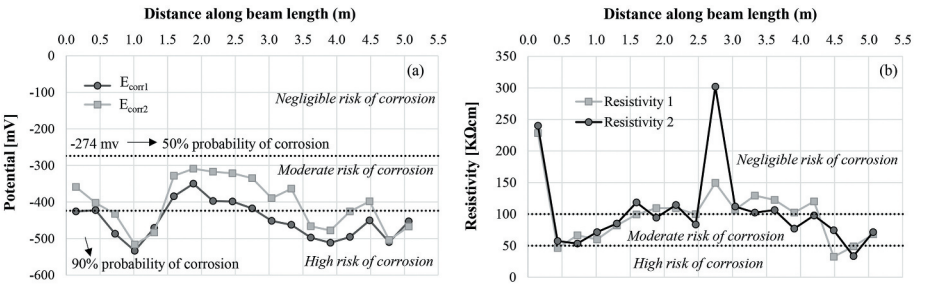

Figure 3. Corrosion measurements: (a) potential and (b) resistivity mapping along the beam length.

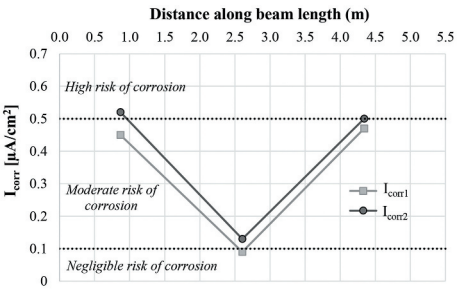

Figure 4. Corrosion rate measurements along the beam length.

2.4 *Chloride concentration*

The measurement of chloride concentration in the concrete was conducted by evaluating the chloride concentration at the reinforcement level. This measurement was carried out by extracting a powdered sample by means of a drill from one side of the beam. The analyses were conducted twice, and then the values obtained were averaged, distinguishing only between the non-cracked and cracked areas. By assuming a cement content of 350 kg/m^3, the percentage of chloride by weight of cement was found to be equal to 2.85% and 2.73%, for cracked and not-cracked areas, respectively. These values are much higher than the limit set by standards, where a value of 0.6% by weight of cement, is the threshold value set for active reinforcement.

2.5 *Measurements of cross-section and weight loss for reinforcement*

The measurement of cross-section loss and weight loss was carried out on both bottom and top reinforcement. The reinforcements were stripped using an acid solution (with eurotropine) to remove corrosion products and allow accurate measurements. A calibre was used to measure the remaining section in the reinforcement areas with cover loss, and an analytical balance was used for weighing. Weight loss values of over 15% have been measured in areas with active corrosion as measured by electrochemical techniques, reaching values of up to 40% in areas where cracking has occurred.

2.6 *Repairing system*

After the visual inspection, a repairing system was designed to be applied to the beam, with the aim of restoring the pull-out resistance of strands. The corrosion of the strands and the related rust volume expansion resulted in cracking and spalling of the concrete cover, especially at the beam extremities, which in turn caused the bond loss, refer to Figure 2. Hence, at beam ends the concrete-to-strands interaction was lost and the beams resulted without residual prestressing force.

At first, the part of the concrete cover affected by cracks caused by reinforcement corrosion was removed by using manual and mechanical methods (Figure 5a). After this removal, the exposed concrete surface was cleaned of dirt and rust residues, leaving the strands clean up to the non-corroded area. For a thorough cleaning, a mechanical sandblasting method was used on both the concrete and steel surfaces. The final clean-up to remove any remaining sand residues was done by using a metal bristle brush and a plastic bristle brush.

Then, at the bottom extremity of the beam where spalling of concrete cover and cracks had been found, 304L stainless steel sleeves designed on purpose (Figure 6) were installed to restore the pull-out resistance of strands. The severely deteriorated parts of the strands were cut, and they were connected to the sleeves by using epoxy resin, as shown in Figure 5b. The diameter of the tubular sleeves was greater enough with respect to that of strands to ensure that the chemical anchoring worked correctly. Then, these sleeves were embedded within a repair mortar used for the patch repairing to re-establish the structural integrity, i.e. the original shape of the transversal cross-section. To this aim, formworks were placed around the beam, and the repair mortar Sika Monotop 4200 Multiflow was used, as seen in Figure 5c. It is worth noting that this type of mortar does not require a bonding bridge with the base concrete. Once poured, compacted, and manually trowelled, the mortar was cured for one day before removing the formwork.

Figure 5. (a) Mechanical cleaning of the beam; (b) placement of metallic sleeves on reinforcement; (c) pouring of repair mortar for the replacement of the beam section and final state after 28 days of curing.

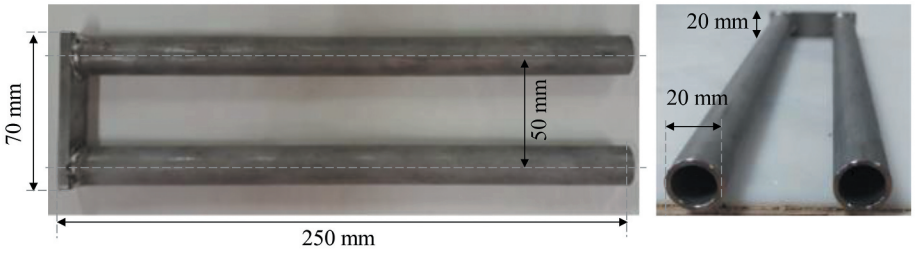

Figure 6. Photos of metallic sleeves for bonding renewal.

3 SHEAR TESTS AND DISCUSSION

3.1 *Experimental setup*

The experimental tests were performed at the "Instituto de Ciencias de la Construccion Eduardo Torroja" in Madrid. The shear behaviour of the corroded and repaired PC beam was investigated by means of three-point bending tests, which were performed thrice: at the two extremities - where the strands were corroded, and the beam was repaired - and in the central zone - where the strands were uncorroded and the beam was unrepaired. Therefore, three experimental tests were carried out on the same specimen. More in detail, the beam was firstly tested on the left end zone (Test 1), then it was tested on the right end zone (Test 2), and finally also in the central part (Test 3).

All three tests were performed by adopting the same ratio between the applied load position, "a" (equal to 750 mm), and the effective depth "d" of the beam (equal to 250 mm), so obtaining a shear span-to-effective depth ratio (a/d) equal to 3. The sketch of the setup of the three tests is reported in Figure 7. The experimental tests were carried out under displacement control, to control the tests during critical phases, as such load drops, sudden cracking, or brittle failure. A quasi-static loading rate of 0.50 mm/min was applied by means of a servo-hydraulic actuator with a loading capacity of 200 kN. The load was applied on the beam by means of steel plates with dimensions 100 mm x 150 mm x 20 mm, while supports were made by roller and 200 mm x 150 mm x 20 mm steel plates. Two linear variable displacement transducers (LVDTs) were utilized for measuring deflections at mid-span and under the loading point.

3.2 *Shear-displacement curves and failure mechanisms*

Figure 8 Shows the shear vs. deflection response, measured under the loading point as well as the crack pattern at failure for the three tests performed.

As can be seen in Figure 8a, the shear resistance of the PC beam tested in the uncorroded central zone (Test 3) was almost double with respect to that obtained in the corroded and repaired areas (Test 1 and Test 2).

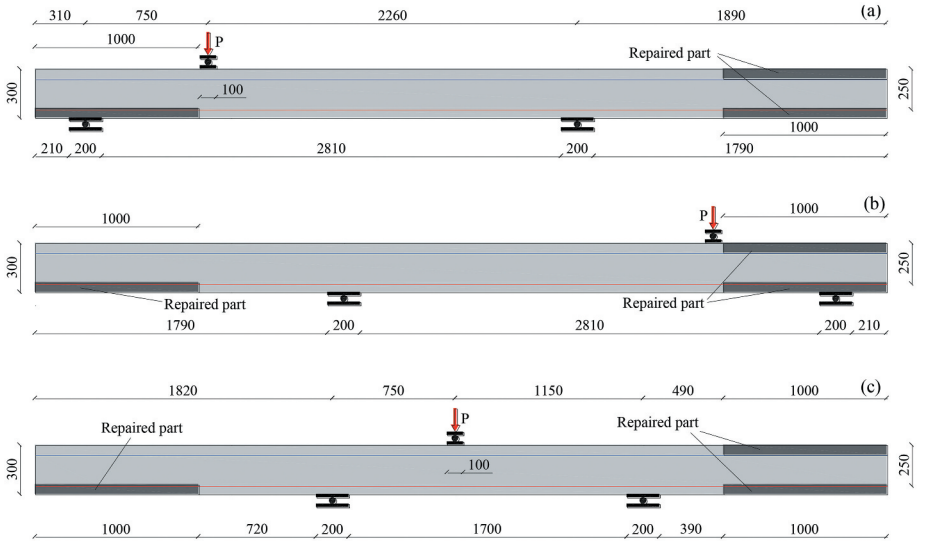

Figure 7. Three-point bending tests performed: (a) at the left end zone (Test 1); (b) at the right end zone (Test 2); (c) in the central zone (Test 3).

More in detail, in Test 3, where the load was applied in the uncorroded and un-repaired central region, flexural cracks developed for a higher value of applied load than Test 1 and Test 2, thanks to the active prestressing force. A main shear diagonal crack suddenly developed causing the failure of the beam (Figure 8d).

In Tests 1 and Test 2 the failure mode of PC beam was similar and characterised by the formation of an inclined shear crack in a region previously cracked in bending. However, in these cases, the anticipated formation of vertical cracks in bending which lead to the premature shear failure, was caused by the loss of residual prestressing force - due to concrete cover spalling during corrosion propagation and concrete removal during cleaning and repairing.

The shear resistance, attributed to the concrete in PC beams without transversal reinforcement, can dramatically decrease when the residual prestressing force is lost by corrosion and/or repairing interventions and the transversal area of strands is reduced due to the formation of pits. The repairing system can effectively protect the strands and re-activate the pull-out resistance but cannot re-introduce the prestressing level previously acting in the uncorroded PC beam. Therefore, particular attention must be paid during the repairing of PC members because patch repairing and other solutions dealing with pull-out strengthening cannot solve the problems related to the loss of the prestressing force.

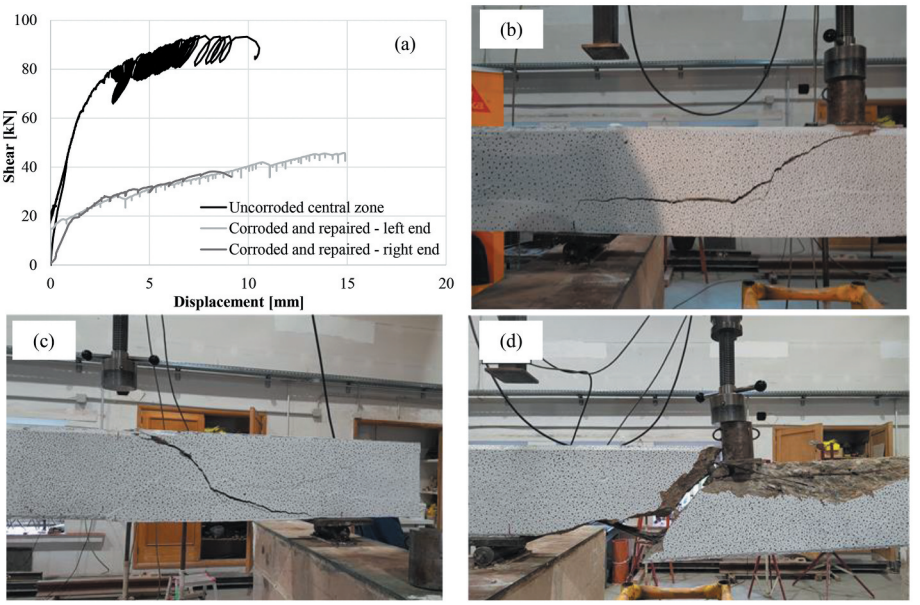

Figure 8. Results in terms of: (a) shear vs. deflection curve; (b-c) crack pattern at failure for the corroded and repaired beam, tested at the left (Test 1) end and at the right end (Test 2), respectively; (d) crack pattern at failure for the test performed at the uncorroded central zone (Test 3).

4 CONCLUSIONS

In this paper, the results regarding the shear behaviour of naturally corroded and repaired PC beams are presented. According to the results obtained, the following conclusions can be drawn.

- The visual inspection is important to highlight longitudinal cracks and concrete cover spalling that reveal corrosion. However, electrochemical tests are required to detect corrosion also in zones without defeat visible to the naked eye and asses the corrosion level distribution along the length of PC elements.
- The presence of corroded strands in PC beams without transversal reinforcement is particularly dangerous since the loss of prestressing force affects the shear resistance attributed to concrete.
- The shear resistance of the PC beam tested in the uncorroded and un-repaired central region was almost double with respect to the shear resistance in the corroded and repaired zones, since the corrosion propagation and the cover removal during repairing caused the total loss of prestressing force.

- The risk of failure in repaired PC members could be even higher than in damaged members because the patch repairing could hide the pre-existing damage, such as splitting cracking or cover spalling that is a sentinel warning of prestressing force loss.

ACKNOWLEDGEMENTS

This study was developed within the PRIN project FIRMITAS "multi-hazard assessment, control and retroFIt of bridges for enhanced Robustness using sMart IndusTriAlized Solutions", which was funded by the Italian Ministry of University and Research.

Risk-based retrofit optimization of deteriorating reinforced concrete bridge columns subjected to corrosion and earthquakes

Sunyong Kim & Yanzhi Yang
Wonkwang University, Iksan, Republic of Korea

Dan M. Frangopol
Lehigh University, Bethlehem, PA, USA

ABSTRACT: This paper presents an approach for risk-based retrofit optimization of reinforced concrete (RC) bridge columns. The proposed approach consists of (a) time-variant seismic performance assessment, (b) time-variant risk assessment, and (c) retrofit optimization. The bridge performance is represented by the time-variant exceedance probability, which indicates the probability of an RC structure exceeding a specific damage state under a given ground motion intensity over time. The effect of corrosion on the exceedance probability is addressed. The damage states of an RC bridge column are defined using the displacement at the top of the column. A 3-dimensional finite element model of the bridge is used to simulate the seismic responses of the RC columns with and without retrofitting. In order to reduce the computational cost for the time-variant exceedance probability, a machine learning technique is adopted. For the time-variant risk assessment, the consequences associated with a specific damage state and associated occurrence probabilities are estimated. The risk assessment is used to formulate the optimization problem for determining the retrofit time for RC bridge columns. The optimization is based on maximizing the benefit ratio during a predefined lifetime.

1 INTRODUCTION

Maintaining the safety of existing bridges under various environmental stressors, deterioration mechanisms, and natural hazards is crucial for ensuring public safety and infrastructure longevity. Over the last several decades, risk has been treated as a rational performance indicator to integrate the occurrence probability of an adverse event for deteriorating bridges and the resulting monetary loss (Zhu & Frangopol 2012; Dong & Frangopol 2015; Frangopol & Kim 2022). Accordingly, several approaches to assess the risk of deteriorating individual bridges and bridge networks have been developed, considering earthquakes, floods, hurricanes, and climate conditions (Stein et al. 1999; Padgett & DesRoches 2007; Decò & Frangopol 2011; Saydam et al. 2013; Zoubir & McAllister 2016; Yang & Frangopol 2019). Based on these approaches, it is necessary to optimize the bridge retrofit for reducing the risk and extending the service life.

In this paper, an approach for risk-based retrofit optimization of reinforced concrete (RC) bridge columns is presented. This approach requires (a) time-variant seismic performance assessment, (b) time-variant risk assessment and (c) retrofit optimization. The seismic performance indicates the probability of exceeding a specific damage state under a given ground motion intensity, where the corrosion propagation is considered. The damage states of an RC bridge column are determined by the displacement at the top of the column. To estimate the effect of retrofit on the seismic responses of the RC columns with and without retrofitting, a 3-dimensional (3D) finite element (FE) model of the bridge is adopted. Through a machine learning (ML) technique, the time-variant seismic performance is computed cost-effectively. Using

DOI: 10.1201/9781003483755-60

the computed time-variant exceedance probability for each damage state, the time-variant risk can be obtained for formulating the optimization problem to determine the retrofit times for RC bridge columns. The optimization is based on maximizing the cost-benefit ratio during a predefined lifetime.

2 TIME-VARIANT SEISMIC PERFORMANCE

The seismic performance can be considered the probability of exceeding a specific damage state under a given peak ground acceleration (PGA). This exceedance probability is expressed as a fragility function at time t

$$P(Dmg(t)|PGA) = \Phi\left[\frac{ln(Med_d(t)) - ln(Med_c(t))}{\sqrt{(\sigma_d(t))^2 + (\sigma_c(t))^2}}\right] \tag{1}$$

where $Dmg(t)$ = damage state of a bridge at time t; $\Phi(\cdot)$ = standard normal cumulative distribution function (CDF); $Med_d(t)$ = median of the seismic demand; $Med_c(t)$ = median of the seismic capacity; $\sigma_d(t)$ = standard deviation (SD) of the seismic demand; and $\sigma_c(t)$ = SD of the seismic capacity. $Med_d(t)$ is estimated using the nonlinear time-history analysis with a 3D FE model. $Med_c(t)$ is predefined for the damage states to be considered. In this study, the denominator in Eq. (1) is assumed to be 0.5 (HAZUS 1999; Banerjee & Ganesh 2013). The effect of corrosion on the fragility function is addressed in estimating $Med_d(t)$.

2.1 *Corrosion initiation and propagation*

The corrosion in the bridge column consists of corrosion initiation and propagation. The corrosion initiation time t_{ini} can be estimated as indicated in Mortagi & Ghosh (2020). Based on both uniform and pitting corrosion propagation models, the remaining reinforcement area $A_r(t)$ at time t can be estimated as indicated in Ghosh & Sood (2016). Finally, the yield strength $f_y(t)$ and ultimate strength $f_u(t)$ of the reinforcement, and compressive strength of the cover concrete $f_{c,cov}(t)$ at time t can be expressed as indicated in Coronelli & Gambarova (2004).

2.2 *Effect of bridge column retrofit on seismic performance*

A bridge column plays a crucial role in providing support and stability to a bridge structure, especially during seismic events. To enhance the seismic performance of bridge columns, retrofitting techniques such as the use of wraparound jackets have been adopted. These jackets, commonly made of materials including steel, carbon fiber, and glass fiber, are applied to existing columns to strengthen and confine them, improving their resistance to earthquakes. Assuming that bridge column jacketing increases the median of PGA resulting in a particular damage state, the logarithm of the median of the seismic demand after bridge column jacketing $ln(Med_d^*(t))$ is expressed as

$$ln\left(Med_d^*(t)\right) = ln(Med_d(t)) \cdot (1 - r_{rt}) \quad \text{for } ln(Med_d(t))0 \tag{2a}$$

$$ln\left(Med_d^*(t)\right) = ln(Med_d(t)) \cdot (1 + r_{rt}) \quad \text{for } ln(Med_d(t)) < 0 \tag{2b}$$

where r_{rt} is the reduction factor associated with retrofit. In this paper, the carbon fiber composite (CFC) jacket is used as a bridge column retrofit. The seismic demand of the bridge column is characterized by the displacement ductility, defined as the ratio between the maximum displacement at the top of the column and the displacement at the same location when the reinforcement attains its yield strength.

3 TIME-VARIANT SEISMIC RISK AND COST-BENEFIT ANALYSIS

Risk is an effective bridge performance indicator for addressing both the probability of occurrence of a specific adverse event and the associated monetary loss (Frangopol & Kim 2022). Based on risk, the cost-benefit analysis can be performed to optimize the bridge column retrofit.

3.1 *Time-variant risk assessment*

The expected seismic risk can be expressed as (Padgett et al. 2010)

$$R(t) = \int_{P_l}^{P_u} R(t|PGA = x)\left|\frac{dP_{exd}(x)}{dx}\right|dx \tag{3}$$

where P_u and P_l are the upper and lower bounds of PGA, respectively; $R(t|PGA = x)$is the seismic risk for a specific PGA equal to x at time t, and $P_{exd}(x)$ is the annual probability of exceeding PGA = x. The annual exceedance probability $P_{exd}(x)$ can be determined by the seismic hazard analysis with the historical earthquake data for a region. The seismic risk $R(t|PGA = x)$ can be computed as (Dong & Frangopol 2015)

$$R(t|PGA = x) = \sum_{i=1}^{N_D} C_{lss,i}(t) \cdot P(Dmg_i(t)|PGA = x) \tag{4}$$

where $C_{lss,i}(t)$ = monetary loss for the ith damage state; $P(Dmg_i(t) \mid PGA = x)$ = fragility function associated with the ith damage state; and N_D is the number of damage states. The fragility function $P(Dmg_i(t) \mid PGA = x)$ is estimated using Eq. (1). The monetary loss $C_{lss,i}(t)$ can be computed as

$$C_{lss,i}(t) = C^{dir}_{lss,i}(t) + C^{ind}_{lss,i}(t) \tag{5}$$

where $C^{dir}_{lss,i}(t)$ and $C^{ind}_{lss,i}(t)$ are the direct and indirect monetary loss, respectively, for the ith damage state at time t.

3.2 *Cost-benefit analysis based on risk*

The cost-benefit analysis for application of the bridge column retrofit can be based on risk assessment. The retrofit reduces the risk by improving the resistance of bridge columns to earthquakes. The cost-benefit can be analyzed by comparing the risk with and without bridge column retrofit. Therefore, the cumulative benefit C_{ben} by applying the retrofit can be expressed as (Padgett et al. 2010; Mondoro & Frangopol 2018)

$$C_{ben} = \int_0^{t_{tg}} [R_0(t) - R_{rt}(t)]dt \tag{6}$$

where t_{tg} is the predefined target time; and $R_0(t)$ and $R_{rt}(t)$ are the expected seismic risk without and with retrofit, respectively. When the cumulative benefit C_{ben} in relation to retrofit cost is investigated, the cost-benefit ratio R_{ben} can be used, which is expressed as (Padgett et al. 2010; Mondoro & Frangopol 2018)

$$R_{ben} = \frac{C_{ben}}{C_{rt}} \tag{7}$$

where C_{rt} is the retrofit cost. In this study, the optimum seismic retrofit for RC bridge columns is based on maximizing the cost-benefit ratio R_{ben}.

4 APPLICATION TO AN EXISTING BRIDGE

The approach presented in this paper is illustrated with an existing RC bridge located in South Korea. In this paper, the bridge columns are treated as a critical bridge component under seismic events (Akiyama et al. 2011; Abbasi & Moustafa 2019). Details of the bridge configuration and associated 3D FE model can be found in Ge et al. (2023).

4.1 *Time-variant fragility analysis using machine learning*

For the time-variant fragility analysis, the four damage states (i.e., slight, moderate, extensive, and complete states) are defined by the displacement ductility of the bridge column. The median of the seismic capacity of the displacement ductility for slight, moderate, extensive, and complete damage states are 1.0, 2.9, 4.6, and 5.0, respectively (Banerjee & Ganesh Prasad 2013). They are used to compute the exceedance probability of Eq. (1). The displacement ductility of the bridge column is computed through the nonlinear time-history analysis of the 3D FE model, where the effects of corrosion on the cross-sectional area of the bridge column, degradation of the yield and ultimate strengths of reinforcement and loss of cover concrete strength are addressed. The nonlinear time-history analysis for estimating the time-variant median value of seismic demand is performed with the response spectrum based on the Korean seismic design code (MOLIT 2018). The logarithmic median value of seismic demand at time t can be expressed as (Hwang et al. 2001)

$$ln(Med_d(t)) = \alpha(t) + \beta(t) \cdot ln(PGA) \tag{8}$$

where $\alpha(t)$ and β (t) are the regression coefficients to represent the relation between ln(PGA) and $ln(Med_d(t))$.

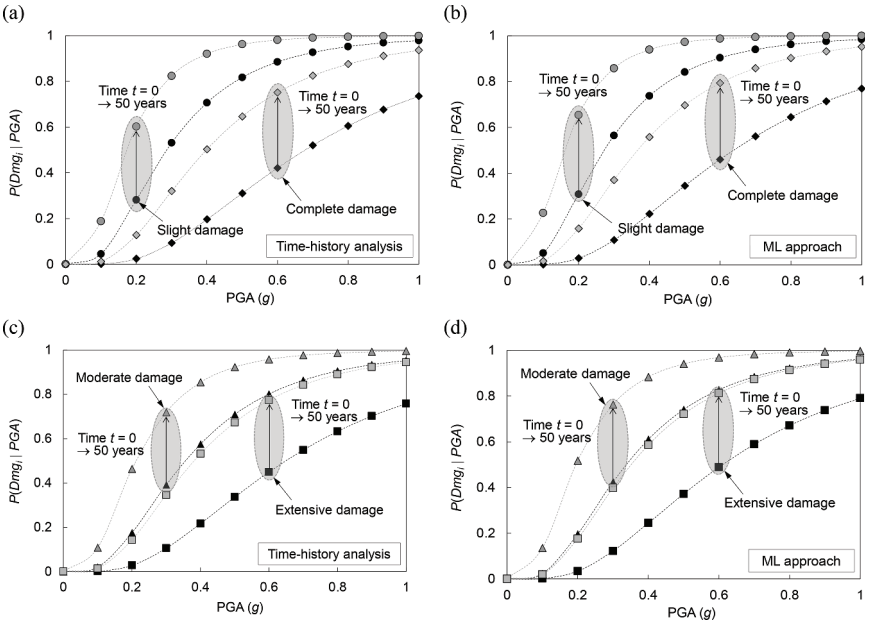

Figure 1. Fragility curves at 0 and 50 years: (a) time-history analysis for slight and complete damage states; (b) ML approach for slight and complete damage states; (c) time-history analysis for moderate and extensive damage states; and (d) ML approach for moderate and extensive damage states.

In order to obtain the coefficients $\alpha(t)$ and β (t) at a specific time t, multiple times of nonlinear time-history analyses should be performed. As the number of times to be investigated for the

time-variant fragility analysis increases, a higher computational cost is required. Recently, ML techniques have been recognized for enhancing the computational efficiency of fragility analysis (Huang & Huang 2020). In this paper, the ML approach based on XGBoost is used. As a result, the coefficients $\alpha(t)$ and $\beta(t)$ in Eq. (8) are expressed in the form of a second-order polynomial as:

$$\alpha(t) = 0.001 \cdot t^2 + 0.0057 \cdot t + 1.02 \tag{9a}$$

$$\beta(t) = 3 \times 10^{-5} \cdot t^2 - 0.0004 \cdot t + 1.89 \tag{9b}$$

Figure 1 shows the fragility curves based on the nonlinear time-history analysis and ML approach at time t = 0 and 50 years for slight, moderate, extensive, and complete damage states. Using Eqs. (8) and (9), the fragility curves at any time t for four damage states can be obtained, and furthermore is used to compute the risk and formulate the optimization for bridge column retrofit.

4.2 *Risk assessment with bridge column retrofit*

The bridge column retrofit using CFC can reduce (a) the seismic demand, which is represented by the reduction factor r_{rt} [see Eq. (2)], (b) the probability of exceeding a specific damage state under a given PGA [see Eq. (1)], and (c) the expected seismic risk [see Eq. (3)]. In order to determine the reduction factor r_{rt}, the relation between $ln(Med_d(t))$ and $ln(Med^*_d(t))$ in Eq. (2) is computed through the nonlinear time-history analysis based on 3D FE model, where the mechanical properties of CFC provided in Chandrasekaran & Banerjee (2016) are used. As a result, the reduction factor r_{rt} is determined as 0.485. Figure 2 shows the seismic risk $R(t|PGA = 0.3g)$ with and without retrofit. It is assumed that the bridge column retrofit is applied to an entire area of the columns, and corrosion of the bridge column continuously propagates after retrofit. The details for the risk assessment are provided in Kim et al. (2023).

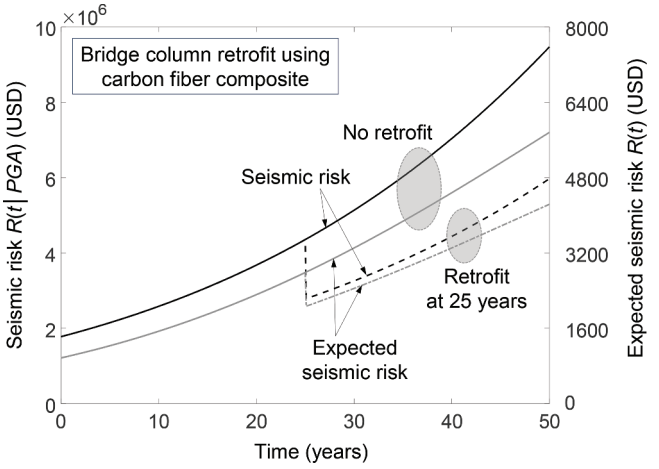

Figure 2. Seismic risk under PGA = 0.3g and expected seismic risk without and with retrofit applied at 25 years.

The expected seismic risk profiles without and with retrofit applied at 25 years are also shown in Figure 2. As indicated in Eq. (3), estimation of the expected seismic risk $R(t)$ requires the annual probability of exceeding a specific PGA, which is based on the seismic hazard analysis for the bridge location. According to Nakajima et al. (2007) and Park et al. (2021), it is estimated as $P_{exd}(x)$ = 0.005·exp[-15x], where x is the PGA ranging from 0g to 1.0g. From

Figure 2, it can be seen that the bridge column retrofit using CFC reduces both the seismic risk for a given PGA and the expected seismic risk.

4.3 *Optimum bridge column retrofit*

The optimum bridge column retrofit using CFC determines the retrofit time to maximize the cost-benefit ratio R_{ben} during the predefined lifetime of 50 years. The cost-benefit ratio R_{ben} is defined as the ratio between the cumulative benefit C_{ben} and retrofit cost C_{rt}, as indicated in Eq. (7). Figure 3 shows the cumulative benefit C_{ben} and cost-benefit ratio R_{ben}, when the retrofit application time t_{rt} ranges from zero to 50 years. The maximum cumulative benefit C_{ben} can be obtained by immediately applying the CFC bridge column retrofit (i.e., t_{rt} = 0 years). The application of the CFC bridge column retrofit at 26.9 years maximizes the cost-benefit ratio R_{ben}.

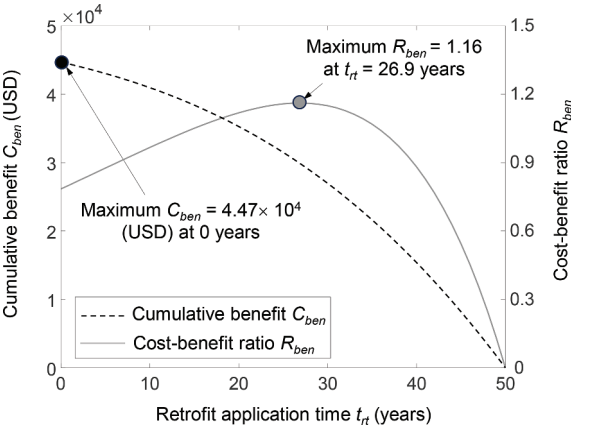

Figure 3. Relation between cumulative benefit and retrofit application time, and between cost-benefit ratio and retrofit application time.

5 CONCLUSIONS

This paper presents an approach to optimize the retrofit of bridge columns. This approach consists of (a) time-variant seismic performance prediction, (b) time-variant risk assessment with and without retrofit, and (c) optimization to determine the retrofit time. The seismic performance is represented by the fragility of a bridge column. The retrofit can reduce the expected seismic risk associated with corroded bridge columns. In the example presented, the cumulative benefit obtained from the retrofit is positive over 50 years. However, it continuously decreases over time. Therefore, to maximize the cumulative benefit, an immediate application of the bridge column retrofit is required. When both the cumulative benefit and retrofit cost are considered, the objective of maximizing the cost-benefit should be adopted for the optimum bridge column retrofit.

Life-cycle assessment of riverine bridges under flood and corrosion

R.K. Arora, S. Banerjee & A. Kumar
Department of Civil Engineering, Indian Institute of Technology Bombay, Powai, Mumbai, India

ABSTRACT: Global bridge failure statistics highlight that hydraulic actions, particularly hydrodynamic forces and scour, contribute significantly to bridge failures. Previous incidents reveal that extreme floods can lead to complete inundation, resulting in collapse of bridges. Recent studies underscore the vulnerability of the superstructure during flood events. Despite prior research, understanding the impact of flood-induced hydraulic forces on diverse bridge components, particularly in life-cycle analysis with gradual degradation from chloride-induced corrosion, remains limited. This study utilizes computational fluid dynamics (CFD) simulations through ANSYS Fluent. It evaluates hydrodynamic forces on superstructure of a typical RC riverine bridge, accounting for gradual performance degradation due to corrosion. The study considers flood-induced scour and conducts finite element (FE) analyses at different stages of the bridge's lifespan, offering insights into its life-cycle performance under diverse flood scenarios. These findings inform strategies to mitigate the enhanced flood vulnerability of inland RC river bridges facing future intense flood events.

1 INTRODUCTION

Bridges play a crucial role in network connectivity, serving as essential links across various landscapes such as valleys, rivers, and roads to facilitate efficient transportation. Among them, riverine bridges face unique challenges, particularly related to flood hazards. Cook et al. (2015) and Wardhana and Hadipriono (2003) highlight that over 60% of bridge failures result from hydraulic-related issues, such as hydrodynamic forces, debris forces, and scour. Hydrodynamic forces, specifically drag and lift, are predominant factors influencing bridge components and depend on factors like inundation ratio, force coefficients, water velocity, and cross-sectional area. Most of the past research has explored hydrodynamic forces on bridge superstructures in isolation and are categorized into three categories: experimental, numerical, and empirical studies. Experimental studies, exemplified by Bushra (2010), Dean (2020), and Kerenyi et al. (2009), involve scaled models in experimental flumes to compute hydrodynamic forces for different submergence levels. Numerical simulations, as seen in studies by Greco and Lonetti (2022), Istrati and Hasanpour (2022), and Pregnolato et al. (2022), employ computational fluid dynamics (CFD) to calculate hydrodynamic forces on submerged bridge superstructures. Empirical studies by Arora and Banerjee (2023) and Mondoro and Frangopol (2018) considered empirical formulae given by international bridge design codes. However, these studies have yet to examine the combined effect of hydrodynamic forces and scour comprehensively. Therefore, the study addresses this research gap by considering the simultaneous action of hydrodynamic forces and scours on riverine bridges. Additionally, the study includes a life-cycle assessment focusing on the deterioration of reinforcement bars due to chloride-induced corrosion, as discussed in the following paragraph.

Owing to the presence of microcracks, aggregate particles, and interconnected pores in concrete, chloride ions can permeate the material when its surface is exposed to a corrosive environment. As concrete possesses alkaline properties, it can withstand chloride exposure up to

DOI: 10.1201/9781003483755-61

a certain concentration. The duration it takes for chloride ions to initiate corrosion on reinforcing bars after intrusion is termed as corrosion initiation time. Prolonged corrosion activity leads to the development of hemispherical pits on the surface of reinforcements. These pits may exhibit non-uniform distribution along the length of the rebar and vary in depth. Consistent pit creation with similar depths across the rebar length is termed as uniform corrosion, whereas uneven pit development is referred to as pitting corrosion. The procedure for uniform corrosion is rather straightforward, entailing reduction of rebar diameter to compute the decrease in the cross-sectional area. The corrosion intensity is influenced by multiple factors incorporated in the corrosion rate formulation. Devendiran and Banerjee (2023) presented a detailed understanding of the reduced area calculation due to pitting corrosion. The next section discusses the methodology adopted for this study.

2 METHODOLOGY

This study used a systematic approach to examine how flood-related issues affect different bridge components (Figure 1). The process begins by establishing extreme flood scenarios to be considered for the study. Ideally, this should be based on a site-specific investigation, but since data for the site was unavailable, different combinations of water velocity and water height were considered, as these are the key factors influencing bridge components during floods. The next step involves developing a finite element (FE) model of the bridge and assessing the forces acting on its components. Computational fluid dynamics (CFD) is employed for the superstructure, while a code-based formula is used for the piers. However, most bridge design codes have defined formulas for pier forces; only AS 5100.2 (2017) and CD 356 (2020) provide hydrodynamic force definitions for the superstructure. Additionally, scour depth is calculated using the empirical formula from Arneson et al. (2001). Subsequently, all computed forces are applied to the FE bridge model at varying scour depths, and the response of the bridge components is recorded. Finally, to consider the bridge's life cycle, the corrosion model is integrated into the study, accounting for reduced cross-sectional area and material properties of reinforcement bars.

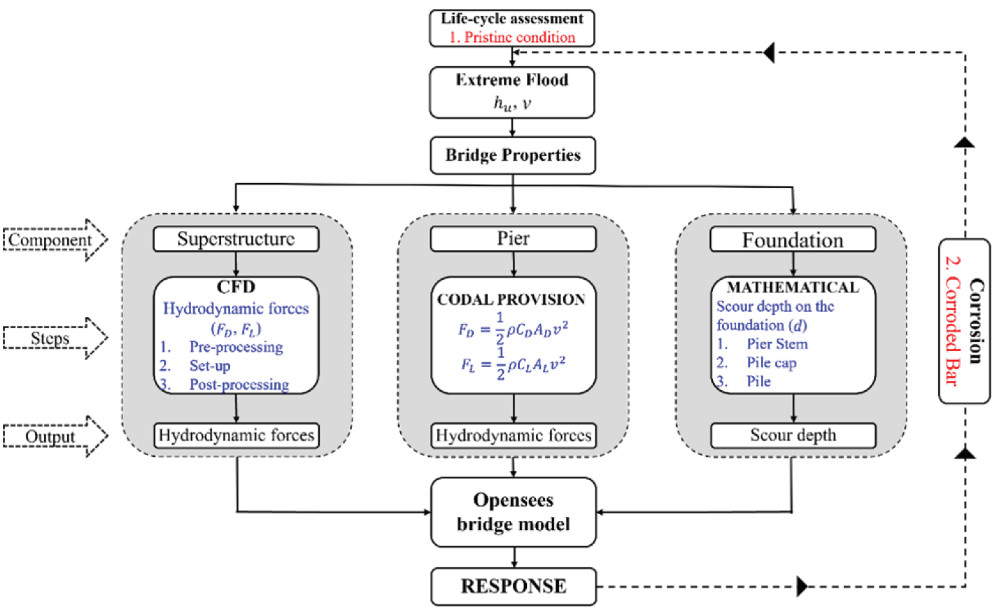

Figure 1. Numerical framework for analyzing the bridge under flood hazard.

3 BRIDGE MODEL

A representative bridge located in the Shetrunji River in Gujarat, India, was chosen as a case study (Figure 2). The bridge is 3-span simply supported with a span length of 20m and a width of 10.1m. The bridge deck is upheld by five concrete T-girders positioned on elastomeric bearings. The bridge consists of two bents, each featuring two piers measuring 0.75m in diameter. The foundations include a pile cap beneath each pier supported by eight circular piles, each with a diameter of 0.46m. A finite element bridge model is developed in OpenSees using Concrete07 for concrete and Steel02 for reinforcement bars. For bridge superstructure, rather than using a single beam stick model, a deck grillage was developed, which can distribute the hydrodynamic load more efficiently. The entire superstructure was modeled as linear elements due to the high lateral stiffness of the bridge. The validity of deck grillage model is cross-checked with an experimental study performed by Song et al. (2016), and the outcomes align favorably with the study at hand. Furthermore, elastomeric bearings with dimensions 0.451×0.146×0.060m are modeled. The bearing pad was modeled as an elastic material, whereas the bars in bearings were modeled as perfectly plastic material. Similar properties are assigned to the bearing in both horizontal directions. Elastomeric bearing is highly stiff in the vertical direction. The cross-section of the pier has 14 number 32mm diameter reinforcing bars, which are modeled as displacement-based fiber elements that consider distributed plasticity. The bridge has two seat-type abutments on both sides with soil modeled as bilinear hysteretic behavior. Further impact elements are also modeled in the bridge between 2 adjacent spans and between span and abutments. At last, the foundation was modeled, which has a 1m thick pile cap with dimensions shown in Figure 2. The soil surrounding the piles is simulated using p-y, t-z, and q-z springs in accordance with the API (2000) recommendations. The p-y spring characterizes soil properties in both horizontal directions. In contrast, the t-z spring represents the vertical soil properties, and the q-z spring signifies the lowermost spring at the piles. The subsequent section describes the hydrodynamic forces considered for this study on different bridge components.

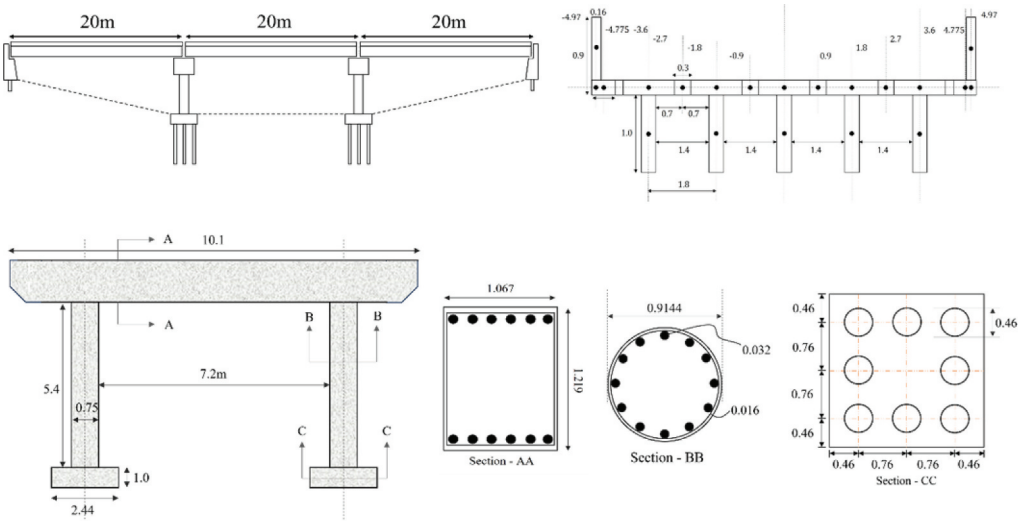

Figure 2. Bridge model considered in the study.

3.1 *Hydrodynamic loads on piers*

This research focused on analyzing the hydrodynamic loads, specifically the drag and lift forces, exerted on bridge components during extreme flood conditions. The hydrodynamic forces exerted on bridge piers were computed in accordance with established bridge design

codes, as these codes typically provide clear guidelines for calculating hydrodynamic loads on piers. Based on major design codes, the following expressions are used in this study to compute the drag (F_d) and lift (F_l) forces on piers.

$$F_d = \frac{1}{2}\rho.C_d.A_d.v^2 \tag{1}$$

$$F_l = \frac{1}{2}\rho.C_l.A_l.v^2 \tag{2}$$

In this context, ρ represents the density of water, and v represents the mean flow velocity. The variables A_d and A_l denote the respective cross-sectional areas that experience drag and lift forces. However, concerning the bridge superstructure, detailed information on hydrodynamic loads is only mentioned in AS5100.7 (2017) and CD356 (2020); other codes lack comprehensive descriptions in this regard. Therefore, numerical modeling approach has opted to compute the forces on superstructure.

3.2 *Hydrodynamic forces on superstructure*

To compute the hydrodynamic forces exerted on the bridge superstructure, a Computational Fluid Dynamics (CFD) simulation is employed, and Ansys Fluent is selected among various available software for this purpose. The superstructure model detailed in Section 2 is recreated in ANSYS Fluent at a reduced scale of 1:40. In Ansys, the κ – ε turbulence model is widely used for fully submerged superstructures. The Shear Stress Transport (SST) κ – ω turbulence model combines the advantages of κ – ε and κ – ω models, enhancing boundary layer behavior and flow separation capture. Past studies employed the Volume of Fluid (VoF) transient multiphase model for free surface tracking (Kerenyi et al., 2009). In this study, VoF multiphase (air and water) with κ – ω SST turbulence model is applied. Inlet, outlet, and free surface boundary conditions, including velocity and submergence, are detailed further. The hydrodynamic forces acting on superstructures are influenced by various crucial parameters, with water height and water velocity being two key determinants. Water height is alternatively expressed as the inundation ratio, defined as the ratio of the difference between the water level (h_u) and the soffit level of the girder (h_b) to the thickness of the superstructure (s) (Equation 3).

$$h^* = \frac{h_u - h_b}{s} \tag{3}$$

Essentially, it signifies the degree of submergence of the superstructure relative to water. In this study, two scenarios are examined: one involving partial submergence ($h^* = 0.5$) and the other a full submergence ($h^* = 2$). The water velocity range selected in this study was based on prior research done on submerged superstructures and varies from 1 to 3 m/s, For the CFD simulations aimed at calculating hydrodynamic forces, an interval of 0.25 m/s is employed. Further, to ensure accuracy, a mesh convergence study is conducted using three distinct meshing schemes: single-face, double-face, and multi-block meshing. The validation of these meshing strategies is cross-checked by Kerenyi et al. (2009), with the double-face meshing method being adopted for this study in accordance with Kerenyi's findings. Additionally, a time-step convergence study is carried out, and a time step of 0.005 seconds is chosen for the subsequent analysis.

3.3 *Life-cycle consideration*

To assess the life cycle deterioration of the bridge, corrosion initiation time (T_{ini}) was computed using Equation 4.

$$T_{ini} = \left\{ \frac{X^2}{4k_e k_c D_{cl,0} (t_0)^{n_{cl}}} \left[\text{erf}^{-1} \left(\frac{C_s - C_{th}}{C_s} \right) \right]^{-2} \right\}^{\frac{1}{(1-n_{cl})}} \quad (4)$$

The variation of corrosion rate over time for pitting corrosion is illustrated in Figure 3. The correction parameter for curing (k_c) is 0.16, and environmental influences (k_e) is 0.68, X (50.8 mm) is the concrete cover of the exposed component, $D_{cl,0}$ (473 mm/year) denotes the reference diffusion coefficient, C_s (9.5 kg/m^3) denotes the surface chloride concentration of the bridge component (Dey & Sil, 2021), C_{th} is the chloride concentration threshold, which is set at 0.52 kg/m^3 (Caltrans, 2018), and n_{cl} (0.65) is an age exponent that represents the susceptibility of reinforcing bars to corrode owing to cement densification caused by hydration. The initiation time for this study comes out to be 7.7 years. The time-varying area reduction ratio of rebar (Reduced Area/Original Area) due to pitting corrosion is shown in Figure 4. After the computation of reduced area, the area of reinforcement in the T-girder is reduced in the FE (Finite Element) model for that particular year, and the modified degraded bridge is used for further analysis.

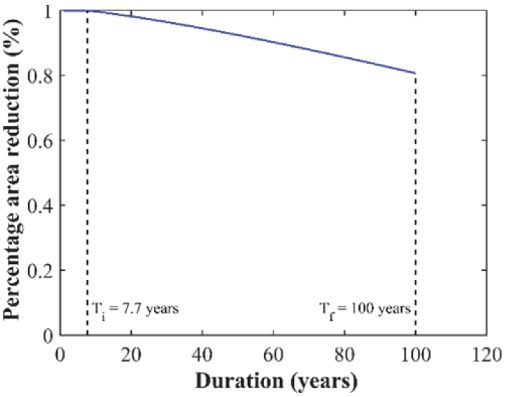

Figure 3. Percentage area reduction vs time.

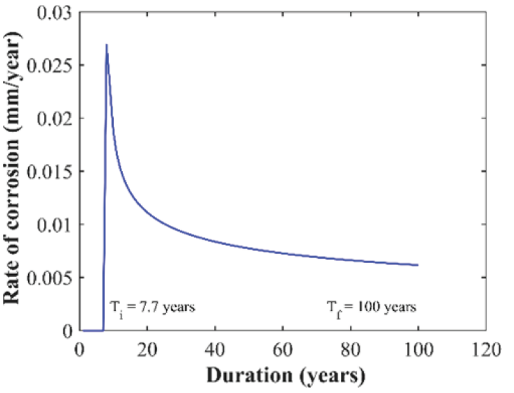

Figure 4. Rate of corrosion vs time.

3.4 *Damage states associated with different bridge components*

Once the bridge model, hydrodynamic forces, and corrosion model is done, the subsequent step involves defining the damage states linked to various bridge components. Specifically, damages to the bridge superstructure are evaluated in relation to the bearing dimensions (which are 25%, 50%, and 75% of half of bearing length), as the bridge girders rely on these bearings for support. The bearing damage states are adopted from Yilmaz et al. (2016). To define the damage state associated with pier, curvature ductility is selected as the governing parameter as they are generally designed as flexural components. Moment-curvature analysis is performed for the pier section to compute the curvature ductility associated with each damage state. Based on this, the actual moment-curvature curve is established. Further, based on the actual moment-curvature curve, an idealized curve is derived. In this context, four damage states are defined. The curvature associated with rebar yielding (ϕ_y) marks the initiation of piers' plastic deformation representing minor damage. Pier failure occurs when the core concrete crushes (i.e., at $\phi_{cu\text{-}core}$) representing a failure scenario. Between yielding and collapse, two intermediate damage (namely moderate and major) thresholds are defined: one when the concrete cover crushes ($\phi_{cu\text{-}cover}$) and the other when two-thirds of the ultimate core crushes ($\phi_{2/3cu\text{-}core}$). Table 1 provides detailed curvature ductility values (both upper and lower bounds) for each damage state. Identifying such damage states is crucial for determining post-event recovery measures for piers.

Table 1. Damage states for different bridge component.

S.no	Damage states	Superstructure lateral displacement [Δ_S] (mm)	Bearing lateral displacement [Δ_B] (mm)	Pier curvature ductility [ϕ]
1	Minor	*≤ 56*	*30 – 88*	*1.0 – 3.82*
2	Moderate	*56 – 113*	*88 – 282*	*3.82 – 9.91*
3	Major	*113 – 169*	*282 – 335*	*9.91 – 14.38*
4	Collapse	*169 ≥*	*335 ≥*	*14.38 ≥*

4 RESULTS AND DISCUSSION

Figure 5a illustrates the lateral displacement of the superstructure under inundation levels 0.5 and 2, pertaining to water velocity under no scour conditions. The lateral response exhibits a positive correlation with velocity, attributed to the increase in hydrodynamic forces as water velocity rises. While the displacement is minimal at lower velocities, it escalates rapidly once the velocity surpasses 1.5m/s. The maximum displacement under pristine conditions occurs at a velocity of 3.5m/s, reaching 32mm. In contrast, the response for a corroded section under inundation level 2 is 37mm. Figure 5b depicts similar plots for a 5m scour case. The maximum response under pristine conditions for inundation level 2 is 40.5mm, whereas, for a corroded section, the superstructure response is approximately 46mm. It is worth noting that the Opensees bridge model experiences failure under inundation level 2 for a velocity of 4m/s in both scour cases. This basically represents that superstructure is undergoing minor damage and moderate damage for a velocity of around 3.6m/s. There is a noticeable contrast in the superstructure lateral displacement between the two scour scenarios.

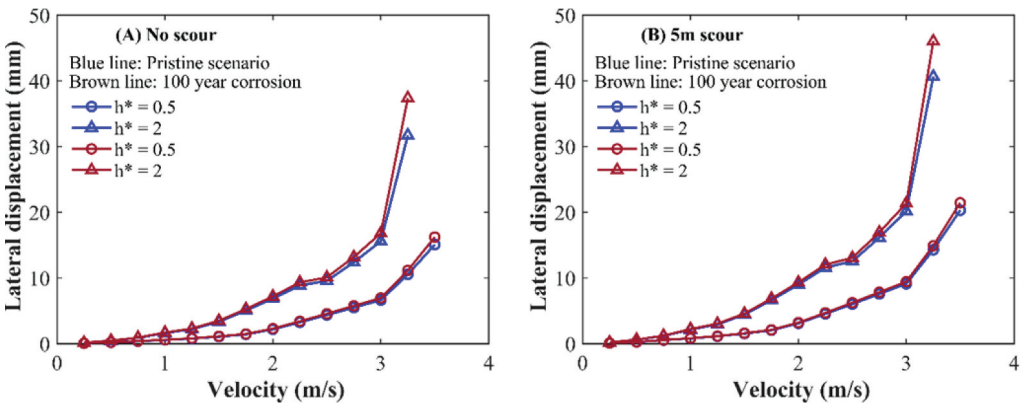

Figure 5. Lateral displacement of the superstructure for different inundation levels and corrosion scenarios (a) No scour and (b) 5m scour.

Figure 6 depicts the lateral displacement of the bearing across various scour scenarios, considering both pristine and a 100-year corrosion case. The recorded displacements for the bearings are notably minimal or no change, even in the presence of scour. Additionally, the marginal difference in response between the two inundation levels suggests that bearings are not susceptible components under hydrodynamic loading and even for maximum scour.

Figure 7 depicts the bridge pier response in terms of curvature ductility for different inundation levels and pristine and 100-year corroded section. The pier response depicted in Figure 7 shows a resemblance in both scour scenarios concerning the specified inundation levels. In each case, the maximum curvature ductility is observed at 3.5m/s, exceeding a value of 2, signifying minor damage to the piers resulting from hydrodynamic forces. This also represents that the pier is the second most vulnerable component in the bridge model due to hydrodynamic forces.

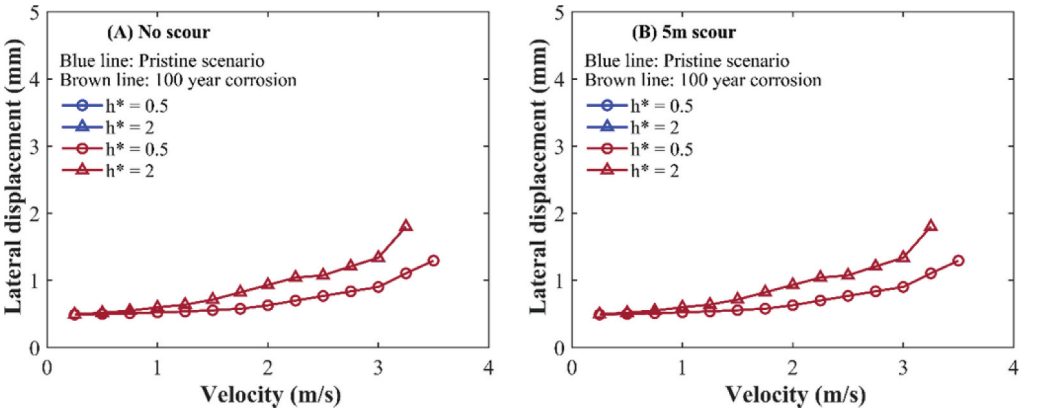

Figure 6. Lateral displacement of the bearings for different inundation levels and corrosion scenarios (a) No scour and (b) 5m scour.

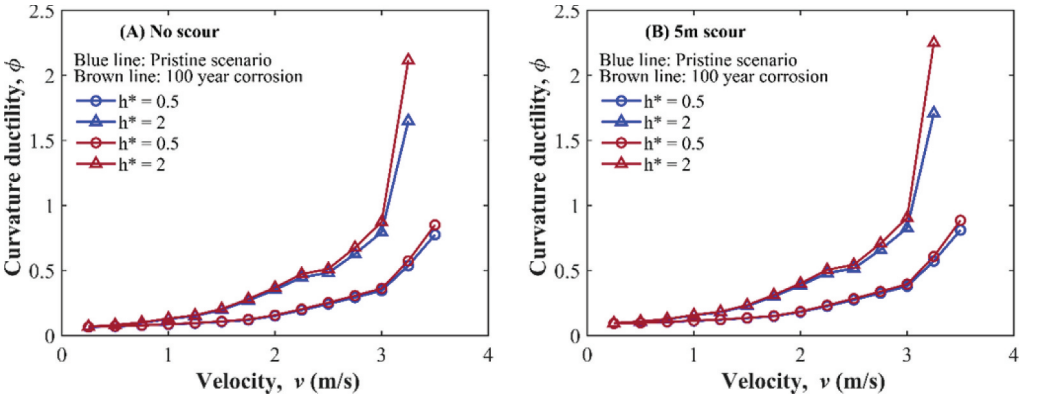

Figure 7. Curvature ductility of the pier for different inundation levels and corrosion scenarios (a) No scour and (b) 5m scour.

The methodology employed in this research draws from both code-based and computational dynamics simulations. To the best of the author's knowledge, no prior study has utilized a comparable approach. While individual studies have explored code-based and numerical methods, this novel methodology requires further refinement, and the results obtained using this approach warrant additional assessment.

5 CONCLUSIONS

This study considers the effect of hydrodynamic forces and scour on riverine bridges at various inundation levels. Additionally, this study conducted a life-cycle analysis that considered the gradual degradation of reinforced concrete (RC) bridges over 100 years. A representative bridge on the Shetrunji River in Gujarat region of India is selected for this study. The bridge is modeled in Opensees with superstructure as deck grillage, pier as fiber-based element and soil below the ground is modeled using p-y, t-z and q-z spring properties following API recommendations. The hydrodynamic forces for the superstructure are computed based on CFD simulations in Ansys fluent, whereas for substructure, these forces are computed using code provisions. These forces are exerted on the bridge model developed in OpenSees, leading to several conclusions drawn from the analysis, which are outlined below.

1) In the context of life-cycle analysis, the onset of pitting corrosion occurred at 7.7 years. Additionally, the cross-sectional area of the rebar, designed for a 100-year lifespan, was reduced by 20%.
2) The maximum superstructure displacement was observed at a velocity of 3.5m/s for 5m scour cases at inundation level 2 under pristine conditions, measuring 40.5mm. In contrast, for the 100-year corrosion scenario, it was recorded as 46mm. Further, the maximum response for superstructure can go up to moderate damage at a velocity of 3.6m/s. The bridge bearings exhibit minimal response to hydrodynamic forces, indicating no damage.
3) The OpenSees bridge model experiences failure at inundation level 2 at velocity 4m/s for both scour cases. This failure primarily pertains to the bridge superstructure, as neither the bearings nor the piers exhibit specific damage.
4) Pier responses were evaluated based on curvature ductility, and various damage states were computed using moment-curvature analysis. Under 5m scour and a corroded section subjected to maximum water velocity, the pier experienced minor damage.

In the future, this study can be extended to explore the uncertainties linked to both flow properties and structural properties.

ABSTRACT: The shape memory alloy (SMA) is a type of advancing material with flag-shaped hysteretic behavior. Compared with the conventional bridge, the SMA-steel reinforced bridge can mitigate seismic hazards due to its self-centering characteristics. The economic cost and carbon dioxide emissions of producing the SMA material are relatively higher compared with conventional steel. Within the life cycle of bridges, multiple earthquakes and continuous deterioration can occur resulting in accumulated consequences. It is necessary to conduct a cost-benefit analysis in a life-cycle context. In this study, the life-cycle earthquakes are modeled using a stochastic process. The deterioration is modeled to compute the time-dependent seismic fragility by considering the chloride attack. The life-cycle benefit of the SMA-steel reinforced bridge is computed in terms of sustainability (e.g., social, economic, and environmental aspects) and resilience. The economic and environmental cost of constructing the novel bridge is obtained from historical data. The life-cycle cost-benefit analysis is finally conducted. The advantages of the novel bridge are revealed in a life-cycle context, which can aid the design of bridges for a sustainable and resilient future.

1 INTRODUCTION

Within the service life of bridges, multiple earthquakes can occur and cause consecutive structural damage, resulting in accumulated consequences in social, economic, and environmental aspects. In the meantime, bridges can deteriorate over time in a marine environment due to chloride exposure, resulting in time-variant performance.

Self-centering characteristics are important for structures to mitigate damages under earthquakes, the concrete walls equipped with friction devices were developed, and their effectiveness of self-centering capability and damage mitigation has been confirmed (Guo et al. 2017, 2018). The shape memory alloy (SMA) is a type of advancing material associated with self-centering characteristics and corrosion resistance (Fang et al. 2022, 2017, 2014, Xiang et al. 2020, Billah & Alam 2012). A novel bridge design equipped with SMA-steel reinforcement has been developed for the purposes of mitigating the consequences by adapting compound earthquakes and corrosion (Fang et al. 2021, Li et al. 2021, Muntasir Billah & Alam 2015, Xiang et al. 2020, Zheng & Dong 2019). The construction of the SMA-steel reinforced bridge needs higher construction cost and produces more carbon dioxide emissions compared with the conventional bridge. Due to the risk associated with climate change, decision-makers have invested tremendous attention in carbon dioxide emissions to achieve the goal of carbon neutrality (Anderson & Peters 2016, Wang et al. 2021). The benefit of an adaptation measure is

DOI: 10.1201/9781003483755-62

event-dependent and can be accumulated from multiple events over time. The performance of SMA-steel reinforced bridge has been assessed (Qian et al. 2022b).

However, the cost-benefit analysis in a life-cycle context for the SMA-steel reinforced bridge has not been well conducted. In this study, a life-cycle cost-benefit analysis covering the criteria of sustainability and resilience is developed. Then, it is implemented on an SMA-steel reinforced bridge. New insights on the cost-benefit results of the novel bridge are provided in a life-cycle context.

2 AN SMA-STEEL REINFORCED BRIDGE

The SMA is a type of advancing material associated with the characteristics of super elasticity. The SMA bars are found to present a flag-shaped constitutive behavior upon loading and unloading. Due to the self-centering capacity, the SMA bar can almost return to its pre-loading position after experiencing considerable deformation. Additionally, the SMA material is associated with superior corrosion resistance, it can be used in a marine environment to prevent the corrosion induced by chloride penetration. Considering the advantages of self-centering characteristics and corrosion resistance, the SMA material can be implemented into structures for adapting to earthquakes and corrosion in a life-cycle context.

The SMA bars have been used in the plastic hinge of the pier to develop the SMA-steel reinforced bridge. Within the service life, bridges can experience multiple stochastic earthquakes and time-dependent corrosion. Under compound earthquakes and corrosion, the sustainability and resilience of the SMA-steel reinforced bridge can be improved compared with the conventional bridge (Qian et al. 2022b), while the construction cost and carbon dioxide emissions of the SMA-steel reinforced bridge are much higher. It is essential to conduct a cost-benefit analysis in a life-cycle context to facilitate the decisions of future implementation.

3 LIFE-CYCLE COST-BENEFIT ANALYSIS: SUSTAINABILITY AND RESILIENCE

3.1 *Deterioration and earthquakes within the service life of bridges*

The bridges can deteriorate along with the service life in a marine or deicing salt environment. The chlorides can propagate through the concrete cover and contact with reinforcing steel, initiating corrosion. The corrosion initiation time for the deicing salt environment is expressed as (Enright & Frangopol 1998)

$$T_{i,deicing} = \frac{x^2}{4D_C}\left[erf^{-1}\left(\frac{C_s - C_{cr}}{C_s}\right)\right]^{-2} \tag{1}$$

where x is the cover concrete depth; D_C is the diffusion coefficient; C_s is the equilibrium chloride concentration at the concrete surface; C_{cr} is the critical chloride concentration; and the *erf* is the Gaussian error function.

The corrosion can cause the loss of steel area over time. The time-dependent area of the steel considering uniform corrosion can be calculated as (Enright & Frangopol 1998, Shekhar et al. 2018)

$$A_U(t) = \begin{cases} \frac{\pi}{4}D_i^2 & \text{for } t \le \mathrm{T_i} \\ \frac{\pi}{4}\left[D_i - 2\int_{T_i}^{t} r_{corr}(t_p)dt_p\right]^2 & \text{for } 2\int_{T_i}^{t} r_{corr}(t_p)dt_p < D_i \\ 0 & \text{for } D_i \le 2\int_{T_i}^{t} r_{corr}(t_p)dt_p \end{cases} \tag{2}$$

where D_i represents the diameter of the original steel bar; r_{corr} is the corrosion rate; and T_i is the corrosion initiation time.

In real observations, the area loss of the steel was found to be nonuniform, deep pits can appear along the length of the steel. To incorporate the nonuniform corrosion effects, the

pitting corrosion model was developed (Zandi Hanjari et al. 2011). A pitting factor is used to describe the relative area loss of pitting corrosion conditioned on uniform area loss.

Rust is produced due to the corrosion of steel, resulting in an increased volume of steel bars. Concrete cracks or even spalling can occur due to the expansion effects. In this circumstance, the concrete strength can be modeled in a time-dependent manner (Rao et al. 2017, Shekhar et al. 2018).

Within the life cycle of bridges, the occurrence time, the number, and the intensity of the earthquakes are uncertain. The probabilistic occurrence time of the earthquakes is generally modeled using a stochastic process. The Brownian passage-time (BPT) renewal process is considered herein to model the nonstationary arrival process of earthquakes (Li et al. 2020, Matthews et al. 2002). The probabilistic inter-arrival time of earthquakes is modeled using a probability density function (PDF) of BPT distribution as

$$f_W(x) = \left(\frac{\mu}{2\pi\alpha^2 t^3}\right)^{1/2} \exp\left\{-\frac{(t-\mu)^2}{2\mu\alpha^2 t}\right\} \tag{3}$$

where μ and α are the mean and coefficient of variation, respectively.

The ground motion prediction models (GMPMs) can be used to output the probabilistic distribution of earthquake intensity (Boore et al. 2014). The GMPMs are expressed as the functions of several characteristic parameters (e.g., magnitude, distance, fault type, etc.). By integrating the stochastic process model and GMPM, the probabilistic earthquake scenarios within the service life of the bridges can be simulated.

3.2 *Sustainability and resilience*

Sustainability is measured by social, economic, and environmental criteria (Dong et al. 2013). The social metric can be expressed as the number of fatalities due to the collapse of the structures. The economic metric can be calculated as the sum of the direct and indirect losses. The direct loss is related to the repair cost of the damaged structures. The indirect loss consists of time loss and running cost which is induced by the loss of functionality of the bridge due to damage. For instance, the traffic capacity and speed can be limited once the damage occurs on the bridges. Some vehicle users may follow the original route by reducing the speed on the damaged transportation network or following the detour to destinations, resulting in additional running cost and time loss (e.g., wage and compensation). The detailed quantification method of the time-dependent social and economic metrics can be found in a previous study (Dong et al. 2013). The environmental metric is considered as carbon dioxide emissions. In the context of carbon neutrality, carbon dioxide which is a greenhouse gas has been receiving increasing attention. It can cause global warming and bring enormous adverse effects to society. The carbon dioxide emissions associated with the repair activities of the damaged bridge can be quantified based on the amount of repair materials used and the relevant transportation conditions.

The time-dependent carbon dioxide emissions induced by the detour traffic is quantified as

$$EN_{DT}(t, IM) = \sum_{i=1}^{4} P_{DS_i}(t, IM).ADTD_{DS_i}.D_l.d_{DS_i}.[Enp_{car}.(1-T) + Enp_{Truck}.T] \tag{4}$$

where $P_{DSi}(t, IM)$ is the probability of being in damage state i given time t and intensity IM; $ADTD_{DSi}$ is the daily traffic following detour for damage state i; D_l is the detour length; d_{DSi} represents the time of detour for damage state i; T is the average daily truck traffic ratio; Enp_{car} and Enp_{Truck} represent the carbon dioxide emitted per unit distance for cars and trucks, respectively.

Resilience is the other emerging indicator that can be used to measure the capability of the systems to withstand, adapt, and recover from extreme events (Timmerman 1981, Yang & Frangopol 2019). The time-dependent resilience loss index is expressed as (Qian et al. 2022a)

$$R_L(t, IM) = \frac{t_h.100\% - \int_{t_i}^{t_i+t_h} Q(t_r|t)dt_r}{t_h} \tag{5}$$

where t_h is the investigated recovery time horizon of interest; and $Q(t_r|t)$ is the time-dependent functionality of the bridge after the hazard event.

3.3 *Life-cycle cost-benefit analysis*

The construction cost and carbon dioxide emissions of the SMA-steel reinforced bridge are higher than those of the conventional bridge. Cost-benefit analysis should be conducted in a life-cycle context to account for the accumulated consequences under multiple events. The long-term sustainability or resilience loss is computed by accumulation (Zheng et al. 2018)

$$L = \sum_{k=1}^{N_h(t_L)} L_k(t_k).e^{-rt_k} \tag{6}$$

where t_L is the considered service time of a system; $N_h(t_L)$ is the number of disruptions within t_L; L is the long-term sustainability or resilience loss; $L_k(t_k)$ is the sustainability or resilience loss induced by event k at time t_k; and r is the monetary discount rate. The monetary discount rate becomes zero for computing the non-monetary metrics of long-term sustainability and resilience.

The relative reduction of long-term loss by implementing a measure is expressed as (Bastidas-Arteaga & Stewart 2015)

$$\Delta L(T_s) = \frac{L_{exicisting}(T_s) - L_{adaptation}(T_s)}{L_{exicisting}(T_s)} \tag{7}$$

where T_s is the service time of the bridge; $L_{existing}(T_s)$ and $L_{adaptation}(T_s)$ are the long-term loss for the existing bridge and the bridge with adaptation measures, respectively.

In cost-benefit analysis, the cost is the cost of implementing an adaptation measure, and the benefit is the reduction of the loss by implementing an adaptation measure. The cost-benefit index (CBI) is expressed as (Bastidas-Arteaga & Stewart 2015)

$$CBI(T_s) = \frac{L_{exicisting}(T_s)\Delta L(T_s)}{C_{adaptation}} \tag{8}$$

where $C_{adaptation}$ is the cost of implementing the adaptation measure for reducing the long-term loss $\Delta L(T_s)$. The cost-benefit index provides information for decision making, an adaptation measure is considered to be cost-effective if the CBI exceeds unity. The CBI depends on the service time of the bridges. An adaptation measure may not be cost-effective in the short term due to the high adaptation cost, it may be cost-effective from a life-cycle perspective as the benefit can be accumulated over service time. The uncertainties associated with the earthquakes and corrosion are considered in this study resulting in probabilistic CBI. The probability that an adaptation measure is cost-effective is expressed as Pr(CBI>1).

4 ILLUSTRATIVE EXAMPLE

The developed approach is illustrated on an SMA-steel reinforced bridge under earthquakes and deterioration. The configuration of the bridge is presented in Figure 1.

The deterioration process of the bridge is modeled following the approach in section 3.1. The life-cycle earthquake scenarios incorporating the stochastic occurrence time and

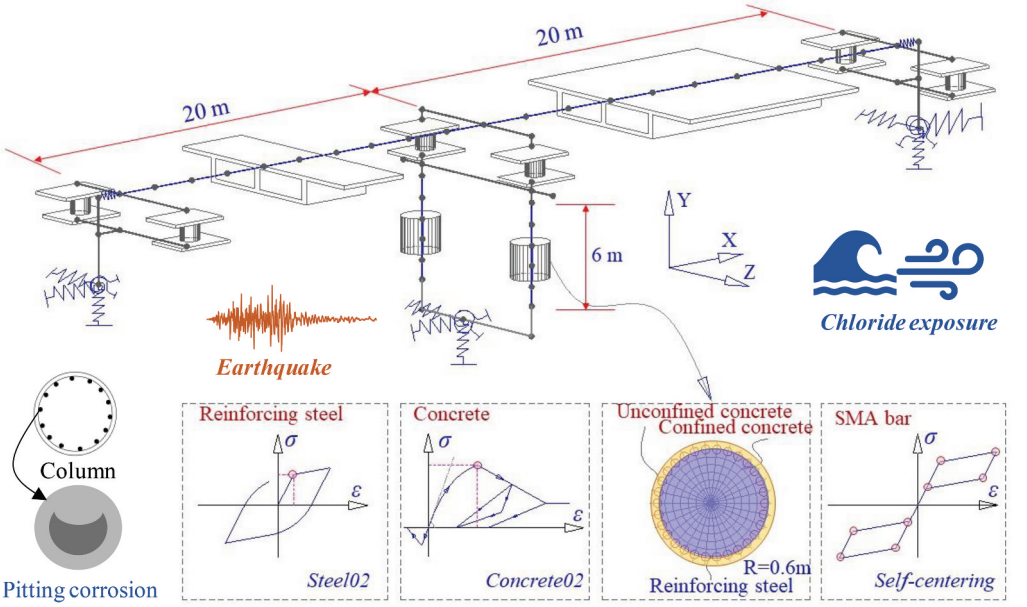

Figure 1. Configuration of the modeling bridge.

intensities are simulated following the procedures in section 3.1. The deteriorated bridge realizations are generated and paired with selected ground motion records. Finite element models are established in the software OpenSees and nonlinear time history analysis is performed for the deteriorated bridge. After computing the probabilistic seismic demand model, the time-dependent seismic vulnerability of the bridge can be computed. By considering the consequences induced by multiple possible events for an investigated time horizon, the long-term sustainability and resilience are computed. The long-term expected number of fatalities and resilience loss of the conventional bridge and the SMA-steel reinforced bridge are presented in Figure 2. The SMA-steel reinforced bridge is associated with less long-term expected number of fatalities and resilience loss compared with the conventional bridge, and the difference increases over service time.

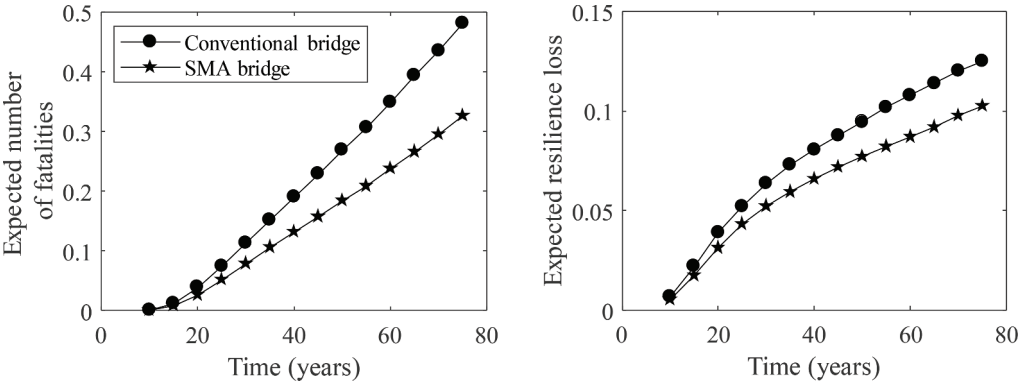

Figure 2. Long-term expected number of fatalities and resilience loss.

Following the approach in section 3.3, the probabilistic cost-benefit indices (CBIs) in terms of economic loss (ECO) and carbon dioxide emission (CDE) are computed and the expected values are presented in Figure 3. Due to the extra construction cost and carbon dioxide

emissions associated with the SMA-steel reinforced bridge, the CBIs are less than 1 for the short term. The expected CBIs increase over the service life of the bridges, as multiple extreme events can occur with the service life and the benefit can be accumulated over time. For the service time of 75 years, the expected CBIs of the ECO and CDE are 2.85 and 48.20, respectively. It is worth noting that an adaptation measure is considered to be cost-effective if the CBI exceeds 1.

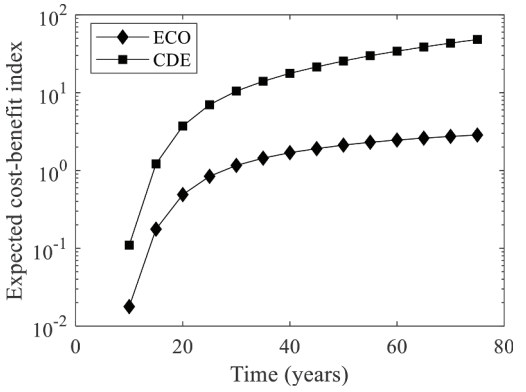

Figure 3. Expected cost-benefit index in terms of economic loss (ECO) and carbon dioxide emission (CDE) over the bridge service life.

The probability of the novel bridge being cost-effective over the bridge service life is presented in Figure 4. The novel bridge is associated with a lower probability of being cost-effective in the short term. Due to the accumulation of benefits within the service life, it is associated with a higher probability of being cost-effective considering the criteria of economic loss and carbon dioxide emissions in a life-cycle context. In addition to the economic loss and carbon dioxide emissions, it is worth noting that the SMA-steel reinforced bridge can also bring benefits in terms of resilience and fatalities which cannot be directly measured by monetary values.

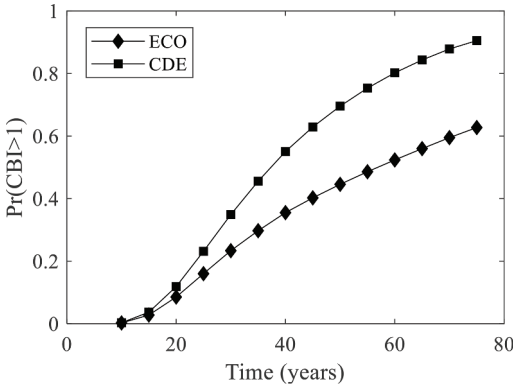

Figure 4. The probability of the novel bridge being cost-effective over the bridge service life.

5 CONCLUSIONS

This study develops a life-cycle cost-benefit analysis approach for structures under earthquakes and corrosion. The earthquakes and deterioration occurring within the life cycle of structures are modeled incorporating uncertainties. The long-term sustainability and resilience loss are computed under the sudden earthquakes and continuous deterioration. The life-cycle

cost-benefit index can be computed by considering the economic loss and carbon dioxide emissions.

The developed approach is implemented on an SMA-steel reinforced bridge under earthquakes and deterioration. As the construction cost and carbon dioxide emissions associated with the SMA-steel reinforced bridge are higher than those of the conventional bridge, the expected CBIs are less than 1 for the short term. The expected CBIs increase over the service life of the bridges, as multiple extreme events can occur with the service life and the benefit can be accumulated over time. The novel bridge is associated with a lower probability of being cost-effective in the short term. Due to the accumulation of benefits within the service life, it is associated with a higher probability of being cost-effective considering the criteria of economic loss and carbon dioxide emissions in a life-cycle context. Besides, the SMA-steel reinforced bridge is associated with benefits in terms of resilience and fatalities which is vital for the society and cannot be directly measured by monetary values. Overall, the SMA-steel reinforced bridge is cost-effective in a life-cycle context under earthquakes and deterioration.

Probabilistic assessment of corrosion initiation in RC structures under chloride attack

G.H. Vieira & L.C. Meneghetti
University of São Paulo, São Paulo, Brazil

R.M. Teixeira & M.A. Silva
Federal University of Pará, Belém, Pará, Brazil

ABSTRACT: Chloride-induced corrosion is one of the main deteriorating mechanisms of reinforced concrete structures. This paper presents a probabilistic study to assess and quantify the impact of key variables during corrosion initiation phase. Evaluations were performed on a bridge pier section under constant and time-dependent surface concentrations, investigating the impacts of both exposure conditions on corrosion initiation. A sensitivity analysis was conducted by testing different values for each variable and quantifying their impact on corrosion initiation. During this analysis, the key variables were identified and discussed. The analyses utilized a probabilistic tool that performs Monte Carlo simulations with a one-dimensional analytical diffusion model. Results highlighted greater significance of surface chloride content in early ages than in later ages, with diminished influence of concentration steps near corrosion initiation time. This paper underscores the importance of considering surface chloride content time-dependency and its impact on corrosion initiation, providing valuable insights for corrosion modeling.

1 INTRODUCTION

During the service life, concrete structures are influenced by various mechanisms, impacting their performance and durability. Chloride-induced corrosion stands out as one of the most significant degradation mechanisms in reinforced concrete structures (Frangopol et al. 1997, Khan et al. 2017). In regions with intense environmental exposure, chloride ions penetrate the concrete and are transported to its interior by different mechanisms (Poulsen & Mejlbro 2006). The transport of chloride ions within the concrete depends on various factors, including the chloride content in the environment, concrete porosity, geometry, type of cement and additives (Mehta & Monteiro 2014). When a critical concentration is reached on the reinforcement, the passivated layer breaks, initiating corrosion, which can be divided into two main phases: initiation, where ion transport occurs, and propagation, where corrosion effectively takes place (Tuutti 1982) and causes the loss of steel area, concrete cracking and spalling of the concrete cover, impacting structural capacity.

During the design phase, durability is usually approached with a technological emphasis, where parameters such as concrete cover and concrete properties are standardized in accordance with environmental exposure classes (ACI 2019, CEN 2004, ABNT 2023). This approach, however, lacks precision in quantifying how the structure's performance is affected over its service life, making it difficult to plan interventions (Biondini & Vergani 2015). To fully address structural degradation effects, models explicitly considering degradation mechanisms are necessary.

This paper introduces a probabilistic study of the corrosion initiation phase, where the transport of chloride ions is simulated. Utilizing an analytical model for chloride diffusion and a real bridge pier section, the different variables are assessed to identify and quantify their respective impacts on the time required for corrosion initiation.

2 CHLORIDE DIFFUSION SIMULATION

2.1 *Diffusion model*

Diffusion is the most relevant chloride transport mechanism in concrete and can be properly modeled using Fick's second law (Bertolini et al. 2004). For an isotropic medium, with homogeneous material, constant diffusivity throughout space and unidimensional flow, Equation 1 is utilized (Crank 1975):

$$\frac{\partial C(x,t)}{\partial t} = D(t).\nabla^2 C(x,t) \tag{1}$$

where: C [wt%/cem] = chloride content; D [m²/s] = chloride diffusivity; x [m] = evaluated point; and t [s] = time.

Solutions to the diffusion problem depend on the adoption of initial conditions, represented by an initial concentration profile, $C_0(x)$, within the element, and boundary conditions, represented by a known surface chloride content function, $C_S(t)$, within the element surface.

2.2 *One-dimensional error function-based solutions*

Analytical solutions are available only under specific initial and boundary conditions (Titi & Biondini 2016). In the case of one-dimensional diffusion in a semi-infinite medium, error function-based solutions are common (Crank 1975, Frederiksen et al. 2008). If chloride diffusivity and surface chloride content are assumed constant, the solution is denoted by Equation 2:

$$C(x,t) = C_s.erfc\left(\frac{x}{2\sqrt{D.(t-t_0)}}\right) \tag{2}$$

where: Cs [wt%/cem] = surface chloride content; and t_0 [s] = exposure time.

Modified versions of Equation 2 allow for the consideration of variable diffusivity and surface chloride content in time. By defining an average diffusivity, D_{av}, according to Equation 3, Equation 2 can be utilized by substituting the instantaneous diffusivity, D, with D_{av}.

$$D_{av}(t) = \frac{1}{t-t_0}\int_{t_0}^{t} D(\tau).d\tau \tag{3}$$

where: D_{av} [m²/s] = average diffusivity.

FIB "Model Code for Service Life Design" (FIB 2006) presents a version of Equation 2 considering the average diffusivity, the presence of an initial chloride content, C_0, and a convection zone, Δ_x, which is a region where transport is not governed by diffusion but by capillarity.

$$C(x,t) = C_0 + (C_s - C_0).\left[1 - \text{erf}\left(\frac{x-\Delta x}{2.\sqrt{D_{av}(t).(t-t_0)}}\right)\right] \tag{4}$$

where: C_0 [wt%/cem] = initial chloride content; and Δx [m] = convection zone depth.

For variable surface content, Poulsen & Mejlbro (2006) employ the superposition of constant surface content solutions, approximating the surface chloride content function with a step function. For the solution presented in Equation 4, Equation 5 is obtained:

$$C(x,t) = C_0 + \sum_{j=1}^{n} C_{sj} \cdot H\left(t - t_{j-1}\right) \cdot \left[1 - \text{erf}\left(\frac{x-\Delta x}{2.\sqrt{D_{av}(t).\left(t-t_{j-1}\right)}}\right)\right] \tag{5}$$

where: C_{sj} [wt%/cem] = surface chloride content step; t_j = step time; and H = Heaviside function.

2.3 *Chloride diffusivity*

Chloride diffusivity measures the speed at which ions are transported inside the concrete, reflecting the porosity of the concrete. Diffusivity's time-dependency is caused by the continuous hydration of the cement and increase in chloride binding capacity (Andrade 2005, Helene 1993, Khan et al. 2017), and is usually modeled by correcting diffusivity at a reference time by an exponential function that increases with the inverse of exposure time raised to an aging coefficient. FIB "Model Code for Service Life Design" (FIB 2006) presents Equation 6 for calculating the average diffusivity over time. This equation introduces the chloride migration coefficient obtained from laboratory tests, D_{RCM}, that can be transformed into the diffusivity at reference time by multiplying it by the test factor, k_t. The environmental factor, k_e, corrects the test temperature to the actual temperature acting on the structure.

$$D_{av}(t) = k_e.k_t.D_{RCM}.\left(\frac{t_{ref}}{t}\right)^m \tag{6}$$

where: D_{RCM} [m²/s] = chloride migration coefficient; k_e [-] = environmental factor; k_t [-] = test factor; t_{ref} [s] = reference time (test time); and m [-] = aging coefficient.

2.4 *Corrosion initiation time*

Reinforcement depassivation occurs when the concentration of chloride ions at the edges of the rebar reaches a critical chloride content, C_{crit}. FIB "Model Code for Service Life Design" (FIB 2006) recommends a value of C_{crit} = 0.60 wt%/cem. The instant when C_{crit} is reached sets the initiation of corrosion. The calculation of the corrosion initiation time for the solution of Equation 4 is given by:

$$t_i = C^{-1}(x_r, C_{crit}) = \left[\frac{(c-\Delta x)^2}{4.k_e.k_t.D_{RCM}.t_{ref}^m} \cdot \text{erf}^{-1}\left(\frac{C_s - C_{crit}}{C_s - C_0}\right)^{-2}\right]^{\frac{1}{1-m}} \tag{7}$$

where: t_i [s] = corrosion initiation time; C_{crit} [wt%/cem] = critical chloride content; x_r [m] = rebar position; and c [m] = concrete cover.

3 CORROSION INITIATION ANALYSIS

The assessment of corrosion initiation will be conducted on a pier section from the Rio Torto Bridge, Italy, as presented by Pugliese et al. (2022). The pier has a hollow circular section with an external diameter of 1.50 m and a wall thickness of 0.30 m, subjected to chloride exposure on the external face. The problem will be addressed through a one-dimensional diffusion model.

The analyses utilize a tool developed in MATLAB™ that performs one-dimensional diffusion analysis based on the analytical solution (Eq. 4) and the diffusivity expression (Eq. 6) proposed by FIB "Model Code for Service Life Design". For time-dependent chloride surface content, the tool employs an approximation using a step function, as per Equation 5. The results obtained from the analysis include the chloride content history at the point corresponding to the concrete cover and the corrosion initiation time, obtained through Equation 7 for constant surface chloride content and through linear interpolation of the concentration profiles for time-dependent surface chloride content.

The tool performs both deterministic and probabilistic analyses. Therefore, in addition to the mean values of each variable, it receives the parameters that define their probability distributions. Probabilistic analyses were conducted through conventional Monte Carlo simulation, where the tool generates random values for each variable based on input data and performs the analysis for each set of values. In probabilistic analyses, an additional factor θ is introduced, multiplying the concentration results to account for model uncertainty (Cui et al. 2018).

3.1 *Probabilistic corrosion initiation time*

In the probabilistic analysis of the corrosion initiation time, two cases are considered: one with constant surface chloride content and another with time-dependent surface chloride content. The time-dependent concentration is equivalent to the constant concentration adopted for the first case, using the same ratios of variable to constant concentration as Poulsen & Mejlbro (2006). The function has an initial step equivalent to 70% of the constant concentration. At the subsequent steps, occurring at 20 and 40 years, the increases are equivalent to 50% and 40%, respectively, of the constant concentration. A Spearman correlation analysis is also conducted based on the probability distributions obtained from the analysis, providing an initial assessment of the impact of each variable on the corrosion initiation time. The parameters adopted in the analysis are obtained from Pugliese et al. (2022) and are presented in Table 1.

Table 1. Statistical distributions of the parameters in the probabilistic corrosion initiation time analysis.

Variable	Description	Distribution	Distribution Parameters
D_{RCM} [m²/s]	Chloride migration coefficient	Normal	$\mu = 15.80 \times 10^{-12}$; $\sigma = 0.20\mu$
m [-]	Aging coefficient	Beta	$\mu = 0.30$; $\sigma = 0.12$ lb = 0.00; ub = 1.00
C_{crit} [wt%/cem]	Critical chloride content	Beta	$\mu = 0.50$; $\sigma = 0.15$; lb = 0.20; ub = 2.00
c [m]	Concrete cover	Lognormal	$\mu = 0.04$; $\sigma = 0.008$
C_S [wt%/cem]	Surface chloride content	Normal	Cs = 1.30; μ = Cs; $\sigma = 0.30\mu$
C_{Sj} [wt%/cem]	Surface chloride content step	Normal	Csj = [0.70, 0.50, 0.40].Cs Csj = [0.91, 0.65, 0.52] μ = Csj; $\sigma = 0.30\mu$
θ [-]	Model uncertainty	Lognormal	$\mu = 1.00$; $\sigma = 0.05$

Δx [m]	Convection zone depth	Deterministic	[0.0025, 0.0050, 0.0075, 0.0100]
C_0 [wt%/cem]	Initial chloride content	Deterministic	[0.05, 0.10, 0.15, 0.20]

3.2 *Sensitivity analysis*

After conducting a probabilistic analysis of corrosion initiation time, a sensitivity analysis was carried out for both cases (constant and time-dependent surface chloride contents). Different values were adopted for each variable, while keeping the other variables at the same values used in the base cases (Table 1). The objective of this analysis was to identify the most relevant variables and how each one impacts the corrosion initiation, complementing the results obtained from the Spearman correlation analysis. The new analysis also allows the evaluation of variables such as the depth of the convection zone and the initial chloride content, which were not considered in the previous analysis. The values adopted for each variable were chosen within a range of possible values (FIB 2006) and are presented in Table 2. In the time-dependent surface chloride content cases, each concentration step C_{Sj} was treated as an individual variable. Therefore, the values for each concentration step were assessed while keeping all other variables, including the other concentration steps, constant and with the same values of the base case. The values for each step were calculated based on the range of possible values adopted for the constant surface chloride content, C_S, following the same ratios of variable to constant concentration utilized in the base case.

4 RESULTS

4.1 *Corrosion initiation time*

Figure 1 Presents histograms of the corrosion initiation time and empirical cumulative probability functions for both base cases. The results reveal a substantial impact of the time-dependency of surface chloride content, with the mean corrosion initiation time increasing from 20 years to approximately 28.3 years, representing a 41% rise. Theoretically, surface concentration is always time-dependent, influenced by factors such as exposure conditions and concrete properties (Yang et al. 2021). Assuming constant surface chloride content, while prioritizing safety, may lead to excessively conservative estimates of corrosion initiation time. Figure 2 illustrates the results of the Spearman correlation analysis for the same cases. These results highlight a greater impact of the aging coefficient, followed by cover depth and critical and surface chloride contents. The significance of these variables was expected, as they are directly associated with decreasing diffusivity over time, the distance chloride ions need to travel, and environmental exposure. The analysis further validates observations derived from the corrosion initiation time distributions, suggesting a greater significance of surface chloride content during early ages, i.e. those more distant from corrosion initiation time. Conversely, its importance diminishes in the later ages, i.e. those near corrosion initiation.

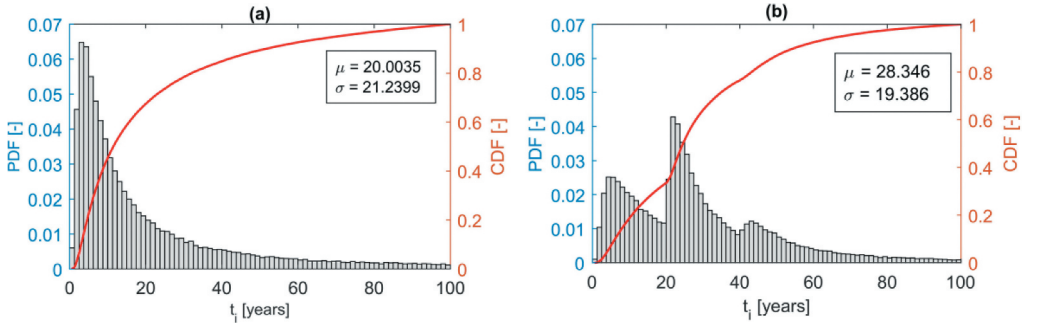

Figure 1. Histograms and empirical cumulative probability functions of corrosion initiation time for constant surface chloride content (a) and time-dependent surface chloride content (b).

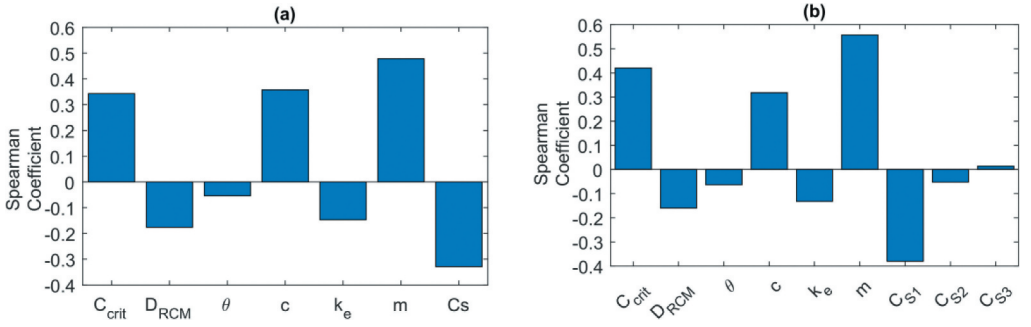

Figure 2. Spearman correlation analysis for constant surface chloride content (a) and time-dependent surface chloride content (b).

4.2 *Sensitivity analysis*

Figures 3-7 present the results obtained in the sensitivity analysis for both constant and time-dependent surface chloride content, illustrating the mean corrosion initiation time, a two-standard deviation confidence interval, and box plots, where red markers identify the outliers. These results confirm those initially obtained in the Spearman correlation analysis and quantify the impact of each variable. Notably, the chloride migration coefficient (Figure 3a) stands out as the most relevant variable, causing variations in the corrosion initiation time in a range of 10 to 70 years. This behavior was expected since this parameter defines the ion transport velocity. In the correlation analysis, the evaluated values of the migration coefficient were around the mean value of 15.8×10^{-12} m/s², a region where small variations do not significantly impact the corrosion initiation time, justifying the reduced influence observed in that initial analysis. The aging coefficient (Figure 3b) also showed a high impact on corrosion initiation time, which was also observed in the correlation analysis. As previously stated, this can be explained because the parameter considers the decrease of diffusivity over time, directly affecting diffusion speed.

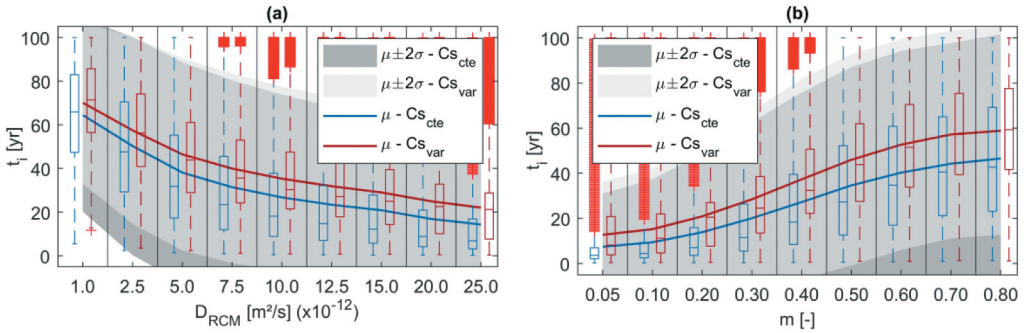

Figure 3. Sensitivity analysis – Impact of chloride migration coefficient (a) and aging coefficient (b).

The concrete cover depth, which assumes low values and has a significant impact on the corrosion initiation time (Figure 4a), is of great importance since it can be easily neglected during execution. A decrease of 0.5 cm, for instance, can lead to a reduction of 4 years in the corrosion initiation time. A similar conclusion is valid for the convection zone depth (Figure 4b), as values of about 10 mm can be easily established depending on the exposure condition, resulting in a reduction of about 5 years in corrosion initiation time. The initial chloride content (Figure 5a) did not show a significant variation for the tested values; however, it should be considered that some standards allow elevated levels of this variable, up to 0.3 wt%/cem (ABNT 2023). When the contribution of all these different factors is combined, the service life of the structure can be significantly impacted.

Both the critical chloride content and the surface chloride content (Figs 5b, 6a) showed a high impact on corrosion initiation time, confirming the results initially obtained during the correlation analysis. This impact was expected, as these parameters measure the chloride content necessary for depassivation and the environmental exposure, respectively. Results from Figures 6-7 also confirm and quantify the conclusions drawn in previous analyses. It was observed that the impacts of the constant surface chloride content and of the first step of time-dependent surface chloride contents are similar, leading to reductions of about 15 years within the range of tested values. The impact of the second step of time-dependent surface chloride content is smaller, causing reductions of up to 5 years in depassivation, while the impact of the third step is negligible. If these steps occurred at early ages, e.g. $t_2 = 10$ and $t_3 = 15$ years, a more significant relevance should be expected due to a greater distance to corrosion initiation. The comparison between results with constant and time-dependent surface chloride content (Figs. 3-5) showed that considering the time-dependency resulted only in a translation of the mean initiation time curve, which remained almost parallel for both cases in all variables tested. This result indicates that the surface chloride content time-dependency does not directly affect how each variable impacts corrosion initiation.

In the cases with constant surface chloride content, the boxplots showed a reduction in dispersion and an increase in kurtosis for lower corrosion initiation times, consistent with the shape of the histogram for constant surface chloride content (Figure 1a). In these situations, a higher positive skewness was also observed, reflected in a greater deviation of the median from the mean. In the cases with time-dependent surface chloride content, a similar behavior is observed, except for the situations where the mean corrosion initiation times are slightly higher than the ages when the concentration steps occur. In these situations, the histogram of corrosion initiation time approximates the shape of Figure 1b, resulting in a boxplot showing lesser skewness, with a smaller deviation of the median from the mean.

5 CONCLUSIONS

This article addressed the corrosion initiation due to chloride ion attack and conducted a probabilistic analysis to improve the understanding and quantify the impacts of each variable in this phase. In the first stage of this analysis, results from the cases with constant and time-dependent surface chloride content highlighted the significant relevance of this temporal variation, often ignored in diffusion models. At this stage, variables with the greatest impact on the corrosion initiation time were identified, a result that was complemented by the sensitivity analysis. The variables that proved most relevant were the chloride migration and the aging coefficients. The cover depth was also important, as its reduction during execution can accelerate the onset of corrosion. During this analysis, surface chloride content in the early ages proved to be more relevant than in later ages, as the influence of concentration steps near corrosion initiation time diminished. Thus, the accurate assessment of the surface chloride content is essential for precise predictions of corrosion initiation. Constant surface chloride content is usually estimated based on long historical data, resulting in higher values than the actual concentrations in early ages. This may lead to excessively conservative estimates of corrosion initiation time. When surface chloride content is experimentally obtained in the early ages, e.g. immediately after construction, assuming constant concentration throughout time may lead to contrary to safety predictions, since it may ignore important concentration build-up before corrosion initiation.

The study explicitly evaluated corrosion initiation, in contrast to the purely technological approach defined by standards. Since one-dimensional diffusion models were utilized, the results obtained in this study can be extrapolated to other geometries under the hypothesis of

one-dimensional diffusion. Future work will explore the effects of bidimensionality on the evaluated section, as well as the impacts of different boundary conditions, e.g. a real surface chloride content function, in contrast to the step function approximation (Author, in prep.).

Why is maintenance and management of rails so important to railway bridges?

J. Wuorenjuuri
Sweco Finland Oy, Finland

ABSTRACT: Answer to the question is simple. Disasters can happen. Worst-case scenario is derailments and failures of bridge superstructure. The railways bridges can be categorized in two types: bridges with ballast and bridges without ballast. Ballastless bridges have many sub-types such as old wooden sleepers and more new age embedded rails. General public can see only sleepers and rails on railway bridges, but each type of rail also has many details and special solutions, that are very critical to the behavior of the bridges. Rail structures also include the rails, guard rails and their fastenings, expansion joints, and transitions zones.

1 INTRODUCTION

The railway is a very aggressive environment for a bridge. One of the challenges with track structures on bridges is the high precision demands due to safety. On high-speed lines defects are measured in millimeters. Even on slower track lines, there is very little room for failures of tracks. All defects on the track may be harmful for the bridge and for the trains. Of course, the worst-case scenario is derailments and failures of bridge superstructure.

The other challenge is related to the maintenance procedures. There are no specialists or experts in this field anymore. Usually bridge engineer and inspectors of bridges do not know how to evaluate these structures and leave it to the track maintenance personnel. The track maintenance personnel usually are not very interested in the bridges because they are special structures to them. The track superstructure has so many different components that it really would need experts who understand the rails.

One of the challenges is that many rail solutions on bridges are unique. From a maintenance point of view, every time some new rail innovation comes along and is implemented into the track, it means that the maintenance needs more expertise. Every component requires special maintenance, and management. Track -bridge interaction requires special expertise, for both bridge and track maintenance crews. This makes the detail so important to be maintained and managed optimally.

The great thing about the rail that it is monitored many times a year on every bridge as track measurement vehicles run through the lines. Valuable information is gathered many times aa year to ensure the safety of the tracks for trains. But challenges come up if there is a problem with the measurements. Where is the problem? On the track? On the bridge? Does the track work on the bridge correctly? What are the corrective actions? When is the track superstructure aged? When is it beneficial to do renewal instead of maintenance? Can the track be modernized somehow? After all the technology is in many cases from the 1800 century.

2 BALLAST AND SLEEPERS

The first railway tracks on bridges were ballastless tracks, where wooden sleepers were attached to the steel of wooden bridge. One of the advantages of wooden sleepers was that it was soft, gentle for both the train and the bridge. It softened the impacts of the train to the

DOI: 10.1201/9781003483755-64

bridge, but also softened the impacts to the train's bogeys. Also, the easy maintenance of these wooden sleepers has been an advantage.

Later in the start of 1900's railways developed, and railway engineers wanted to have continuous ballast layers over the bridge. This meant that bridges started to be built out of stone, masonry or later with concrete. Larger bridges were still built with "old" rail technology as the span lengths of stone or concrete bridges were limited for some decades.

Up to these days railway bridges are ballastless or with ballast. The quality of ballast has of course developed from sand to stone. Also, sleepers are mainly concrete these days on mainlines. But still on many steel bridges the wooden sleepers are fixed to the steel girders.

In the recent years however, new technology has come along. In Europe the wooden sleepers have been handles with creosote. Now this is banned for environmental reasons and new materials have been developed for sleepers on bridges. New composite sleepers are introduced into the market. This may be a good solution but for now it has been much more expensive than the wooden sleepers. There are also uncertainties with these composite sleepers.

First, we know that the steel bridges have defects, we know they have rivets. How much can these composite sleepers be prefabricated or is there a way to fit them on a bridge? How are the possible uneven surfaces of the steel plates fixed? Current idea is to use fitting pieces. How much can the maintenance personnel correct the rail defects if something comes up? How does the composite sleeper behave in cold weather in the long term? Also, the noise levels of composite sleepers on steel bridges are yet to be tested.

Also ballasted tracks with sleepers have been replaced by different kinds of embedded rails. This means that the track is glued onto a bridge deck with several kinds of solutions. One advantage of embedded rail is said to be the maintenance free track, but on a short bridge, the transition from embedded track on a bridge to the softer transition zone on the embankment is difficult for maintenance. Usually, it must be done manually with tamping machines, which of course is not so high-quality maintenance.

On steel bridges, the traditional wooden sleepers are fixed to the bridge with vertical and horizontal bolts. traditionally these bolts have required a lot of maintenance as the wooden sleeper expands and decreases in size during time and in different weather conditions. And there are many new innovations for this fastening, which again means that it is a challenge for the maintenance.

3 RAILS AND GUARD RAILS

Over the history of railways, rails have also developed. The profile of the rail has grown and In Finland, new rails on mainline are mainly 60 kg/m rails. Every time the rail profile grows, also the fastening to the sleepers also changes. The fastening depends on the rail profile, but also on the length of the bridge. There are different kinds of washer plates, springs, and screws for rails, and it is not the same which kind of fastening the maintenance uses.

One of the challenges is the different fastening for maintenance. In many cases, the cause of rail defects is that wrong fastenings are used. The rail behaves uncontrollably. It is very understandable that the maintenance personnel are call to fixed a problem on the bridge, and take the first available spare parts from the warehouse. But not making sure that they are the right parts.

All misuse of rail parts can influence the bridge and finally its load capacity or fatigue loads. That is why the maintenance of rails is so important on the bridge.

On longer bridges there is usually also another set of rails on a bridge. The additional rails are guard rails, and they are supposed to prevent a derailment of a train to cause extra damage to the bridge or for the people on the train. In Finland guard rails are used mainly on bridges over 30 meters long and that have a greater risk of derailment to have serious consequences.

Table 1. Requirements for guard rail in Finland.

Bridge type/rail type	Bridge length L < 30 m	Bridge length L ≥ 30 m
Concrete bridge. Edge beam is higher rail, and further than 2500mm to rail	Not required	Not required
Concrete bridge. The ballast layer is more than 450mm and edge beam is further than 2400mm	Not required	Not required
Concrete bridge. The ballast layer is more than 450mm and edge beam is no more than 2400mm	Not required	Required
All bridges. The ballast layer is less than 450mm/or no ballast layer	Not required	Required
Steel girder bridge with thin deck structure	Required	Required
All bridges. Rail has additional structures to prevent derailments	Not required	Not required
All bridges. Bridge has expansion joints	Required	Required
All Bridges. Bridge or embankments have curve less than 300m	Required	Required

In Finland the theory is that the locomotive is the part of the train that derails. But in some rail networks, the theory is that one of the wagons may be derailed on a long train and may cause damage to the bridge. For this there is special devices to lift a derailed wagon on to the rails before coming on to the bridge.

The maintenance of the guard rail is as important as that of the main rail. It must function properly in case of a derailment. But unfortunately guard rails are many times fastened with secondary fastening and not very much attention to this is paid by maintenance. We have been lucky not to have had any incidents that have been caused by guard rails being maintained poorly.

Guard rails are sometimes used also on a normal track where for example a overpass and its foundations need to be protected from possible derailment. From a maintenance point of view, this is not a very good solution again because maintenance must either remove the guard rails before tamping or do the maintenance of the tracks manually. And of course, the guard rails require a special sleeper, which make a guard rail a costly protective system. The best solution would be to choose the bridge type to be such that there would not be any extra risk in case of a derailment. This is true for both underpasses and over passes.

4 EXPANSION JOINTS AND DEVICES

In the first decades of railways, the track superstructure of the railway networks were mainly short rails. As continuous rail technology developed, there was a need for rail expansion joints. In Finland, by the 1960's and 1970's, the first rail expansion joints had been developed so that they were already in use on the Finnish railway network.

Rail expansion joints are as critical to maintain properly as the switches and the crossings on the track yards. Rail expansion joints are mainly used on long bridges with continuous rails and occasionally in other special structures. The expansion joint device must allow the longitudinal movements occurring on the bridge with their extreme values without changing the track width. It must also withstand the longitudinal forces of the track. The need for a rail expansion device is determined by the type of bridge and the expansion length of a bridge. The rail expansion device is always a point of discontinuity on the track and for that reason, very critical to work and be maintained properly. Many times, in the bridge design phases, it is possible to find a solution that reduces the expansion length of a bridge, and the use of rail expansion devices can be replaced with ordinary rail systems.

Rail expansion device requires a lot of maintenance. The old 54 kg/m rail expansion device requires constant maintenance and checking of the adjustments. In addition, the structure of the device has a quality that there is a lot of wear in the running surface of the rail. It does not remain as good for as long as with new devices. In Finland after 1990, many of these old expansion devices have been removed from the railway bridges during the renovation of railway sections. By using solutions such as sliding fastening, it has been possible to remove devices even from bridges where the total length of the bridge deck would otherwise not have allowed it.

The first rail expansion devices of the new era began to appear in the early 1990s. The new rail moving devices were of manufactured as elements. The same element contained the rail expansion device for both rail lines. The first rail expansion device of this type for a 60 kg/m rail was installed on the Halssila bridge in Jyväskylä in 1996. The official type of number of this device was SA60-200, where 200 means the allowed expansion length of the device. The finished battened element also includes protective guard rails.

Types of certified rail expansion joints used:

- 54E1/69-L100
- 54E1/69-L160
- 54E1 SA-54-200
- 60E1 SA-60-200

There is a city tram bridge being built now to Helsinki. It will have a rail expansion joint, with expansion capacity of 800 mm. The rail network has also many new big bridges being renewed in the near future. There bridges will have a new age rail expansion joint with more challenges for both designers and maintenance crews.

As a rule, these new-age rail expansion devices are designed as a combination of a support rail and a tongue rail. The operating principle is that the support rail, the outer rail is sliding, and the inner rails stay in place. When the device is working normally, the track width remains unchanged.

The rail expansion device is usually shown in the design documents of the bridge, and the installation of the device is usually made into an installation drawing. The device must have a nameplate that shows the manufacturer, type number of the device, serial number and year of manufacture, so that the device can be identified, and in maintenance the correct spare parts can be obtained later if necessary.

There are different types of expansion joints for different superstructures and bridge lengths. The most important selection criteria when choosing an expansion device are the length of the bridge, the total length of the decks affecting the same expansion joint, and the location of the decks and fixed support bearings.

The rail expansion device divides the running rail forms an almost uniform running surface for the train wheels. This is made possible by a longitudinally moving support rail and an almost stationary tongue rail.

It is recommended to install and maintain the prefabricated rail expansion device element at temperatures where the factory 0 setting can be directly utilized. The expansion device can be moved in advance according to the prevailing conditions, but the need for moving power is great. The rail expansion is preset at the factory and locked with a transport lock. Before the installation of the device, it is ensured that the equipment does not have a transport lock that prevents the operation of the device.

Installations of modern expansion equipment have generally been successful and there have been no problems with their operation on the track network and the bridges. The biggest problem in the installations has been caused by the fact that the bridge designer has left the expansion joint of the bridge unnecessarily large. Unnecessarily increasing the expansion joint of the bridge increases the tensions and vertical displacement of the running rail.

In some cases, the ballast also must have a device in the joint and it must be installed in the same expansion joint. There are different types of ballast gutting devices and usually vertical ribs may cause the distance between the sleepers to increase too much. In these areas, special solutions with the bridge designer and the superstructure designer to reach a good result. There are cases on the Finnish railway network where the installation requires removing the manufactured structures to fit sleepers in the right places.

As a rule, cleaning and lubrication are necessary for the inspection and maintenance of expansion device. Other important items in maintenance are:

- the running surface and running edges of the rail of the expansion device,
- sliding rail attachments between the washer of the expansion device and the movement joint of the bridge
- inspection of rail anchors
- the expansion device must be cleaned, for example with a pressure washer,
- inspection of the tightening torque of tie screws and fasteners

The timing of inspections is important. It would be important that in the summer periods, at the highest possible temperatures, inspection measurements, inspection of devices and rail anchoring, and general maintenance are carried out. Correspondingly during the winter period, inspection measurements should be made at temperatures as low as possible.

The first inspection should be done 6-8 weeks after commissioning, which includes at least the following measures:

- removing the burr formed in the tongue and support rails by sanding.
- tightening of all screw connections without cotter protection with the prescribed torque
- visual inspection of all shocks and structural parts

Follow-up inspections, which must be carried out annually after the first inspection, include the following minimum measures:

- track width inspection
- checking the tips of the tongue with the help of an interpreter tool
- visual inspections, observations on the running surfaces, the appropriateness of all screw connections, observations on the plate fastenings of the bridge joints, the condition of the flexible rib washers

To ensure the proper functioning of the rail expansion device, the operation of the bridge and the expansion device must be monitored. In connection with the installation, it is important to use a inspection form, that should have the history of the inspections starting from the installation. There are special inspection measurements forms for the rail expansion devices in the maintenance contracts.

It must be remembered that a malfunctioning rail expansion device is a potential place for train derailments, as are faulty switches. On the Finnish rail network there are approximately

30 rail expansion devices on the bridges. This makes it a special maintenance point for any contractor.

5 CONCLUSIONS

Ballast, sleepers, rails, and expansion devices are all very important part of a bridge. Failure of any of these can have crucial consequences. That is why more maintenance and management should be focused on these rail elements on bridges.

In Finland the maintenance companies are mainly responsible for the maintenance of these structures. There is not enough know-how of bridge inspectors about these structures. The number of experts of this field is diminishing in both design and maintenance phases. But the experts taking care of these parts of the railway network are true experts. There is a definite need in the future for more people to understand the bridge and rail interactions to keep the rails on bridges safe.

Retrofit of PRC bridges by external post-tension under different corrosion scenarios

G. Santarsiero, V. Picciano, A. Masi & G. Ventura
School of Engineering, University of Basilicata, Potenza, Italy

ABSTRACT: Prestressed reinforced concrete bridges with post-tensioned strands are subjected to heavy corrosion deterioration problems due to injection defects and chloride ingress by de-icing salts or sea airborne. The peculiarity of this prestressing system is recognized by the new italian guidelines on existing bridges prescribing special assessment procedures. Therefore, these bridges need reliable strengthening techniques able to enhance durability reducing the risk of collapse. This paper examines the application of post-tension to rehabilitate pc bridges with injected cables, considering corrosion initiation and propagation, estimated through a chloride ingress model included in the finite element models. Assuming a high chlorides surface concentration, a case study bridge is investigated to design an external post-tension intervention evaluating the time evolution of the capacity-demand ratio under gravity and traffic loads. The capacity loss is estimated depending on the considered corrosion period also assessing the response in terms of cracking and deformation.

1 INTRODUCTION

Following the Second World War, Italy witnessed a growing development of its infrastructure network, so much that it could compete with the main European cities. The majority of the bridges along the road networks were constructed during that period and, as a result, they are now in a state of obsolescence and degradation due to reaching the end of their design service life (Di Prisco 2019).

During those years, the most used technologies for bridge construction were reinforced concrete and prestressed reinforced concrete with post-tensioned cables, which presented significant issues related to degradation due to cable corrosion. In fact, due to the execution deficiencies of this technique, which was still in its early stages during those years, a widespread error was primarily associated with the incorrect or sometimes complete lack of grout injection into the ducts (Smith & Wood 2001), resulting in the creation of voids that facilitated chloride ingress due to the use of de-icing salts or marine aerosol, subsequently initiating and promoting tendon corrosion (Gjørv 2009).

Another critical aspect is that, for this type of structure, is difficult to detect ongoing corrosion phenomena through simple visual inspection or the most common non-destructive diagnostic techniques. Therefore, they may be in a significantly degraded condition not visible from the outside, which can lead to the sudden collapse of the structure (Godart 2015).

For these reasons, within the Italian code for existing bridges, namely the Guidelines on risk classification and management, safety assessment and monitoring of existing bridges (Ministry of Infrastructure, CSLP 2020), prestressed concrete bridges with post-tensioned cables are classified as structures that require accurate assessments and the implementation of special inspections, given their inherent vulnerability.

Therefore, an accurate assessment of safety levels and residual functionality is of fundamental importance, primarily for bridges that are clearly in a state of degradation, but also for bridges that, while appearing to be in optimal preservation conditions, may still exhibit obsolescence, even if only in terms of regulatory compliance, as they were designed according to the specifications of older technical standards (Santarsiero et al. 2023).

DOI: 10.1201/9781003483755-65

Following the safety assessments required by current regulations, most of the existing bridges and viaducts show an actual capacity lower than the demand generated by current traffic loads, which are significantly higher than those considered at the design time of each structure. Therefore, it is necessary to take action through strengthening measures to restore the lost load-bearing capacity due to current degradation conditions and/or the gap in terms of the capacity-demand ratio to satisfy safety verifications.

The purpose of this study is to evaluate the effectiveness of a rehabilitation intervention for existing bridges with a prestressed reinforced concrete girders deck, employing external post-tensioning cables. Specifically, using nonlinear numerical analyses conducted with the finite element software ATENA (Červenka et al. 2021), the overtime decay of the load-bearing capacity of the most stressed beam was first evaluated, considering different time scenarios of damage associated with the onset of chloride-induced corrosion phenomena.

Subsequently, following the innovative approach underlying the new Italian Guidelines, an accurate assessment of the beam's residual capacity was performed by comparing it with the maximum expected stresses, in order to determine the potential need for a static rehabilitation intervention. As for the proposed intervention, the key aspects influencing its design and, consequently, its effectiveness were highlighted.

Thanks to nonlinear finite element simulations, it was possible to conduct a long-term analysis that simultaneously takes into account both the effect of the intervention and the overtime evolution of degradation induced by corrosion. Therefore, the novelty of the proposed approach is to accurately assess the overtime variation of the load-bearing capacity of the beam, even when subjected to an intervention, in order to quantify its long-term effectiveness as well as the whole durability.

2 FINITE ELEMENT ANALYSIS OF THE CASE STUDY BEAM

2.1 *Modelling*

The analysed case study is represented by an edge beam of a highway bridge with a simply supported span system, built in 1966 using prestressed reinforced concrete technology with post-tensioned cables. The bridge deck has an overall length of 32.80 m and a width of 11.05 m, consisting of 5 prestressed reinforced concrete beams with a height of 1.7 m, spaced at a distance of 2.20 m (Figure 1a). The 5 beams are connected at the top by a reinforced concrete slab with a thickness of 20 cm and by 5 reinforced concrete transverse beams. Furthermore, crucial information for the analysis, related to the arrangement of the beam and slab reinforcement, as well as the prestressing cable layout, was derived from the design documents (Figure 1b).

The software used for finite element analysis is ATENA (Červenka et al. 2021), which allows for detailed analysis by constructing three-dimensional models. Additionally, the software accounts for concrete and reinforcement nonlinear behaviour. Specifically, for concrete a constitutive model capable of reproducing its behaviour under both compressive (crushing) and tensile (cracking) loading was utilized (Bazant & Oh 1983). Further details on the constitutive model used can be found in the work conducted by (Santarsiero et al. 2021). As for the reinforcement and prestressing cables, an elastic-plastic hardening constitutive model for steel was employed (Ministry of Infrastructure 2018).

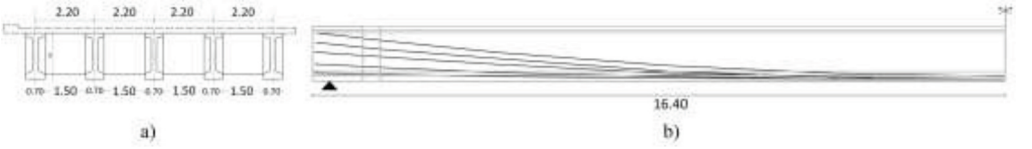

Figure 1. a) Bridge deck's cross-section; b) longitudinal profile of the beam and layout of the post-tensioning cables for half length.

To determine the mechanical properties of reinforcement bars, prestressing cables, and slab concrete, a reference to literature studies was made. However, to estimate the prestressing applied to the cables and the concrete class of the beam, the approach followed was that of "simulated design". This type of approach involves the ability to follow the design phases of the structure, using the regulatory tools of the time, in order to have an understanding of the materials used and construction details, even in the absence of explicit information.

Regarding the reinforcements of the slab and the beam, two types of steel, namely "TOR50" and "AQ50", were used. Given the steel types, it was possible, with the studies of Masi & Digrisolo (2013) and Verderame et al. (2011), to deduce the mean and characteristic values of the parameters necessary for modelling, such as yielding and ultimate tensile strength and strain. In order to conduct safety verifications in accordance with the current regulations (Ministry of Infrastructure 2018), the design strengths used in the software were calculated from these values (Table 1), as specified in the Italian Guidelines (Ministry of Infrastructure, CSLP 2020). In particular, the design values are derived through the following expression:

$$f_d = \min\left(\frac{f_m}{CF \cdot \gamma_m}; \frac{f_k}{CF}\right) \tag{1}$$

where γ_m represents the material safety factor (equal to 1.15 for steel and 1.5 for concrete) (Ministry of Infrastructure 2018), while the term CF represents the confidence factor, which depends on the level of knowledge of the structure (Circolare No. 7/C.S.LL.PP 2019), and has been assumed equal to 1.

As for the prestressing cables, reference was made to the studies by Jacinto et al. (2012) to obtain the characteristic values of strength at 0.1% deformation and rupture ($f_{p0.1k}$ = 1632 MPa, f_{ptk} = 1860 MPa, ε_t = 5%) and, from these, design strengths used within the modelling were derived. Furthermore, in order to model the presence of the protective duct for the prestressing cables (Corven & Moreton 2013), reproducing a certain delay in the onset of cable corrosion during the degrading simulations, the cross-sectional area of each cable has been increased by an amount equal to the cross-sectional area of the duct itself. Therefore, the strength values were reduced to ensure equivalence in terms of force within each cable. Knowing that each cable is made up of 44 strands with a 6 mm diameter and that the duct has a thickness of 0.3 mm, the reduced yield strength values were obtained as $f'_{p0.1d}$ = 1362.54 MPa and ultimate tensile strength as f'_{ptd} = 1552.9 MPa.

Table 2 presents the main strength characteristics of the concrete in the slab and the beam. In the first case, the mean and characteristic strength values were obtained referring to the study by Miluccio et al. (2021). In the second case, the minimum compressive strength value f_{ck} was calculated to ensure that the maximum compressive stress within the beam, subjected to self-weight and cables' prestress, did not exceed the allowable value equal to 48% of the cubic compressive strength, as specified by the regulations in force at the time of design (Circolare No. 384 of 1962). In both cases, once the mean and/or characteristic strength were known, Young's modulus and tensile strength were determined using expressions from the current regulations (Ministry of Infrastructure 2018), while the fracture energy was calculated following the guidelines provided in the Model Code 2010 (Fib, Fédération Internationale du Béton 2010).

Table 1. Strength characteristics of ordinary reinforcement.

	AQ50	TOR50
Young's modulus, E	200 GPa	200 GPa
Design yielding stress, f_{yd}	321.02 MPa	306.55 MPa
Failure stress, f_{td}	475.53 MPa	442.99 MPa
Failure strain, ε_t	0.26 (-)	0.255 (-)

Table 2. Concrete properties for nonlinear simulations.

	Beam	Slab
Design compressive strength, f_{cd}	32 MPa	20.81 MPa
Design tensile strength, f_{td}	2.34 MPa	1.59 MPa
Young's modulus, E	35,220.46 MPa	31,953.76 MPa
Fracture energy, G_F	1.47E−4 MN/m	1.38E−4 MN/m

The assessment of prestressing forces within the cables was carried out by retracing the design phases prescribed by the regulations of that time, in order to achieve a state of integral compressive stress (Leonhardt 1979) within the beam, both when subjected only to self-weight and in operational condition considering permanent and traffic loads (Circolare No. 384 of 1962). In doing so, a value of the prestress applied to the individual cable was obtained, equal to $\sigma_{p,i}$ = 1090 MPa, which is approximately 80% of the cables' yield strength.

Figure 2 shows the 3D finite element model of the analysed beam, discretized into finite elements (3000 hexahedral elements, 49,387 tetrahedral elements, 1824 linear elements, for a total of 22,868 nodes). In particular, taking advantage of the beam's symmetry, only half of it was modelled. Load conditions were applied through a plate located at the midpoint of the beam, while the lower plate transferred the boundary conditions to the model. Both plates were modelled using linear elastic steel behaviour.

The analysis considered the initiation and development of reinforcement and prestressing cable corrosion due to chloride ingress. In fact, the ATENA software allows for mechano-chemical analyses that take into account chloride diffusion inside the concrete, accelerated by the presence of cracking generated by applied loads on the beam. These analyses quantify the time of corrosion initiation and the percentage of corrosion, understood as a reduction in the cross-sectional area, on the reinforcement and prestressing cables. The model was described in detail in Santarsiero et al. (2021) and Santarsiero & Picciano (2023). In particular, by appropriately selecting the values of the main model parameters (surface chlorides concentration C_s, chlorides diffusion coefficient D_{ref}, and critical chlorides content C_{crit}) to consider an aggressive environment due to the use of de-icing salts (Hájková et al. 2018), it was possible to simulate a common degradation condition within bridge beams, where the most deteriorated areas are evident at the locations of water drainage systems and the ends of the beams.

In this way, several analyses were implemented to assess the beam's capacity in as-built conditions and under degraded conditions following time scenarios of 56, 86, and 106 years, which respectively correspond to the current age of the bridge and an additional 30 and 50 years of corrosion development. In each analysis, different intervals can be distinguished as follows: from the first to the fifth interval, the self-weight of the beam and the prestressing force $\sigma_{p,i}$ in each of the 5 prestressing cables are applied; in the sixth interval, the weight of the slab and permanent loads are applied; in the analyses with corrosion simulation, the seventh interval corresponds to the application of the mechano-chemical model; in the final interval, through a displacement-controlled analysis, the beam is brought to failure to assess its ultimate capacity.

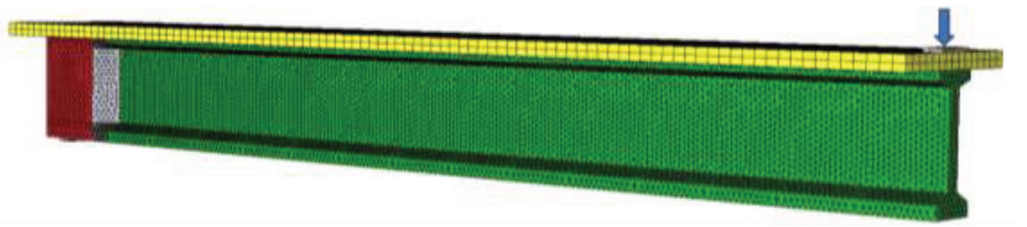

Figure 2. Finite element model of the beam.

2.2 *Analyses' results and verifications*

Thanks to the finite element analyses, it was possible to assess the overtime progression of the beam's load-bearing capacity following the considered corrosion scenarios. The beam's capacity was evaluated in terms of flexural strength, resulting in a value of 15,130 kNm in the as-built condition. This capacity undergoes reductions of approximately 10.7% (M_{rd} = 13,520 kNm), 46.5% (M_{rd} = 8100 kNm), and 55.3% (M_{rd} = 6771 kNm), following corrosion development scenarios respectively of 56, 86, and 106 years. As shown in Figure 3, which represents the overtime progression of the maximum corrosion percentage on the prestressing cables, the variations in the beam's strength are justified by a reduction in the cross-sectional area of the cables, ranging from a minimum of 20.5% to a maximum of 36.5% after 56 years, between 30.1% and 67.1% after 86 years, and between 36.2% and 82% following 106 years of corrosion development.

It is worth noting that the mechano-chemical model implemented takes into account the presence of cracks, which increase the possibility of chloride ingress. Furthermore, due to the specific arrangement of the cables within the beam, they are subject to different initiation times, and therefore, the function representing the corrosion progression does not maintain the same concavity throughout the structure's life. This also results in terms of the beam strength variation, showing a nonlinear trend, as demonstrated by the different values of the decay rate obtained in the various time intervals considered. In particular, the first 56 years show a decay of 0.19%, compared to 1.34% between 56 and 86 years, and 0.82% between 86 and 106 years (Figure 4).

Subsequently, to perform the flexural strength verification of the beam, the demand in terms of flexural stress was calculated considering the application of traffic and permanent loads according to the current Italian regulations (Ministry of Infrastructure 2018). Regarding the traffic ones, load pattern No. 1 for global verification includes both tandem concentrated loads Q_{ik} and distributed ones q_{ik}, arranged in 3 conventional lanes with a width of 3 m, as shown in Figure 5. Proceeding with the transverse load distribution procedure by Courbon Engesser (Raithel 1977), a load of 40.62 kN/m on the edge beam is obtained. Using the ultimate limit state combination, this value is combined with structural permanent loads (self-weight of the beam, slab, and concrete curbs) and non-structural permanent loads (pavement and safety devices), resulting in an overall load value on the edge beam of 99.6 kN/m, which produces a maximum midspan flexural demand, for a simply supported beam, of M_{ed} = 13,391.15 kNm.

Figure 4 shows the overtime progression of the ratio between the beam's capacity, assessed through numerical simulations considering the corrosion-induced degradation, and the demand assessed according to current regulations. As can be seen, the flexural verification is satisfied in the as-built condition, with a value of ζ = 1.13, and in the current condition (t = 56 years), although with a very limited safety margin (ζ = 1.01), which leads to exceeding the capacity in subsequent periods (ζ = 0.60 at t = 86 years and ζ = 0.51 at t = 106 years). Therefore, in the next section, the design of a strengthening intervention is carried out.

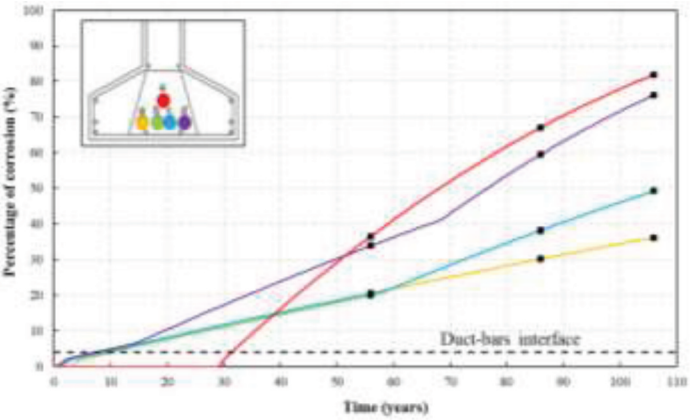

Figure 3. Progression of maximum prestressing cables' corrosion over time.

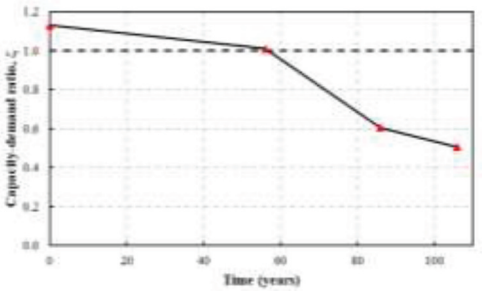

Figure 4. Capacity-demand ratio as a function of time.

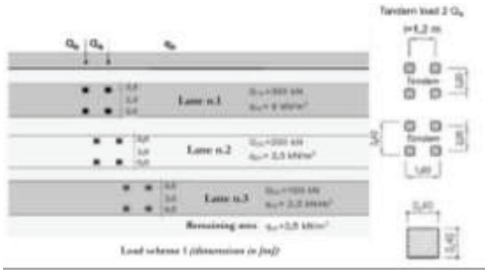

Figure 5. Load pattern No. 1 according to Ministry of Infrastructure (2018).

3 DESIGN AND MODELLING OF EXTERNAL POST-TENSION INTERVENTION

The intervention consists of 2 post-tensioned external cables appropriately arranged along the lateral surfaces of the beam and anchored to it through anchoring plates and deviator plates required for the transfer of the imposed load state. Through cables' tensioning, a compressive force is applied to the structure, increasing its flexural capacity, reducing deflection, and partially or fully recovering existing crack patterns, improving both the serviceability and ultimate limit state performance (Daly & Witarnawan 1997).

In this case, the strengthening system was designed by evaluating the cable prestressing force required to compensate for the deficit in terms of the beam's flexural resistance, as assessed in the previous section. In addition, the assessment of the design prestressing value also depends on the cable's geometry, by evaluating its inclination and eccentricity at the deviator plates. Through iterative steps, the design force of each cable was evaluated equal to T = 1733.13 kN, considering an inclination of 11 degrees and an eccentricity value of 1760 mm. Based on the calculated design force, a cable consisting of 12 strands with a 15 mm diameter was selected from a commercial catalogue, with a yielding strength of $f_{y,e}$ = 1550 MPa, an ultimate tensile strength of $f_{t,e}$ = 1770 MPa, and a failure load of 3180 kN. According to the procedure proposed by MacGregor et al. (1989), the designed cable must also be verified against the increased force to which it would be subjected following a possible failure of the beam, considering a collapse mechanism with the formation of a plastic hinge at midspan. In the end, taking into account this additional verification, a cable prestressing stress of $\sigma_{p,e}$ = 963 MPa was obtained.

Figure 6 shows the 3D model of the beam with the intervention, in which 3 C-plates in S275JR ordinary steel (EN 1993-1-1 2005) have been inserted to anchor the cables at the beam's head and at the locations where they change direction. Therefore, a preliminary nonlinear analysis was implemented to assess the capacity of the reinforced beam, considering that the intervention was applied at t = 56 years, during which the corrosion progression was simulated as seen earlier. Subsequently, two additional scenarios were analysed in which, following the intervention, the beam was subjected to further 30 and 50 years of corrosion development.

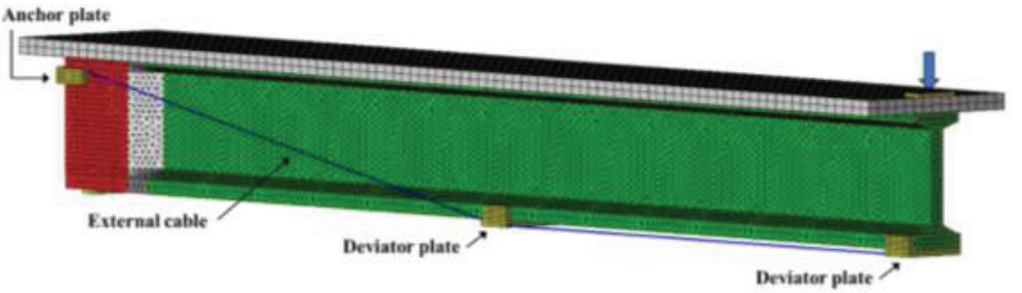

Figure 6. Finite element model of the beam with the intervention.

4 MAIN RESULTS AND DISCUSSION

The implemented nonlinear analyses allowed for the evaluation of the overtime evolution of the beam's capacity-demand ratio, both with and without the strengthening intervention using post-tensioned external cables, as shown in the graph of Figure 7. As can be observed, compared to the conditions without intervention at t = 56 years (current bridge conditions), there is an increase in flexural capacity of approximately 46%, which goes from a value of 13,520 kNm to 19,758 kNm. Additionally, thanks to the intervention, the beam's capacity remains higher than the demand even during the subsequent years of simulated corrosion progression, unlike the case without intervention. In particular, capacity-demand ratio values ζ are 1.48, 1.15, and 1.10, respectively at t = 56, 86, and 106 years with intervention. Another result that can be deduced from the graph is that there is a delayed decrease in strength over time. This is evident from the shallower slope of the lines with the intervention compared to those in as-built corroded conditions in the periods between 56 and 86 years and between 86 and 106 years. In fact, there is an annual decay rate of 0.73% compared to 1.34% without intervention in the first period, while there is a decay of 0.23% compared to 0.82% without intervention in the second one.

Furthermore, the intervention allows for a reduction in the extent of cracking observed at the beam's failure condition. In fact, nonlinear simulations enable the quantification of the maximum crack width, which, in the degraded condition after 56 years of corrosion development, amounts to 2.4 cm (corresponding to reaching a flexural capacity of 13,520 kNm). Conversely, under similar degradation conditions but with the intervention, the maximum crack width is reduced to 1.1 cm (with a flexural capacity of 19,758 kNm), resulting in a 54% reduction. The beneficial effect of external post-tensioning is also evident in terms of beam deformation, reaching a maximum displacement at failure of 16.3 cm, compared to the value of 33.4 cm achieved without intervention and under similar degradation conditions.

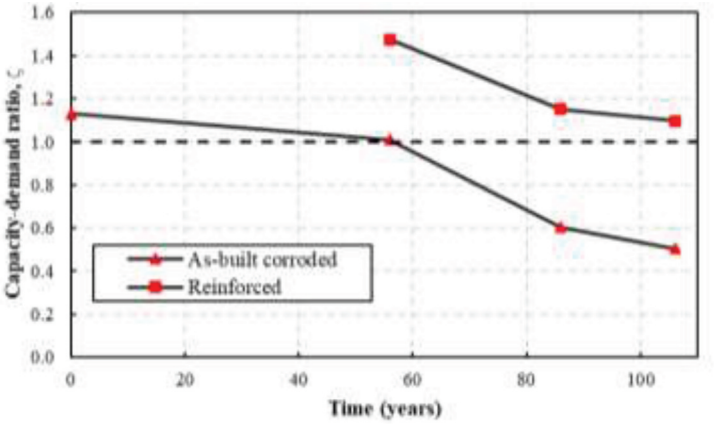

Figure 7. Overtime evolution of capacity-demand ratio in the presence and absence of intervention.

5 CONCLUSIONS

In this study, the structural behaviour of a prestressed reinforced concrete bridge beam built in the 1960s was analysed. The beam was assessed using the finite element software ATENA, which is capable of conducting nonlinear analyses and durability assessments, taking into account chloride-induced corrosion through an advanced mechano-chemical model. The primary objective was to initially evaluate the time-dependent evolution of the structure's capacity under various corrosion scenarios, simulating the current condition of the bridge as well as an additional 30 and 50 years of degradation. Subsequently, this evaluation was compared

to the demand derived from traffic loading patterns in accordance with current Italian regulations. This comparison revealed the need for a strengthening intervention. Therefore, an intervention was designed and modelled, involving the use of external post-tensioned cables. The effectiveness of this intervention was evaluated through a long-term analysis, subjecting the beam to the same corrosion scenarios as before. The results indicate that the intervention increases the flexural capacity of the beam by 46%, raising the capacity-demand ratio from 1.01, in the absence of intervention, to 1.48 in the current state, and maintaining this ratio above 1 even after additional 50 years of degradation. This highlights the effectiveness of the intervention over the long term. Additionally, the beam experiences beneficial effects in terms of cracking and deformation at failure, reducing the maximum crack width and mid-span displacement by 54% and 51%, respectively.

ACKNOWLEDGMENTS

The studies presented here were carried out as part of the activities envisaged by the Agreement between the Italian Department of Civil Protection and the ReLUIS Consortium (DPC-ReLUIS project 2022-24, WP5-Task 5.4 "Upgrading and retrofitting interventions of existing bridges"). The contents of this paper represent the authors' ideas and do not necessarily correspond to the official opinion and policies of DPC.

ABSTRACT: The growing emphasis on carbon neutrality and sustainability within the global infrastructure sectors exerts a profound influence on the decision-making processes concerning construction materials. Now, it become imperative to select the primary construction materials not only based on economic feasibility but also by taking into account the quantified environmental impact in terms of life-cycle assessment. The cost and environmental impact may vary significantly depending on the maintenance strategy during operation and the recycling rate after the end-of-life stage. In this study, life-cycle assessments were conducted on steel plates and pre-stressed concrete girder bridges under identical structural conditions. We systematically quantified the effects of primary construction materials and environmental conditions on the overall environmental impact.

1 INTRODUCTION

The relationship between the infrastructure industry and its environmental impact has been a focal point of discussions, addressing key concerns such as energy consumption, greenhouse gas emissions, raw material depletion, and waste generation (Barbhuiya and Das, 2023). Notably, 90% of CO_2 emissions within the infrastructure sector are concentrated in the product stage of construction material (Blanco et al., 2021). The crux of mitigating the environmental impact of the infrastructure industry lies in the engineer's sustainable conceptual design decision and optimized designs (Kanyilmaz et al., 2023). Alongside life-cycle performance assessment (LCPA), ensuring sustainability based on quantitative life-cycle impact assessment (LCIA) is paramount. Precedent studies have conducted comparative LCIA of alternative designs for several types of infrastructure, including bridges (Du et al., 2014, Gervásio and da Silva, 2008) and buildings (Desai and Bheemrao, 2022, Katebi et al., 2023).

Infrastructures inevitably experience structural performance deterioration over time due to their lengthy design life (Biondini and Frangopol, 2016). The extent of performance deterioration can be significantly influenced by environmental conditions to which the structure is exposed and long-term climate changes (Cai et al., 2018, Xie et al., 2018). Both the life-cycle environmental impact and cost can be affected by the maintenance scenarios and strategies employed to address performance deterioration (Kere and Huang, 2019, Orcesi et al., 2010). For instance, if technical actions such as member replacement or reinforcement are integrated into the maintenance strategies, notable differences can emerge in the environmental performance and cost throughout the life cycle (Cadenazzi et al., 2020, Han et al., 2021). Moreover, the incorporation of a construction material recycling strategy introduces complexity and challenges to the life-cycle assessment (LCA), as investigated by Kanyilmaz et al. (2023) Therefore, it is essential to establish appropriate

DOI: 10.1201/9781003483755-66

maintenance strategies and understand their implications through time-variant performance analysis from a life-cycle perspective (Alfredo and TANG, 2007, Strauss et al., 2008).

This study systemically quantified the life-cycle environmental impact of bridge design alternatives of different primary construction materials (concrete and steel) while maintaining identical conditions in all other aspects. A two-step LCA framework was employed. First, a time-variant LCPA was conducted, accounting for the deterioration of structural components induced by corrosion. The influence of corrosive environments on the final environmental impact was investigated by considering three distinct corrosive environments. Second, by integrating the information on technical actions derived from LCPA into LCIA, the environmental impacts associated with bridge construction materials were quantified. The outcomes of case studies provide insights into the environmental impact of bridge design alternatives, taking into the interplay of bridge deterioration, time-variant performance, and material recycling.

2 LCA FRAMEWORK

2.1 *LCPA*

LCPAs were conducted on the flexural capacity of the maximum positive moment section under the design truck load, extending up to the target service life of 100 years for the service limit state according to AASHTO LRFD guidelines (AASHTO, 2020). The structural performance degradation due to corrosion was considered. Three corrosive environmental conditions were investigated; rural, urban, and marine environments (Albrecht and Naeemi, 1984). Throughout the use stage, the maintenance strategies for the bridge were categorized into preventive (patching, repainting, etc.) and essential maintenance (girder replacement, reconstruction, etc.) each involving different technical actions (Biondini and Frangopol, 2016). In this study, the preventive maintenance interval (t_m) was set as 10 years. Essential maintenance of deteriorated girder replacement was set to occur when the probability of failure (P_f) reached 0.6% of target P_f according to AASHTO MBE (AASHTO, 2018). Figure 1 illustrates the LCPA framework.

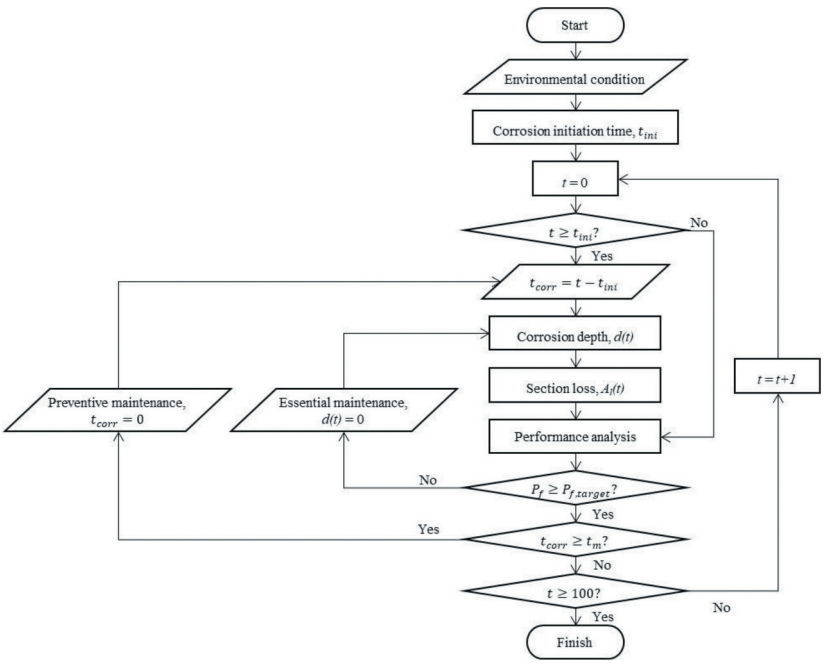

Figure 1. LCPA flowchart.

2.2 *LCIA*

The bridge LCA of alternative designs under identical structural conditions were carried out in accordance with ISO 14040 (ISO, 2006a), 14044 (ISO, 2006b), and 21930 (ISO, 2017) standards. The system boundary was defined as cradle-to-grave, including the potential benefits and loads of a circular economy. For the assessment of the circular economy of steel, adherence to ISO 20915 (ISO, 2018) is crucial to accurately evaluate industry-specific data and the losses and benefits associated with recycling processes. The OpenLCA (GreenDelta, 2023), utilizing the ecoinvent database (DB) (RIVM, 2016), was employed for the LCIA. In cases where products were absent in the ecoinvent DB, the industrial environmental product declaration (EPD) DB registered in TOTAL (KEITI, 2023), a Korean LCA program, was utilized. Environmental data related to all included materials throughout the bridges' lifetimes were gathered and characterized using the ReCiPe 2016 method (RIVM, 2016), yielding results for the six environmental categories (Table 1). Environmental impacts, considering loss and benefits from the recycling of steel, were determined based on data provided by Korean industries and environmental reports (ME, 2023).

Table 1. Environmental categories.

Impact category	Reference unit
abiotic depletion potential (ADP).	10 kg Cu eq
eutrophication potential (EP)	kg PO43- eq
global warming potential (GWP)	t CO2 eq
ozone-layer depletion potential (ODP)	g CFC11 eq
acidification potential (AP)	kg SO2 eq
photochemical ozone-creation potential (POCP)	10 kg NOx eq

3 CASE STUDY

3.1 *Target Bridge*

The target bridge for design consist of two one-way bridges, each with widths of 12.3 m (B1) and 15.9 m (B2), and a total length of 175 m (5 spans at 35 m each). LCAs were conducted for two types of bridge design alternatives: one with pre-stressed concrete (PSC) girders and the other with steel plate girders. The same framework was applied to both alternatives. Figure 2 illustrates the plane view of the bridge.

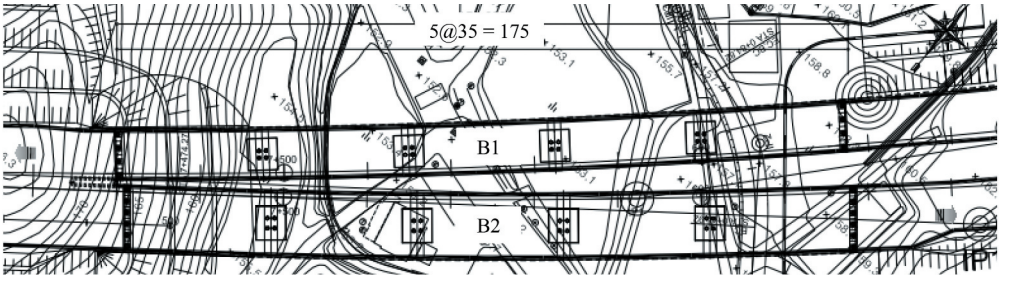

Figure 2. Plane view of target bridge.

3.2 *Results of LCPA*

Performance deterioration of the PSC girder bridge was evaluated according to the chloride-induced corrosion model under different environmental conditions (Vu and Stewart, 2000) considering a chloride penetration scenario where chloride infiltration into the tendon leads to

corrosion (Al-Mosawe et al., 2022). The corroded cross-sectional shape and loss model of the tendon were applied by Yoo et al. (2018). For the steel plate girder bridge, the corrosion progression model was adopted based on Kayser (1988), and the cross-sectional loss model was applied according to Kere and Huang (2019).

The LCPA results considering two maintenance strategies are shown in Figure 3. Depending on environmental conditions, the rural case did not require replacement for both PSC girder and steel plate girder bridges. However, in the urban case, the replacement was projected to be necessary twice for PSC girder and not at all for the steel plate girder, while the marine case predicted seven replacements for PSC girder and two for the steel plate girder. It is noted that the frequency of the maintenance could vary based on the chosen maintenance strategies and structural deterioration model.

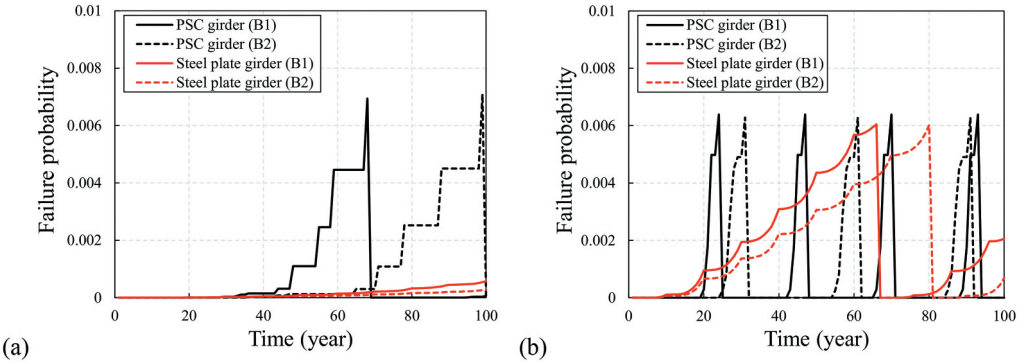

Figure 3. LCPA results for environmental conditions: (a) urban case; and (b) marine case.

3.3 *Results of LCIA*

The frequency of technical actions calculated in Section 3.2 was considered in conjunction with maintenance and disposal amounts to conduct LCIA. Figure 4 illustrates the results of LCIA for the marine case. A recycling rate of steel was commonly applied as 40.1% in Republic of Korea (BIR, 2022). The environmental impacts of the PSC girder bridge, which was evaluated with a relatively higher frequency of technical actions, consistently showed higher values.

Figure 5 presents the sensitivity analysis results for recycling rates ranging from 0% to 100%. It was observed that the proportion of environmental impacts that can be reduced in a circular economy varies significantly based on the recycling rate of steel, with the greatest reduction observed in EP, AP, and GWP, in that order.

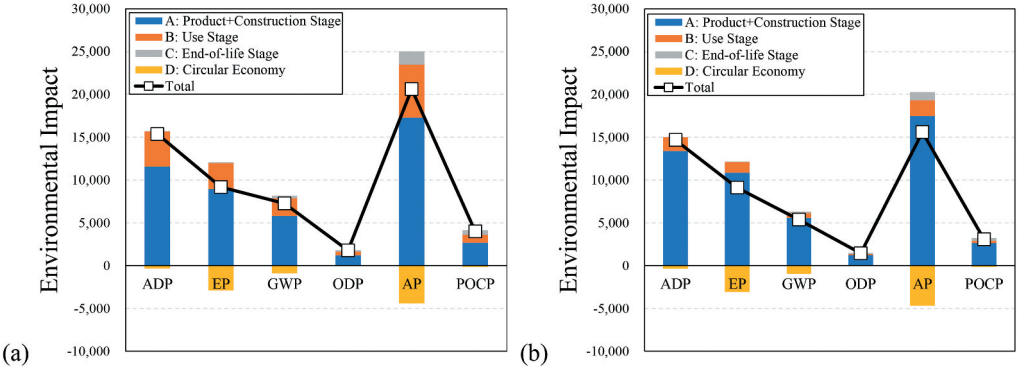

Figure 4. LCIA results for marine case: (a) PSC girder bridge; and (b) steel plate girder bridge.

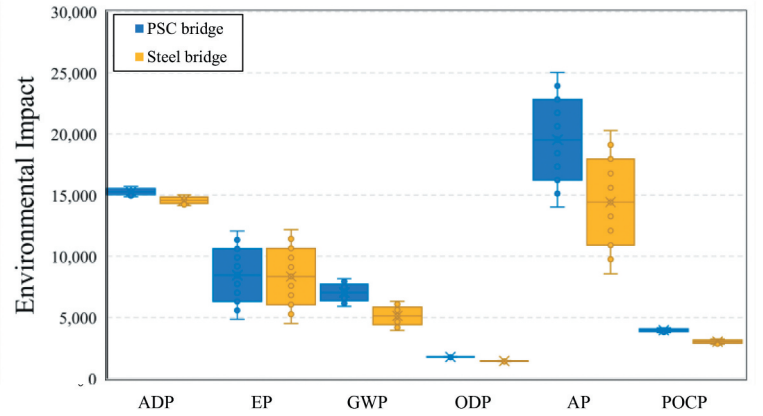

Figure 5. Influence of steel recycling rate into the environmental impact categories.

4 CONCLUSIONS

This study conducted LCPA considering structural performance degradation due to corrosion and LCIA case studies for two types of bridge designs: PSC girder bridge and steel plate girder bridge. Depending on the environmental conditions, it was calculated that the PSC girder may require a maximum of 7 replacements, while steel plate girder may need a maximum of 2 replacements. The tendon corrosion scenario was found to be particularly critical for the performance deterioration of the PSC girder bridge. Technical actions for maintenance strategies, such as girder replacement, demonstrated a significant impact on the overall LCIA results. Additionally, sensitivity analysis on recycling rates of steel revealed that the effect of circular economy plays a crucial role in reducing the final environmental impact.

A. Strauss
Institute of Structural Engineering, University of Natural Resources and Life Sciences, Vienna, Austria

ABSTRACT: In the face of the limited development of the transport infrastructure, maintaining the condition of the existing structures is becoming more and more important. The majority of structures are made of reinforced or prestressed concrete. Due to their intensive use and the harsh environmental conditions, they are exposed to increased aging. This results in a progressive form of degradation. The application of durable repairs at the optimum time for rehabilitation is a key challenge. The decision to select repairs is often made under unclear conditions. The information from preliminary investigations can be misinterpreted in many ways and the reduction to purely visually detectable damage can lead to wrong conclusions. The aim is to use systematized damage assessments to make decisions on the type of repair more objective and focused on scientific knowledge and expertise. Using a multimodal approach to measure the degradation of reinforced concrete components, the assessment is systematized so that the condition is always objective, comprehensive, and accurate. For this purpose, the results obtained from preliminary investigations are transformed into four damage classes and an objective and by weighting representative condition index. The developed fuzzy logic decision algorithm uses the condition index as input parameter for the selection of optimal repair methods. Hence, this assessment methodology is Fuzzy-Logic (FL), which treats and combines input data in not clear-cut borderlines to choose an optimal maintenance measure. A case study will proof the method to deal with lack of knowledge and uncertainty in this fuzzy decision process.

1 INTRODUCTION

Accurate information on road structure conditions is crucial for safety, maintenance planning, and route availability. Corrosion of reinforced concrete, primarily caused by reinforcement corrosion, poses economic challenges. Globally, five tons of steel corrode every second, amounting to about 6% of a developed country's GDP. To ensure optimal preservation within budget constraints, estimating remaining service life and understanding degradation progression is vital. Existing guidelines in Austria rely on visual assessments, overlooking issues like chloride penetration and carbonation that lead to hidden corrosion. An objective condition assessment is needed to bridge the gap between visual perception and the actual state, enhancing the effectiveness of mandatory inspections.

Developing a practical and objective method for assessing the preservation of reinforced concrete components is the goal of this work. The method aims to determine the preservation state through simple yet objective means, enabling a preselection of targeted and sustainable repair methods. The effectiveness and duration of repair systems are considered, taking into account the current preservation state and component exposure.

DOI: 10.1201/9781003483755-67

2 METHODOLOGY

Road infrastructures face increased degradation from various damaging effects, with exposure to chlorides being a major driver, particularly at the rebar level. Concrete degradation occurs when chlorides surpass a threshold the concrete can no longer absorb, leading to indicators like cracking and a drop in electrochemical potential. This chapter presents objective assessments of reinforced concrete degradation, utilizing examinations that align with established standards and literature (Casas 2017). Results categorize degradation indicators into four damage classes, mirroring long-standing practices in road condition assessment. While such classification is common for asphalt and concrete roads, its application in reinforced concrete construction is still evolving, and this paper serves as a foundational guide for the development of indicators based on measured values.

Detecting corrosion in concrete-reinforced steel is challenging due to various overlapping factors, often requiring indirect methods like potential measurement. Degradation signs may not be immediately visible on the surface, demanding high qualifications for accurate interpretation. Chloride-induced corrosion is a key driver of degradation, necessitating preliminary surveys for a comprehensive assessment.

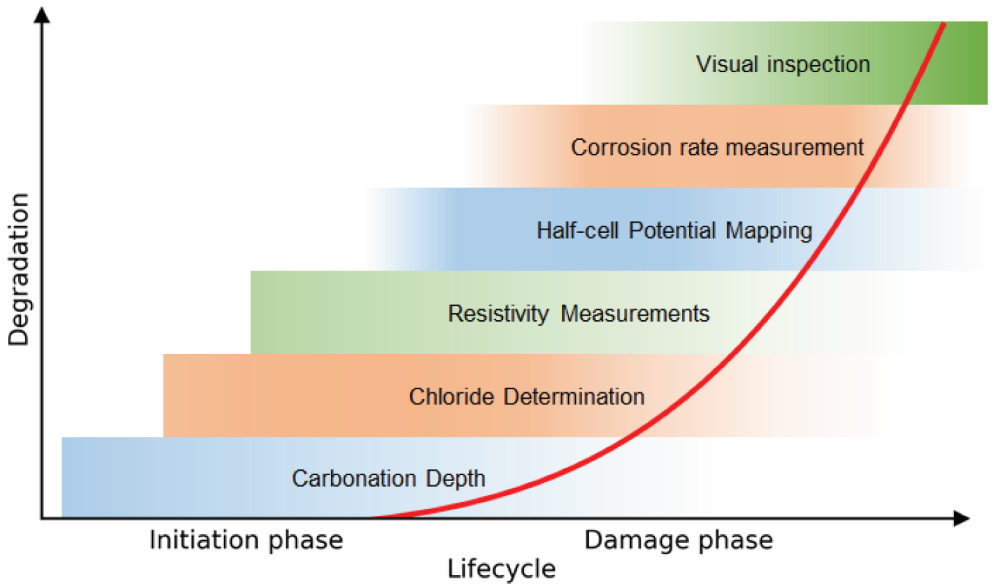

Figure 1. Effectiveness of different condition survey methods for condition assessment depending on the state of degradation based on (Pailes & Gucunski 2015).

Figure 1 shows the efficiency of condition survey techniques as a function of the condition state. For example, a determined investigation for a specific problem, such as half-cell potential mapping, does not provide more accurate information about the state of preservation until parts of the reinforcement are already affected by corrosion and the concrete components can be therefore already in the damage phase. Furthermore, the figure shows an important insight for the engineer, that with single visual condition assessment, damage is detected very late. Therefore, it is of enormous importance to know when and how accurate a possible degradation can be detected.

The examination techniques mentioned in Figure 1 are established procedures and allow to obtain acceptable good and quantitatively sufficient results with sufficient monetary expenditure. It is always important that the procedures enable and support the increase of knowledge of the overall objective of the condition analysis.

As already mentioned, it is difficult to determine the true dimension of damage only based on visual appearance of the concrete component. Nevertheless, different condition survey techniques are available depending on the stage of degradation (see Figure 1).

2.1 *Indicators for degradation*

The condition, which is initially determined mainly visually, as well as the development of damage due to corrosion over time, is serving as the basis for decisions regarding the time and intensity of repair. A simple and objective method for assessing the condition of concrete structures is of decisive economic interest.

Based on all available results from preliminary examinations, the condition of the structural element should be determined simply and objectively. The primary basis in the procedure for objectifying and standardizing the results of condition assessment is a thorough and, above all, complete inspection, which thus makes it possible to take further steps towards classification and indexing of the results obtained. The indicators obtained individually from the various pre-liminary inspections are of varying degrees of importance for degradation. Therefore, the indicators were subjected to weighting via an analytical hierarchy process (AHP) before being synthesized into a condition index.

Additionally, the results of condition assessments are often not clearly interpretable, as they also contain a subjective perspective. This results in unclear decisions regarding the maintenance strategy. Therefore, a fuzzy logic expert system is introduced which can deal with this vague decision space.

Table 1. Indicator for degradation and their levels.

			Degradation indicator level			
Degradation Ind.	Akr.	Unit	1 Negligible	2 Low	3 Moderate	4 High
Visual appearance	Vis	[mm]	< 1	≥ 1 - 4	≥ 4 - 10	≥ 10
Carbonation depth	X_{CO}	[mm]	0% C	≤ 75% C	> 75% C	≥ C
Chloride content	X_{Cl}	[m%]	≤ 0,2	0,2 - 0,6	0,6 - 1,0	> 1,0
Concrete resistivity	ρ	[Ωm]	> 1000	500 - 1000	100 - 500	< 100
Corrosion potential[1]	E_{corr}	[mV]	> -200	-200 - -350	-350 - -500	< -500
Corrosion state	KG	[-]	0 < 1	≥ 1 - 2	≥ 2 - 3	≥ 3 - 4

[1] using Cu/CuSO4 reference electrode
C means thickness of the concrete cover

2.2 *Condition index*

For the determination of a condition index, all available results from preliminary investigations at the evaluation time, such as carbonation depth and chloride content at the reinforcement level, are divided into classes. From these, information is obtained that can provide information on the current state, respectively the intensity of the damage due to corrosion. The index is divided into four classes as follows:

1.= no damage and negligible or no corrosion,
2.= minor damage and low corrosion,
3.= moderate damage and moderate corrosion,
4.= high damage and high corrosion.

The corrosion damage index (CDI) is obtained by first transferring measured values to Corrosion indicator levels, see Table 1. These scenarios represent common evaluation approaches which have to be proven and possibly updated in practical use. The mean of the corrosion indicator levels results in the "Corrosion Damage Index":

$$CDI_{Mean} = \sum_i^n \frac{Degradation\ indicator\ level_i}{n} \quad (1)$$

here n is the number of corrosion indicators used, according to Table 1.

The mean value is calculated for simplification purposes. In principle, it is possible to assign more importance to individual indicators.

A weighting can be based on the type of measurement on the one hand and on the significance of the indicator on the other. The indicators carbonation, visual appearance, chloride content at reinforcement level and cracks are all indicators that provide indirect information about the degradation, whereas potential, corrosion rate or cross-section loss of the rebar represent direct measured values related to the corrosion of the reinforcement and may therefore weighted stronger. A method for determining the weights, the analytical hierarchy process (AHP) (Saaty 1977). The calculation of the condition index when weighted indicators are used is as follows:

$$CDI_{AHP} = \sum_i^n Degradation\ indicator\ level_i \cdot w_i \quad (2)$$

where w_i is the weighting factor for the particular degradation indicator used.

The method enables transparent traceability of how prioritization was calculated and, thus, strengthens the understanding and acceptance in decision making. Thus, a comprehensible and expert based weighting is achieved. The approach of the method is to simplify the problem by breaking it down into a hierarchical system and to form a systematic procedure to structure and solve the decision processes. Which indicators are used in particular and how they are ranked and prioritized can be seen in Table 2. Therefore, the corrosion indicator chloride content is two times more important than the corrosion potential (X_{Cl}) and seven times more influential than the carbonation depth (X_{CO}). This additional information is processed in the AHP algorithm and derives the weighting in percent, which is given in the last column of Table 2 labeled as priority.

Table 2. Weights of the degradation indicators to determine the condition index.

		Importance						
Degradation indicator DI	Rank	1	2	3	4	5	6	w_i [%]
Chloride content	**1**	1	3	4	5	7	8	**43,7**
Corrosion potential	**2**	1/2	1	2	3	6	7	**23,9**
Concrete resistivity	**3**	1/3	1/2	1	2	5	6	**15,7**
Corrosion state	**4**	1/4	1/3	1/2	1	4	5	**10,3**
Carbonation depth	**5**	1/7	1/6	1/5	1/4	1	2	**3,8**
Visual appearance	**6**	1/8	1/7	1/6	1/5	1/2	1	**2,7**

The CDI is thus a measure of the direct quantifiable damage due to corrosion the reinforcement has undergone, combined with the expected corrosion progress. The result is therefore a measure that provides information about damage already caused and describes the current status of the degradation. The level of the index (CDI) shows the extent of the damage that has already occurred. The higher the damage index, the greater the damage and extent of the degradation. By using AHP the decision problem is decomposed into a hierarchy of more easily comprehensive sub-problems, which can be analyzed independently. Once the hierarchy is built, the process consists of systematically evaluate the elements and determine their interrelations and by comparing them to each other with respect to their impact on an element above them in the hierarchy. In making the comparisons, concrete data about the elements can be used to enhance the judgments about the elements' relative meaning and importance. The AHP converts these evaluations to numerical values that can be processed and compared

over the entire range of the proposed problem. Finally, a numerical weight or priority is derived for each element of the hierarchy, allowing diverse and often incommensurable elements to be compared in a rational and consistent way. After incorporating these judgments this yields to a set of overall priorities for the hierarchy. With every kind of pairwise comparison, inconsistencies can also occur. For the examination of these inconsistencies a so called Consistency Ratio (CR) is used, where CR < 10 % is considered to be acceptable. For the examination of these inconsistencies a so called Consistency Ratio (CR) is used, where CR < 10 % is considered to be acceptable (Saaty 1990).

2.3 *Fuzzy-logic decision support system*

It is indeed difficult to perform a quantitative evaluation of the effectiveness of repairs. This problem has many sources. They include environmental influences, time pressure during implementation, lack of root cause analysis, price wars among repair companies and poor execution quality.

It is not possible to evaluate the effectiveness of repair procedures quantitatively. Complex tests on site and in the laboratory are required for realization.

It is more appropriate to use an expert system so that knowledge can be made available to experts. A rule-based expert system (RES) models an expert who can handle the system instead of the system to be operated. This makes the expert knowledge accessible to non-experts, who can thus make decisions with the help of the RES. Furthermore, the conception of a RES enables the knowledge of the experts, which is intuitive and empirical, to be readable and processable by computers.

Fuzzy RES are based on qualitative (fuzzy) expert statements and thus on (fuzzy) stored qualitative knowledge. In addition to the use of linguistic variables and operators, an essential concept is the method of defuzzification. In this paper, it is shown how the effectiveness of individual repair measures can be estimated as a function of the damage classes or corrosion indicators using the fuzzy logic approach.

The simplest form of a fuzzy logic application is a fuzzy controller. This takes input, then performs calculations and finally provides an output value. Fuzzy sets were first applied by (Zadeh 1965). The following steps must be gone through:

- Setting the input and output values as linguistic variables,
- Definition of the fuzzy sets of input and output values,
- Converting the input values into fuzzy values (fuzzyfication),
- Formulation of the rules and store in the knowledge base,
- Applying the rules to the fuzzy values (inference),
- Convert obtained statements into numerical form (defuzzyfication).

Figure 2 illustrates the basic structure of a fuzzy logic expert system with focus of the presented problem.

3 FIELD STUDY

The survey was undertaken on a retaining wall situated in Vienna at the Austrian motorway network of ASFiNAG. The retaining wall is 3.80 m beside the motorway lane. The wall is 133 m long and between 0.5 m and 5.90 m of height. It is retaining a slope before an overpass. Taking into account that the surveyed structure is 38 years old, the evaluation of the conditions shows already degradation phenomena, like delamination, cracks and particularly corrosion of the reinforcement. The preliminary survey shows a mean carbonation depth of 2.4 cm and chloride contamination over 1 % Chloride per mass binder up to approximately 4 cm in the concrete surface (see Figure 3).

4 CONCLUSIONS

The paper presented a methodology to assess the condition of concrete components. The condition is determined from real and therefore objective values which are suitable to indicate degradation. The obtained data is mainly derived from condition surveys and may also monitoring data, like humidity, electrical resistivity, and corrosion potential.

The demand of an exact as possible determination of the condition state is a key mission for the asset management to decide which maintenance measure is the best for a certain condition at certain time. This is considered by using objective indicators (degradation indices) to derive an overall performance index. This condition indicator (CDI) is handled through an analytic hierarchy process (AHP) for the sake of objectivity and comprehensibility.

The AHP was utilized in this paper to develop a useful tool for determining the corrosion damage condition of a reinforced concrete bridge component based on different corrosion indicators. AHP method was used to help determine weight factors for different indicators relative to the determination of the final corrosion condition. AHP method can reduce the influence of certain expert's mistakes in the judgment by using pairwise comparison method. A final and more accurate CDI value can be obtained.

The condition index has been transformed into a fuzzy logic system. An overview of the whole fuzzy logic process for determining the effectiveness of repairs based on the condition index CDI was given. A simple expert-based decision rule regime was used to determine the effectiveness of individual repair principles.

At first, membership functions of the sharp input, here condition index, and output variables, here theoretical effectiveness of repair, are conceived. Fuzzy ranges of values are created. These values are related in the inference via a rule database, which was designed empirically and based on expert knowledge. After defuzzification, the effectiveness of the respective maintenance principle is the output to the corresponding condition index CDI.

In Figure 3.h it can be seen that the effectiveness of a certain maintenance measure is not completely ineffective or fully effective in any of the cases. The developed decision algorithm can reliably represent the state of knowledge of experts in the field of repair of reinforced concrete structures. The structure of the system is deliberately kept simple and the reconstruction of the decisions is also clearly comprehensible.

In addition, the fuzzy logic expert system can be extended with respect to the degradation indicators forming the condition index. Furthermore, the developed system is machine-readable, therefore simultaneously applicable to a collective of reinforced concrete components or even entire infrastructure networks.

The methodology was evaluated, proofed, and demonstrated within the case study. If enough data from the condition assessment is available, it can provide a more accurate condition overall and so serve for more profound input for the Fuzzy Logic expert system to choose an optimal repair measure.

The strict rely on only visual inspection data for condition assessment to manage repair measures is considered as critical by the authors.

The paper presents a comprehensive methodology for structural monitoring with the aim of showing how directly usable results from monitoring can be, obtained in the long term for service life prognosis, asset management and maintenance with acceptable effort.

In addition, with the application of this approach on a larger, representative building stock, the perspective of an even more reliable service life prognosis will take place. Therefore, the data already acquired, but also future data, can be described as valuables. In the future better forecasts will be possible based on more precise condition assessments. An important point is that uncertainties on both the impact and the resistance side can be concretized or reduced through dense NDT in time and space, or monitoring.

5 OUTLOOK

The transfer of damage to reinforced concrete components into damage classes can be extended to include indicators for freeze-thaw attack or sulfate attack. Also, such damage classifications can be applied to other materials, such as steel by extension. The application of the degradation indicators allows an objective representation of the state and contributes to the homogenization of the data.

With this more accurate data, at the structure level, the fuzzy logic algorithm can serve as a decision support tool in choosing the optimal repair method. In addition, the fuzzy logic expert system can be extended with regard to the degradation indicators forming the condition index. In addition, the developed system is also applicable to a collective of components, structures or even entire infrastructure networks.

At the network level, the fuzzy logic algorithm can provide more accurate results when calculating the budget requirements of future maintenance activities. This allows to take full advantage of the optimal rehabilitation at the optimal time and so effectiveness of financial resources.

ABSTRACT: Bridge damage and landslide resulting from rainfall significantly disrupt transportation systems. To enhance the performance and resilience of road networks due to torrential rainfall events, it is essential to assess the connectivity of road network while considering the failure of bridges and slopes. This study presents a methodology for probabilistic connectivity assessment of road network incorporating the potential failure of bridges and slopes under rainfall hazard. The proposed method selects surface runoff as a critical parameter to establish a spatial correlation model for the hazard intensities exerted on bridges and slopes. As an illustrative example, the proposed method is applied to a hypothetical road network in Yamagata Prefecture, Japan, susceptible to rainfall-induced floods and landslides.

1 INTRODUCTION

The devastating consequences of torrential rainfall events (e.g., concurrent flooding and landslides) have not only caused individual structural damage but also disrupted road networks (Ario et al., 2022; Dave et al., 2021; Mori and Ono, 2019). In July 2020, Kyushu island in Japan experienced torrential rain, resulting in floods and various geo-disasters (e.g., slope failures and road subsidence). These led to substantial damage to road infrastructure with 10 bridges washed away by floods, and road closures due to landslides (Mukunoki et al., 2021). Therefore, a methodology assessing road network connectivity considering failure of bridges and slopes due to rainfall is imperative.

Fragility assessments of bridges and slopes exposed to rainfall hazards has become a focal point (Donnini et al., 2017; Loli et al., 2022; Zhang et al., 2023). Traditional studies, however, focus on road disruption, often considering only a singular structure type. Furthermore, despite the well-established concept of spatial correlation in seismic hazard assessment (Baker and Chen, 2020; Jayaram and Baker, 2009), its application to bridge damage and slope failure resulting from rainfall remains limited. During heavy rainfall, flow discharge associated with surface flow serves as the hazard intensity measure leading to bridge damage (Mondoro and Frangopol, 2018), while infiltration into the slopes influences the slope stability (Huang and He, 2023; Xu et al., 2021). With spatially correlated hazard intensities exerted on bridges and slopes, a framework for assessing road network connectivity should be developed.

Under uncertainties associated with hazard intensity and structural fragility, probabilistic connectivity of origin-destination (OD) pairs can be an effective indicator to quantify the performance of road networks in post-disaster activities (Bocchini and Frangopol, 2013, 2011).

DOI: 10.1201/9781003483755-68

This assessment involves measuring the simultaneous occurrence of hazard intensity among spatially distributed bridges and slopes. Spatially correlated hazard intensity is determined based on physical properties associated with hazard characteristics and random field simulations. Therefore, a comprehensive methodology for probabilistic connectivity assessment of road network considering simultaneous failure of bridges and slopes under rainfall hazard should be established to evaluate the performance of the road networks.

This study presents a methodology for probabilistic connectivity assessment of road networks considering failure of bridges and slopes under rainfall hazard. The hazard intensity exerted on bridges and slopes is modeled through a key hydrological parameter (i.e., surface runoff resulting from rainfall). As an illustrative example, the proposed method is applied to a hypothetical road network with bridges and slopes in Yamagata Prefecture, Japan.

2 PROBABILISTIC CONNECTIVITY ASSESSMENT OF ROAD NETWORK CONSIDERING FAILURE OF BRIDGES AND SLOPES UNDER RAINFALL HAZARD

Figure 1 shows the proposed methodology for estimating the probabilistic connectivity of road network considering failure of bridges and slopes under rainfall hazard.

2.1 *Definition of road network*

The configuration of the initial road network, denoted as G_0, involving both bridges and slopes is defined as follows:

$$G_0(\mathbf{V}, \mathbf{E}),\ \mathbf{E} \subseteq \{uv | v \in \mathbf{V}, u \neq v\} \tag{1}$$

where vertices **V** represent OD pairs, bridges, slopes, and highway intersections; edges **E** define road segments connecting vertices; and *uv* is a subset of edges.

2.2 *Spatially correlated hazard assessment*

Surface runoff is chosen as the key parameter to establish the spatial correlation model for the hazard intensities exerted on bridges and slopes. After generating the annual maximum rainfall intensities based on the Gamma distribution and historical rainfall daily data, the spatial correlated run off is modelled by Geographically Weighted Regression (GWR).

The hazard intensity for bridges is assessed with flow discharge (Mondoro and Frangopol, 2018; Firdaus et al., 2023). The time series of flow discharges is generated using Soil and

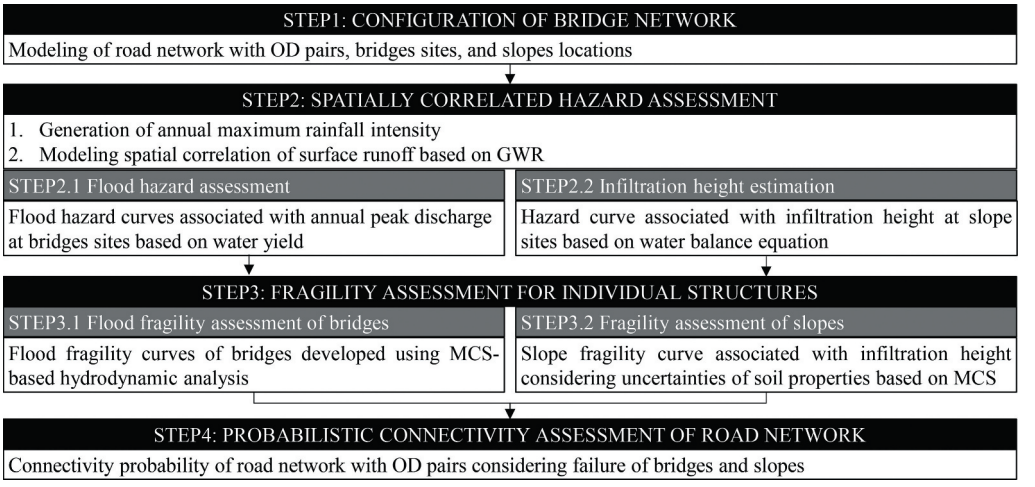

Figure 1. Framework for connectivity of road network with bridges and slopes under rainfall hazard.

Water Assessment Tool (SWAT) considering spatially correlated surface runoff. Since this study focuses on hazards induced by heavy rainfall, only the water balance components when the discharge reaches its annual peak (i.e., annual peak flow) are extracted for further analysis. The hazard intensity for slopes is estimated by spatially correlated change of soil wetting (i.e., infiltration height) based on the water balance performed in SWAT. The probability distribution of the initial infiltration height, calculated at each grid, is used. Subsequently, the mean infiltration height at slope locations can be calculated.

2.3 *Fragility assessment*

Firdaus et al. (2023) developed fragility curves of bridges under flood hazard based on Monte Carlo simulation-based hydrodynamic analysis. Their fragility curve for a bridge at site j is expressed as:

$$P_{vb,j} = P\left(g_{Fm,j} \leq 0 | Q = q_{vb,j}\right) \tag{2}$$

where $P\left(g_{Fm,j} \leq 0 \mid Q = q_{vb,j}\right)$ is the conditional failure probability of bridge given flood hazard intensity $Q = q_{vb,j}$; and m represents multiple failure modes of a bridge including flexural failure in bridge columns and washout of the superstructure. The details about the performance functions of bridge can be found in Firdaus et al. (2023).

The slope fragility curve is calculated using the infinite slope model, considering the uncertainties associated with soil parameters and slope geometry. The fragility curve for any slope at site k given infiltration heights is expressed:

$$P_{vs,k} = P\left(g_{H,k} \leq 0 | H = h_{vs,k}\right) \tag{3}$$

where $P\left(g_{H,k} \leq 0 \mid H = h_{vs,k}\right)$ is the conditional failure probability of slope given infiltration height $H = h_{vs,k}$ resulting from rainfall. The detail of performance function of slope $g_{H,k}$ can be found in Phoon (2014).

2.4 *Probabilistic connectivity assessment of road network*

The probabilistic connectivity of the road network accounting for failure of bridges and slopes caused by rainfall is assessed based on the Monte Carlo simulation (MCS) considering the spatial correlation of hazard intensities. The states of a structure following a heavy rainfall event can be expressed as a binary variable (Bocchini and Frangopol 2011):

$$S_{v,n} = \begin{cases} 1, & \text{if } P_{ve,n}(\mathbf{g}_n \leq 0 | \gamma_n) > r_{v,n} \\ 2, & \text{if } P_{ve,n}(\mathbf{g}_n \leq 0 | \gamma_n) \leq r_{v,n} \end{cases} \tag{4}$$

where $s_{v,n}$ is the service state of bridge or slope at site n given the corresponding hazard intensity γ_n (i.e., $h_{vb,n}$ for bridges and $h_{vs,n}$ for slopes); $P_{ve,n}$ (i.e., $P_{ve,n} = P_{vb,n}$ for bridges and $P_{ve,n} = P_{vs,n}$ for slopes) is the failure probability given γ_n; $\mathbf{g}_n$ is the performance function of a bridge or slope at site n; and $r_{v,n}$ is a uniformly distributed random number between 0 and 1 associated with hazard-induced damage. The states of a structure (i.e., 1 or 0) correspond to the impassable and passable states of road segment, respectively.

Following a heavy rainfall event, the vertices describing bridge and slope sites within the road network fail to maintain the connection between road elements. The new road network after a heavy rainfall event, denoted as G_R, is defined by:

$$G_R(\mathbf{V}_R, \mathbf{E}_R) = \left(\mathbf{V} - \left\{v_{s,n} \in \mathbf{V} | s_{v,n} = 1\right\}, \mathbf{E} - \left\{u v_{s,n} \in \mathbf{E}, u \in \boldsymbol{V}\right\}\right) \tag{5}$$

where $\mathbf{V}_R$ is the set of vertices in the road network excluding sites of bridges and slopes (i.e., $v_{s,n}$); $\mathbf{E}_R$ is the set of edges in the road network excluding road segments that are connected to $v_{s,n}$; $\mathbf{V}$ and $\mathbf{E}$ represent the vertices and edges, respectively, before the occurrence of the rainfall hazard event; and u is a vertex joining bridge $v_{s,n}$.

The probability of road network disconnection between OD pairs is determined by evaluating the presence of disconnected links, which is expressed as:

$$P_{f,OD} = 1 - \frac{1}{M}\sum_{m=1}^{M} L_{OD}(\exists \text{ OD connectivity} \in G_m \text{ is true}) \quad (6)$$

where M is the total number of the MCS. If there is at least one route G_R between OD pair in the road network after the event in the m-th MCS trials (i.e., $\exists$ OD connectivity $\in G_m$ is true), L_{OD} =1; otherwise, L_{OD} =0.

3 ILLUSTRATIVE EXAMPLE

3.1 *Analyzed region and road network*

The connectivity probability of an OD pair within a hypothetical road network, spanning the Mogami and Miomote watersheds in Yamagata Prefectures, Japan, is estimated herein. Figure 2 illustrates the schematic road network with specified OD pair, and the locations of bridges and slopes. Table 1 shows the reach slope, stream network and channel type at bridge sites.

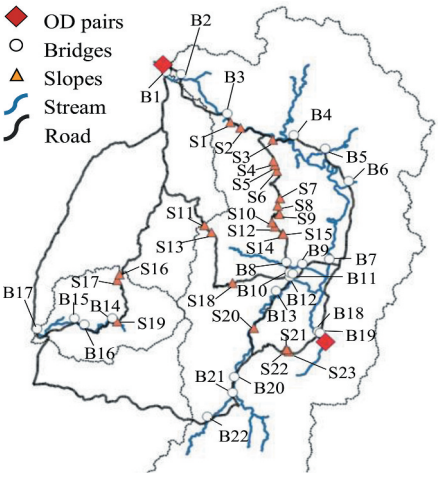

Figure 2. Schematic of analyzed road network.

Table 1. Reach slope and channel type at bridge sites.

Bridge ID	Slope (%)	Stream network	Channel type
B1, B2	1.94×10^{-6}	Mogami	Main
B3	7.82×10^{-1}	Mogami	Tributary
B4	1.39×10^{-1}	Mogami	Main
B5	4.52×10^{-1}	Mogami	Tributary
B6	5.70×10^{-1}	Mogami	Tributary
B7	1.00×10^{-1}	Mogami	Main
B8, B9	9.46×10^{-1}	Mogami	Tributary
B10, B11, B12, B13, B20	2.02×10^{-1}	Mogami	Main
B18, B19	3.06×10^{-1}	Mogami	Tributary
B21, B22	5.06×10^{-1}	Mogami	Tributary
B14, B15, B16	7.22×10^{-1}	Miomote	Main
B17	1.64×10^{-1}	Miomote	Main

3.2 *Spatially correlated hazard assessment*

Figure 3 depicts the flood hazard curves associated with annual peak flow at the bridge sites. Flood hazard intensities at B1, B2, B4, and B7 are significantly higher than those at other bridge sites. Figure 4 illustrates the hazard curves associated with infiltration height at slope sites. The infiltration heights at S1, S2, S3 S18 and S20 are markedly higher than those at other slope sites. It should be noted that the locations with the maximum flood hazard intensity and the maximum infiltration height are not necessarily closer due to difference in soil properties and other factors.

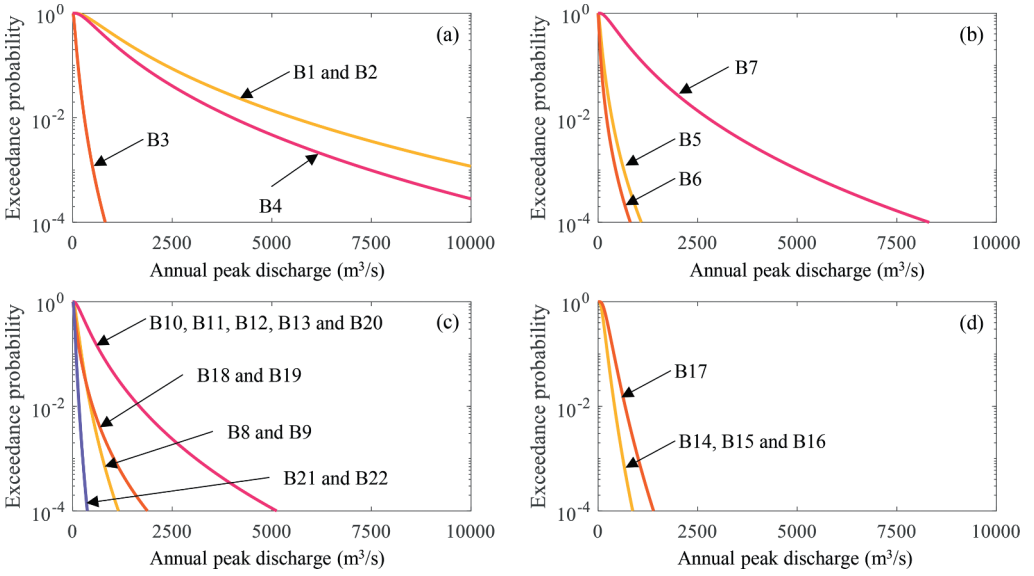

Figure 3. Flood hazard curves at each bridge location.

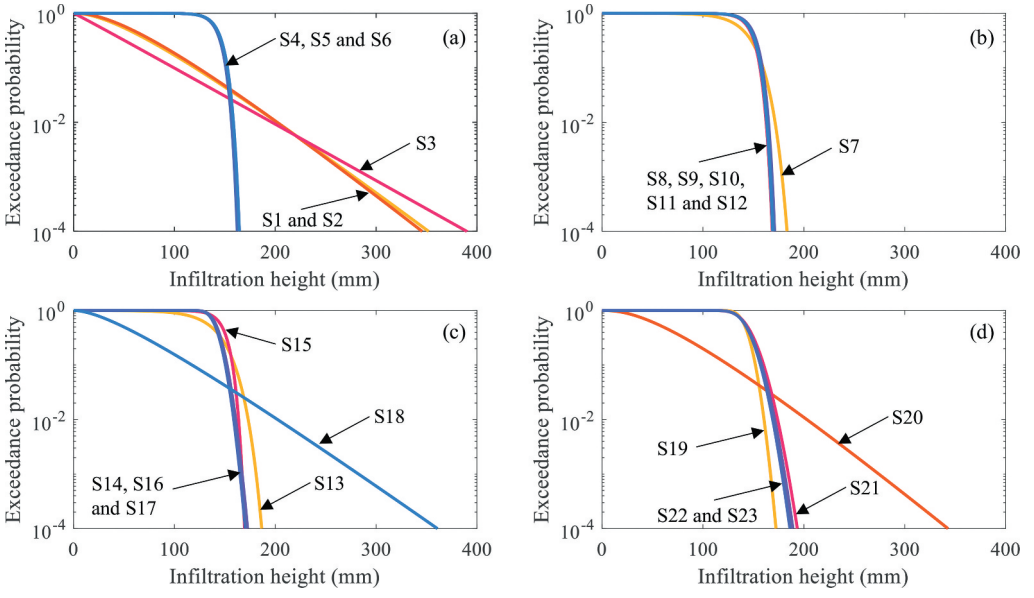

Figure 4. Hazard curves associated with infiltration height at each slope location.

3.3 *Fragility and reliability assessment*

The bridge models presented by Firdaus et al. (2023) and an infinite slope model modified from Phoon (2014) are used in this illustrative example. Figure 5 (a) to (d) and (e) depict the bridge fragility curves given annual peak discharge and slope fragility curve given infiltration height, respectively. The results reveal how vulnerability is affected by reach slope characteristics.

Bridges on steeper slopes and narrow spans are vulnerable to damage in columns, while those on lower slopes and wider spans face susceptibility to superstructure washout due to flooding. Steeper slopes with narrow spans indicate a more larger flow velocity.

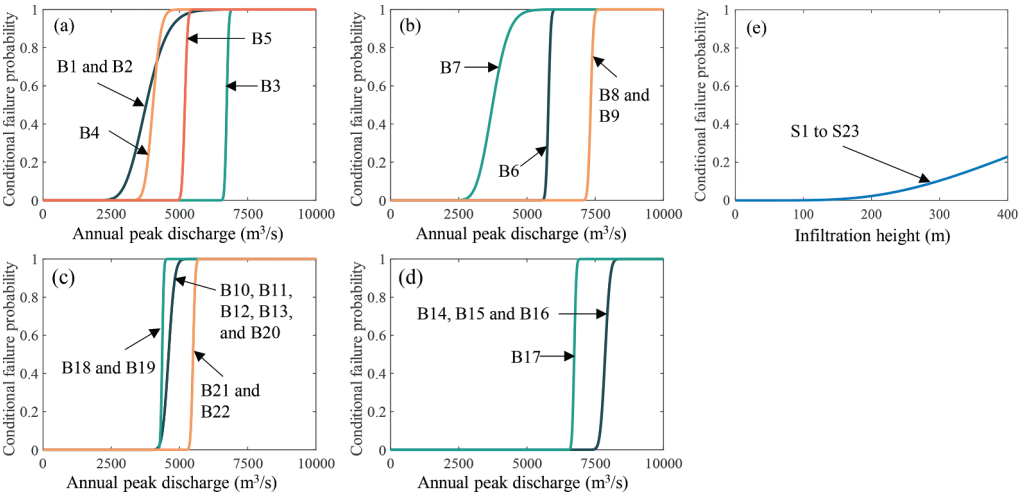

Figure 5. (a) to (d) Flood fragility curves of bridges; and (e) fragility curve of slope given infiltration height.

3.4 *Probabilistic connectivity assessment of road network*

The probabilistic probability of road network, taking into account spatially correlated hazard intensities, is assessed under perfect and independent correlation assumptions for bridge and slope damage states. With 10,000 MCS trials, the connectivity probability of the road network is 0.27 when the damage states of bridges and slopes are perfectly correlated, and 0.23 when they are independent.

4 CONCLUSIONS

Conclusions are as follows:

- A procedure for probabilistic connectivity assessment of road network considering failure of bridges and slopes under rainfall hazard is presented. As an illustrative example, the proposed method is applied to a hypothetical road network in Yamagata Prefecture, Japan.
- Surface runoff is identified as the critical parameter for establishing a spatial correlation model for hazard intensities (i.e., flooding intensity and infiltration height) exerted on bridges and slopes. Spatially correlated flood intensity and infiltration height are evaluated based on water yield and water balance equations, respectively.
- The probabilistic connectivity of road network depends on the spatial relationship of runoff and infiltration, and fragility of bridges against flooding and slopes exposed to infiltration height.

Measuring the extreme risk of coastal bridges under tropical cyclones

Y. Li*
Department of Construction and Quality Management, Hong Kong Metropolitan University, Hong Kong, China

D. Zhu & Y. Dong
Department of Civil and Environmental Engineering, The Hong Kong Polytechnic University, Hong Kong, China

ABSTRACT: Coastal bridges are susceptible to the compounding effects of storm surge and waves in tropical cyclone-prone areas. Over the long term, the vulnerability and risk of bridges may increase due to the uncertain storm conditions under climate change. Thus, evaluating the long-term risk of these bridges can be significant for mitigating financial and societal losses and minimizing interruptions to transportation systems. However, previous studies mainly highlighted bridge reliability, neglecting loss assessment and long-term risk under the uncertain frequency and intensity of cyclones. Particularly, the potential extreme risk has not been investigated. This study aims to develop a framework to assess the extreme risk of coastal bridges subjected to storm waves and surge in a life-cycle context. Within the framework, risks of different failure modes will be investigated and compared. In addition to the conventional deck unseating failure, a failure mode that considers dynamic structural response will be analyzed by incorporating component damage, thereby comprehensively combining the effects of wave load time histories, bearing connections, and overturning moment. Given vulnerabilities to different failure modes, the long-term risk and the associated extreme loss can be calculated based on a stochastic non-homogeneous Poisson process considering the non-stationary frequency and intensity of cyclones. The developed framework will be applied to a coastal highway bridge to identify the extreme risk and long-term performance under cyclone hazards.

1 INTRODUCTION

In cyclone-prone coastal zones, bridge infrastructures are inherently at risk from the synergistic impacts of storm surge and wave forces. The necessity for risk assessment is highlighted by the potential growing vulnerability under the climate-induced alterations in behavior of tropical cyclones. Therefore, assessing the long-term risks posed to bridges is vital for reducing potential financial losses, minimizing harm to communities, and preventing disruptions to transportation networks. Existing literature has mainly concentrated on the structural reliability of bridges and vulnerability modeling. Though few studies looked at the loss assessment of coastal systems (Liu et al. 2022), the long-term risk considering uncertainties associated with stochastic nature of cyclone frequency and intensity is rarely discussed (Alhamid et al. 2022). Especially, the hazard-induced extreme risk of systems in the long time horizon has been ignored.

Thus, this study seeks to formulate a framework to assess the extreme risk of coastal highway bridge structures within their entire operational lifespan, taking into account the confluence of wave and surge forces. Beyond the conventional deck unseating failure mode, this

*Corresponding author: yahli@hkmu.edu.hk

DOI: 10.1201/9781003483755-69

study investigates the overturning failure mode, incorporating a dynamic assessment of structural responses considering the cumulative effects of wave-induced forces, bearing integrity, and the propensity for overturning. The long-term risk and extreme risk measure of these two failure modes are investigated and computed. The introduced risk assessment framework employs a stochastic non-homogeneous Poisson process to capture the non-stationary uncertainties of cyclonic events in both frequency and intensity dimensions, thereby enabling a quantification of long-term assessment. By introducing the time-varying occurrence rate in the non-homogeneous Poisson model, the impact of climate change on frequency and intensity can be easily considered in the stochastic occurrence model. The proposed framework can be introduced to coastal bridge and civil infrastructure systems to manage the structural susceptibility to extreme risk and enhance resilience over the long-term against tropical cyclones.

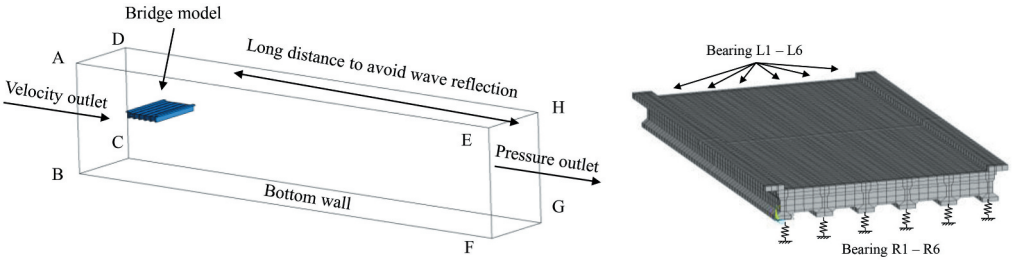
2 VULNERABILITY MODELING UNDER STORM WAVES

For superstructure failure of coastal highway bridges, current methodologies for assessing bridge risk subjected to tropical cyclone waves and surge impact mainly focus on deck unseating and overturning moment failure. For instance, deck unseating is caused by vertical wave load exceeding deck weight (Ataei and Padgett 2013, Mondoro et al. 2017), while the failure can also occur due to wave induced overturning moment and bearing constraints (Zhu et al. 2021). In this study, both the two types of failure models are considered for risk measurement.

For the detailed assessment of vulnerability, uncertainties associated with wave height and surge height should be considered. Due to limited measured data, the surge height used to determine structural demand was assumed to follow a uniform distribution of ±20% (Saeidpour et al., 2019). The wave height distribution was modeled using a Weibull-Generalized Pareto (WGP) model based on observations in shallow water (Wu et al., 2016). The detailed surge height and wave impact modeling directly uses the three-dimensional model established in Zhu et al. (2021).

Vulnerability modeling of highway bridges relies on computation of probability failure. The structural failure probability P_f can be described as the probability of structural capacity C is smaller than the demand D

$$P_f = P[C < D] \tag{1}$$



In terms of deck unseating failure, the bridge's capacity to resist vertical loads is provided by the self-weight Ws of the bridge deck itself (Li et al. 2020).

$$W_s = \left(d_b W_0 + A_g n_g\right)\gamma l \tag{2}$$

where d_b = deck thickness W_0 = deck width, A_g = the total cross-sectional area of bridge girders; n_g = girder numbers; γ = unit weight of the construction material; and l = length of bridge span.

As for the overturning failure mode, the structural damage state is defined that bearing constraints were damaged are damaged due to wave and surge impacts. In this study, the bridge's structural capacity C_M was calculated to be 7696 kNm based on a finite element model of the bridge (Zhu et al. 2021). This capacity value took into account the functional state of the bearings in the model.

The demands associated with the two failure modes should be analyzed by the established three-dimensional computational fluid dynamics (CFD) model and the finite element bridge model to assess the probabilistic demand for wave forces and overturning moments acting upon the bridge deck. The model illustrated in Zhu et al. (2021) is adopted as an illustrative example here. Figure 1 shows the developed CFD model and the finite element model. The bridge model examined is 15.85 m long and 9.6 m wide. The deck has a thickness of 0.18 m and contains 6 evenly spaced I-shaped girders with a height of 1.37 m each. Prior to the arrival of the storm surge and waves, the initial water depth is set at 12.5 m below the bridge, with a 4 m clearance from the water to the bottom of the bridge deck.

(a) (b)

Figure 1. (a) The established CFD model and (b) the finite element bridge model with bearing constraints.

3 LONG-TERM RISK ASSESSMENT AND EXTREME RISK

Following the vulnerability analysis, the cyclone-induced losses can be assessed by multiplying the failure probability and the consequence. Over the service life $(0, t_{\text{int}}]$ of the infrastructure, hazard occurrence can be modeled as a stochastic non-homogeneous process $\{N(t_{\text{int}}), t_{\text{int}} > 0\}$. The arrival times of hazards are defined as random variables $\{T_1, T_2, \ldots, T_k\}$. The time between hazard arrivals, known as inter-arrival times, are $\{W_1, W_2, \ldots, W_k\}$, with T_k equal to the sum of the inter-arrival times $(W_1 + W_2 + \ldots + W_k)$. When a hazard occurs at time T_k, it results in damage loss L_k for the infrastructure system due to necessary repairs. The traditional homogeneous Poisson process with a stationary occurrence rate λ may not be appropriate to represent the time-varying frequency associated with the tropical cyclones under changing climate conditions. Therefore, a non-homogeneous Poisson process with a time-varying occurrence rate $\lambda(t)$ is more suitable when modeling hazard risk considering climate change effects. An illustrative figure of a NHPP is shown in Figure 2.

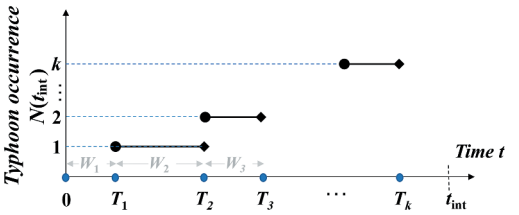


Figure 2. Tropical cyclones occurrence modeled by the stochastic non-homogeneous Poisson process.

The stochastic model describing The NHPP model provides the expected number of hazard events over the lifetime as:

$$E[N(t_{\text{int}})] = \int_0^{t_{\text{int}}} \lambda(t)dt \tag{3}$$

Accordingly, the distribution of the number of hazard events within the lifetime can be

$$\mathrm{P}[N(t_{\text{int}}) = k] = \frac{\left(\int_0^{t_{\text{int}}} \lambda(t)dt\right)^k \exp\left(-\int_0^{t_{\text{int}}} \lambda(t)dt\right)}{k!}, k = 1, 2, \cdots \tag{4}$$

Given these parameters, the long-term loss $DL(t_{\text{int}})$ of the bridge due to damages caused by hazards can be formulated as

$$DL(t_{\text{int}}) = \sum_{k=1}^{N(t_{\text{int}})} L_k e^{-rT_k} \tag{5}$$

where r = discount rate to obtain the present loss value. L_k = damage loss and can be computed from multiplying the repair cost and failure probability.

4 EXTREME RISK

Previous studies focused only on the expected value of total loss. However, since the long term loss $DL(t_{\text{int}})$ is a random variable, then only the expectation does not fully characterize the uncertainty information about the loss assessment. This study examines the probabilistic distribution of $DL(t_{\text{int}})$ along with other statistical indicators - variance, skewness, and kurtosis. These metrics provide additional insights beyond the mean risk. They can be assessed using Monte Carlo simulation or analytically derived from the moment generating function (MGF). This comprehensive analysis of the long-term loss distribution gives a more complete picture of the range of possible losses. The MGF of the long-term loss can be defined as (Li et al., 2020)

$$M_{DL(t_{\text{int}})}(\xi) = \exp\left[\int_0^{t_{\text{int}}} \lambda(s)[M_L(\xi e^{-rs}) - 1]ds\right] \tag{6}$$

By taking derivatives at zero, statistical moments of the long-term loss can be assessed. For instance, the expectation of $DL(t_{\text{int}})$ can be computed as by taking the first derivative at zero. Similarly, the αth order moments of the risk can be calculated by taking derivatives of the MGF

$$E[DL^{\alpha}(t_{\text{int}})] = \frac{dM_{DL(t_{\text{int}})}{}^{\alpha}(\xi = 0)}{d\xi^{\alpha}} \tag{7}$$

This study introduces using quantiles to assess the "worst case" of long-term loss as the extreme risk. The quantile represents tail risk - events with low probability but potentially high losses. While the expected risk is the average case, quantiles characterize extreme cases by focusing on the distribution tail. However, quantile risk measures are most relevant for risk-averse decision makers. Risk-neutral parties may only consider the expected total risk. The quantile of the risk can be defined as:

$$[R_{WC}(t_{\text{int}})] = Quantile_{\sigma}(DL(t_{\text{int}})) \tag{8}$$

where σ indicates the risk level deemed acceptable for the worst-case scenario. It refers to the σth quantile of the random variable $DL(t_{\text{int}})$. As illustrated in Figure 4, the quantile focuses on the tail of the loss distribution. Usually, the worst case of loss is much higher than the mean value.

5 ILLUSTRATIVE EXAMPLE

A highway bridge vulnerable to deck unseating in tropical cyclones is used as an example to demonstrate the extreme risk assessment. The bridge is at risk from storm surges and waves. Several inputs are needed for the NHPP model: the annual occurrence rate for cyclones and the analysis period. Given the NHPP results, the loss distribution and discount rate are used to quantify the long-term loss and the extreme risk. The cost to replace the bridge superstructure is assumed to be 1.283 million US dollars (USD). The bridge service life is taken as 150 years. This cost estimate is derived from previous studies on bridge replacement costs (Mondoro et al. 2017). The first four statistical moments (mean, variance, skewness, kurtosis) of $DL(t_{\text{int}})$ can then be calculated. Ultimately, the full distribution of $DL(t_{\text{int}})$. is obtained, enabling worst case analysis. The initial inputs for this illustration are based on a prior study by Li (2020). For the investigated case, with a maximum hurricane wind speed of 60 m/s subjected to tropical cyclone hazards, the failure probability of deck unseating is 0.53 while that for overturning moment failure mode is 0.72.

Given inputs, the four statistical indicators of $DL(t_{\text{int}})$ for deck unseating failure can be calculated as mean 8.5848×10^6 USD, standard deviation 2.4367×10^6 USD, skewness 0.55, and kurtosis 3.45, respectively. The 5% "worst-case" risk subjected to this mode is 26.1400×10^6 USD. In contrast, the four values for overturning moment failure can be mean 1.1659×10^7 USD, standard deviation 3.3052×10^6 USD, skewness 0.55, and kurtosis 3.46, respectively. The "worst-case" risk for this overturning mode is 35.4713×10^6. The long-term loss distribution and the associated extreme risk of the two investigated failure modes are shown in Figure 3. It shows that the expected long-term losses for the two cases do not vary substantially while the associated extreme risks are significantly different. Analysis of the two cases reveals that although the expected long-term losses are relatively similar, the associated extreme risks diverge considerably. While the mean losses remain similar, examination of the tail risk quantified through the 95% worst case scenario may increase over 30%. This disparity highlights the value of quantile-based risk measures, able to capture risks of catastrophic loss that expectations alone fail to reveal.

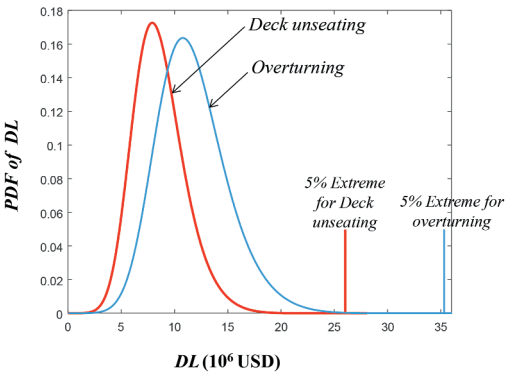

Figure 3. Loss distribution and extreme risk associated with the deck unseating failure and the overturning failure.

6 CONCLUSIONS

In conclusion, this study presents a comprehensive framework to evaluate the extreme risk of coastal highway bridges over their lifetime, considering both wave and surge forces. The analysis goes beyond just deck unseating failures to also investigate overturning modes, incorporating dynamic structural response, cumulative wave loading, bearing integrity, and overturning potential. Both the expected long-term loss and extreme risks are quantified for the failure modes using stochastic modeling. A non-homogeneous Poisson process captures non-stationary cyclone occurrence in frequency and intensity, enabling robust long-term risk assessment. This proposed approach can help manage bridge susceptibility to extreme events and improve resilience against tropical cyclones and can be applied to investigate other hazards. Analysis reveals that while two investigated failure modes may have similar expected losses, their extreme risks can diverge substantially. Although the expected losses stay relatively similar between the two failure modes, analyzing the extreme tail risks using the 95th percentile worst case scenario indicates that catastrophic losses could rise over 30%. This highlights the value of quantile-based measures, able to reveal risks of catastrophic losses that expectations alone miss. The framework provides a powerful quantitative tool for understanding and mitigating coastal infrastructure risk.

Resilience-based countermeasure strategy for bridges under multiple hazards

H. Ishibashi
Nihon University, Koriyama, Japan

M. Akiyama
Waseda University, Tokyo, Japan

S. Koshimura
Tohoku University, Sendai, Japan

ABSTRACT: This paper presents a methodology for identifying optimal pre-disaster strategies for bridges subjected to ground motion and tsunami. The seismic and tsunami hazard curves are estimated based on the Monte Carlo simulation considering the uncertainties associated with fault movement. The seismic and tsunami fragility curves of a bridge pier and bearing are developed by numerical methods. The optimization problem for maximizing the benefit-cost ratio and the resilience is solved to identify the bridges necessary to be retrofitted before the event or replaced immediately after the event and find the optimal countermeasures based on the post-disaster road network functionality depending on the damage state of individual bridges. The application to the road network in Wakayama City expected to be affected by the anticipated Nankai Trough earthquake demonstrates that the proposed method can provide the optimal strategies for bridge management to enhance the road network resilience under budget constraints.

1 INTRODUCTION

Seismic and subsequent tsunami impacts can cause various failure modes to bridges, such as flexural and shear failures of piers and washout of superstructures. The failure mode is determined by the vulnerability of structural components, such as bridge pier and bearing, and the seismic and tsunami intensities. In addition, the effects of damage to bridges on road network functionality after an earthquake depends on the failure mode. For example, in case the bridge superstructure is washed away by tsunami, the reconstruction work would take a very long time, causing significant economic loss and delays in the recovery process. The optimal bridge countermeasure plans should be taken before an earthquake considering the potential failure mode of individual bridges and the negative social impacts caused by damage to bridges.

Optimization techniques on bridge management contribute to improving the cost-effectiveness of countermeasures and enhancing the resilience of communities affected by natural disasters. As examples of studies on the optimization problems for bridge management, Bocchini & Frangopol (2012) proposed a genetic algorithm (GA)-based optimization procedure for the restoration activities for bridges damaged by ground motion considering the transportation network resilience, restoration time and cost. Dong et al. (2015) developed a framework for reducing the extent of earthquake damage to society, economy, and environment (i.e. sustainability) with minimum total retrofit costs of bridge networks. Although the techniques on optimal bridge management have developed, studies considering the effects of multiple hazards on bridges and the associated social impacts are scarce in the literature. In addition, a resilience-based framework for identifying optimal bridge countermeasures before an earthquake is needed to achieve a rapid recovery process.

DOI: 10.1201/9781003483755-70

This paper presents a methodology for developing the optimal pre-disaster countermeasure strategies for bridges under seismic and tsunami hazards. Uncertainties associated with hazard intensity and structural vulnerability are considered based on the Monte Carlo simulation (MCS) to compute the failure probabilities of piers and bearings. The structural vulnerabilities of bridges against tsunamis are estimated considering the effects of seismic damage on the reduction in tsunami capacity. A GA-based optimization approach is adopted to identify which bridges should be retrofitted before the event or replaced immediately after the event to maximize cost-effectiveness and resilience. Resilience is defined in this study as the time-normalized integral of road network functionality (Frangopol & Bocchini 2011), which is quantified based on the damage state of individual bridge piers and bearings. In an illustrative example, the proposed method is applied to the road network with bridges affected by the anticipated Nankai Trough earthquake to investigate optimal pre-disaster countermeasure strategies for bridges under multiple hazards.

2 PROCEDURE FOR DETERMINING OPTIMAL COUNTERMEASURE STRATEGY

2.1 *Hazard assessment*

Probabilistic seismic and tsunami hazard analyses are performed based on the MCS given the occurrence of an earthquake. The average stress drop, which is a key parameter associated with dislocation and moment magnitude of the fault movement, is considered a random variable when estimating hazard curves. In the seismic hazard assessment, the maximum velocity on the engineering bedrock at each bridge location is obtained using the attenuation relationship provided by Si & Midorikawa (1999). Peak ground velocity (PGV) is then estimated by multiplying the maximum velocity on the engineering bedrock with the amplification factor calculated using the empirical formula proposed by Fujimoto & Midorikawa (2006). The model errors associated with these formulas used in the estimation process of PGV are also considered in the MCS.

Inundation depth is used as a tsunami intensity measure in the tsunami hazard assessment. The initial tsunami water level due to fault movement is repeatedly calculated using the formulas developed by Okada (1985) considering the uncertainty associated with average stress drop. Horizontal 2D tsunami propagation simulations based on nonlinear longwave theory (Goto et al. 1997) are then performed using the values of initial water level to estimate tsunami hazard curves at all the locations of individual bridges.

2.2 *Fragility curve*

Sequential nonlinear seismic and tsunami response analyses are performed to develop seismic and tsunami fragility curves of a pier and bearing considering the effects of seismic damage on reducing tsunami capacity. Horizontal force due to ground motion and tsunami and vertical tsunami force are used to assess the horizontal and vertical structural vulnerabilities of the pier and bearing, respectively. The maximum displacement and shear force of the pier are investigated to determine the damage state after an earthquake when estimating the fragility curves of the pier. For the bearing, both horizontal and vertical failure directions due to ground motion and tsunami hydrodynamic and uplift forces are considered in the vulnerability assessment. The damage states of a pier and bearing are defined based on the recovery time required after an earthquake and divided into three levels: none ($=DS_1$), moderate ($=DS_2$) and complete ($=DS_3$).

Seismic waves observed during past earthquakes in Japan are used to perform MCS-based nonlinear seismic response analyses. Horizontal and vertical tsunami forces obtained using the empirical formulas from the Subcommittee on Analysis of Damaged Bridges due to the Great East Japan Earthquake (2015) are used in the tsunami response analyses considering seismic damage to the pier and bearing. The uncertainties associated with material properties and model errors of empirical formulas used in the fragility assessment are considered random variables in the MCS.

Seismic and tsunami fragility curves are developed by a log-normal cumulative distribution function below:

$$P_{fi}(DS_i|\Gamma = \gamma) = \int_0^{\gamma} \frac{1}{\sqrt{2\pi}\sigma_i(x - l_i)} \exp\left[-\frac{\{\ln(x - l_i) - \mu_i\}^2}{2{\sigma_i}^2}\right] dx \quad (1)$$

where DS_i is the damage state, $P_{fi}(DS_i|\gamma)$ is the conditional failure probability that the damage state becomes greater than or equal to DS_i given the hazard intensity $\Gamma=\gamma$, and μ_i, σ_i and l_i are parameters. The natural logarithm of X-l_i is normally distributed with mean μ_i and variance σ_i^2. Although l_i is commonly set to zero when developing fragility curves, it is considered to improve the fitting of the estimated fragility curves to the discrete results of MCS-based response analyses.

2.3 *Optimization problem for pre-disaster bridge countermeasure strategy*

Horizontal and vertical failure probabilities of individual bridge piers and bearings are estimated using the seismic and tsunami hazard, and fragility curves for horizontal and vertical directions, respectively. The road network is assumed to be impassable at the location of bridges that have a pier or bearing with moderate or complete damage states. The MCS-based road network analysis is performed considering recovery time and cost of damaged bridge piers and bearings, and traffic speed of the road network after an earthquake.

NSGA-II (Deb et al. 2002) is adopted to determine the optimal pre-disaster countermeasure strategies for bridges under multiple hazards. Two objectives, benefit-cost ratio (*BCR*) and resilience, are considered in the optimization problem. *BCR* is defined as follows:

$$BCR = \frac{L_{none} - L_{mea}}{C_{mea}} \quad (2)$$

where C_{mea} is the total countermeasure cost, L_{none} is the mean of total economic loss of recovery cost of damaged bridges and indirect loss due to deterioration of road network functionality when no countermeasures are taken for all bridges, and L_{mea} is the mean of total economic loss when countermeasures are taken for some or all bridges.

The resilience R is defined as follows (Frangopol & Bocchini 2011; Ishibashi et al. 2021):

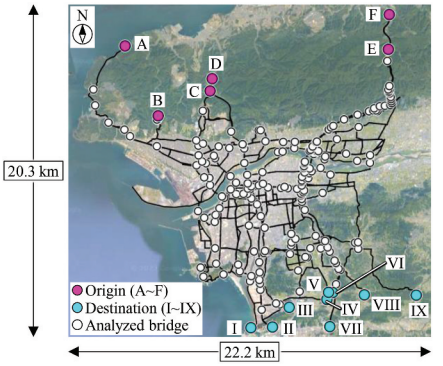
$$R = \frac{1}{t_h} \int_{t_0}^{t_0+t_h} Q(t)dt \quad (3)$$

where t_0 is the time at which the earthquake occurs, t_h is the investigated time horizon, and $Q(t)$ is the road network functionality at time t. $Q(t)$ is calculated based on the indirect loss due to the earthquake. The increase in resilience by countermeasures compared to no countermeasures is considered the objective of the optimization problem.

3 ILLUSTRATIVE EXAMPLE

3.1 *Analyzed road network*

A megathrust earthquake along the Nankai Trough (i.e. the Nankai Trough earthquake) would cause strong ground motion and tsunami in the Pacific coastal region of Japan in the near future (HERP 2013). The proposed method is applied to the road network in Wakayama City, which is expected to be affected by the Nankai Trough earthquake. Figure 1 shows the analyzed road network. In this illustrative example, the road network functionality is assessed based con the transportation between six origins and nine destinations. The data on the location and construction year of bridges are provided by the Ministry of Land, Infrastructure, Transport and Tourism (MLIT) (2022). The analytical conditions on traffic information, such as traffic volume, speed and truck ratio, are determined based on the national road traffic census (MLIT 2015).



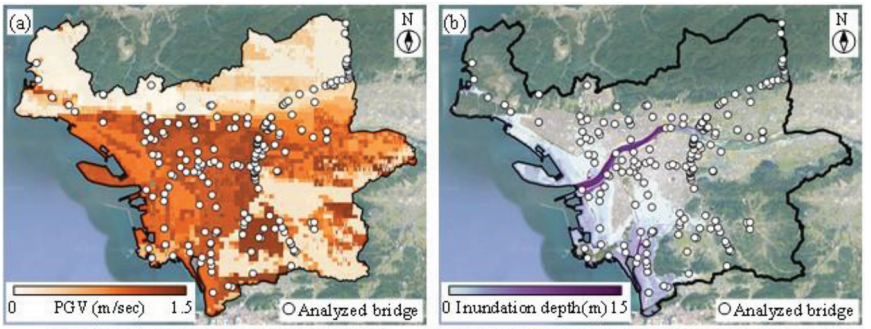


Figure 1. Analyzed road network in Wakayama City.

3.2 *Hazard assessment*

Figure 2 shows the contours associated with mean PGV and inundation depth in Wakayama City. Two seismic and eleven tsunami fault models provided by the Cabinet Office, Government of Japan (2012) are used to estimate seismic and tsunami hazard intensities, respectively, considering the uncertainty associated with large-slip areas. The average stress drop is modeled as a truncated lognormal distribution with a mean of 2.1 MPa and a standard deviation of 1.1 MPa based on the past earthquake data provided by the Cabinet Office, Government of Japan (2012) when estimating seismic hazard curves. In the tsunami hazard assessment, a truncated lognormal distribution with a mean of 1.9 MPa and a standard deviation of 1.9 MPa is assumed (Murotani 2013).

3.3 *Fragility curves*

Four types of bridges are designed according to the Japanese seismic specifications published in 1964, 1971, 1990 and 1996 and applied to investigate the effects of the upgrade of seismic specifications on their performance. Herein, these bridges are referred to as the 1964, 1980, 1990 and 1996 bridges, respectively. The seismic and tsunami fragility curves of the 1996 bridges are shown in Figure 3. The 1996 bridge has seismic performance equivalent to the current Japanese seismic design code. The pier height is assumed to be 6 m regardless of bridge locations. Hence, tsunami forces act on the bearings when the inundation depth exceeds 6 m.

(a) Contours associated with the mean PGV (b) Contours associated with the mean inundation depth

Figure 2. Contours associated with (a) mean PGV and (b) inundation depth in Wakayama City.

3.4 *Optimal countermeasure strategy*

Figure 4 shows the horizontal failure probability of non-retrofitted piers and the vertical failure probability of non-retrofitted bearings. The optimal countermeasure for each bridge depends on

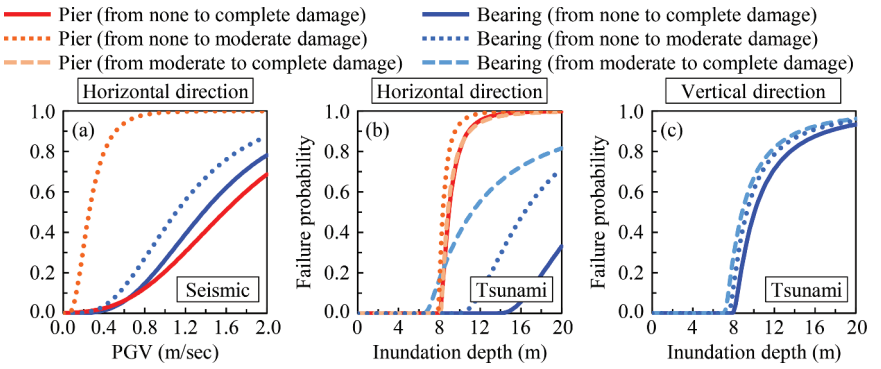

Figure 3. Fragility curves of 1996 bridge: (a) seismic fragility curves, (b) tsunami fragility curves (hori-zontal direction) and (c) tsunami fragility curves (vertical direction).

the potential failure mode, and post-disaster recovery cost and time. In the optimization problem, seismic retrofitting and pre-disaster preparation of temporary bridge girders for vertical damage to bearings are considered countermeasures. The fragility curves of the 1996 bridge are applied to retrofitted bridges. The seismic retrofitting can reduce the failure probability of the pier and bearing, while the preparation of temporary bridge girders decreases the recovery time required for reconstruction of the superstructure washed away by the tsunami.

Figure 5 shows the solutions associated with countermeasures obtained using NSGA-II. The estimation results of optimal countermeasure strategies (i.e., five Pareto solutions in Figure 4)

Table 1. Estimation results of optimal countermeasure strategies.

No	BCR	Increased resilience (%)	Countermeasure cost (billion JPY)	Number of bridges with countermeasures*		
				Type 1	Type 2	Types1 and 2
1	3.410	9.339	2429.560	48	0	2
2	4.560	8.821	1860.220	29	0	1
3	6.088	7.982	1222.565	27	0	1
4	8.078	7.623	972.405	26	0	0
5	9.870	3.585	185.465	9	0	0

* Type 1: Seismic retrofitting.
Type 2: Pre-disaster preparation of temporary bridge girders.
Types 1 and 2: Both seismic retrofitting and pre-disaster preparation of temporary bridge girders.

are listed in Table 1. In this study, t_h in Equation (3) is set to 60 days. Seismic retrofitting is an effective countermeasure for analyzed bridges. However, the preparation of temporary girders for some bridges assuming washout of superstructures can significantly increase resilience. The proposed method provides optimal strategies to maximize *BCR* and resilience.

4 CONCLUSIONS

A framework for determining the optimal pre-disaster countermeasure strategies for bridges subjected to ground motion and tsunami is proposed. The failure probabilities of bridge piers and bearings in horizontal and vertical directions are estimated based on hazard and fragility curves obtained considering various uncertainties in the MCS. NSGA-II is adopted to solve the optimization problem for maximizing the *BCR* of bridge countermeasures and road network resilience. Seismic retrofitting and preparation of temporary bridge girders are considered pre-disaster countermeasures for bridges against an earthquake. The illustrative example of the road network with bridges in Wakayama City affected by the anticipated Nankai Trough earthquake demonstrates that the proposed method can facilitate decision-making for cost-effective pre-disaster bridge management strategies to enhance road network resilience.

In this paper, the recovery time of damaged bridges is assumed to depend only on the damage state. Constraints on the recovery process should be included in the optimal problems when assessing the economic loss and resilience considering the post-disaster severe situation.

Enhancing seismic resilience of aging highway bridges using FRP retrofit

V. Singh

N. Kotoky
Assistant Professor, National Institute of Technology Meghalaya, India

ABSTRACT: Environmental degradation mechanisms such as corrosion can have a significant impact on the resilience of the reinforced concrete (RC) highway bridges present near the harsh marine environment within high seismic zones. This study aims to evaluate the effectiveness of fiber-reinforced polymer (FRP) jackets in enhancing the seismic resilience of deteriorated highway bridges. A representative case-study non-seismically designed highway bridge located close to marine sources within the seismic active region of Gujarat, India is selected. Time-dependent chloride-induced corrosion deterioration of bridge pier is evaluated considering non-uniform pitting corrosion. FRP jacket is used to retrofit the deteriorated bridge pier, and pushover analysis results reveal a significant increase in the damage state thresholds of the FRP retrofitted deteriorated bridge pier. Seismic fragility curves of as-built, 75-year aging and FRP retrofitted bridges are developed and combined with suitable loss and recovery models to calculate the seismic resilience of bridges for varying earthquake intensity. From the result, it is observed that the resilience of the bridge decreases with an increase in earthquake intensity and FRP retrofit significantly enhances the seismic resilience of deteriorated bridge.

1 INTRODUCTION

Highway bridges are the key component of transportation systems and play a significant role in the sustainable economic growth of the nation. Most of the highway bridges are built using antiquated design standards and experience degradation from age-related corrosion. According to the report card for American Infrastructure (2021), there are about 617,000 bridges in the United States, and 42% of them are over 50 years old, and currently, 7.5% of the nation's bridges are classified as structurally deficient, whereas in India, out of 14,500 bridges on the national highway, 1700 bridges are reportedly in need of repair and restoration (Wakchaure and Jha 2011). Corrosion degradation results in an increase in the failure probability of these bridges when located in regions of moderate to high seismicity as observed during the Bhuj earthquake 2001 (Madabhusi and Haigh 2001). In the context of India, inadequate highway bridge performance has been observed in the past earthquake events (Cachar earthquake 1984, Jabalpur earthquake 1997, Chamoli earthquake 1999, and Bhuj earthquake 2001). Past studies highlighted the high vulnerability of existing older bridges in India due to the absence of ductile detailing principles in the seismic standards (Shekhar et al. 2020). Bridge damage caused by such disasters greatly affects transportation networks, reducing their functionality, and as a result, affecting emergency response and socioeconomic recovery activities across the region after the hazard occurrence.

DOI: 10.1201/9781003483755-71

Seismic resilience has been recognized as an important metric to evaluate the performance of infrastructure systems such as bridges considering vulnerability, losses, and post-event recovery. Previous studies on the seismic resilience assessment of aging bridges have observed a reduction in resilience due to corrosion degradation (Vishwanath and Banerjee 2019, Huang and Huang 2021). Seismic retrofitting is a preferred methodology used by several transportation departments to enhance bridge performance during earthquake occurrences. Application of retrofit interventions can significantly reduce post-earthquake losses, improve overall disaster preparation, and lessen the negative effects of seismic occurrences on transportation infrastructure. Several research studies have been conducted in the past on assessing the seismic resilience enhancement of the as-built structures using retrofit methodologies (Venkittaraman and Banerjee 2014; Chandrasekaran and Banerjee 2016; Anwar and Dong 2020), however, there is limited understanding of the seismic resilience enhancement of deteriorating highway bridges using retrofit measures. Qiu et al. (2023) have estimated the effect of FRP wraps on the seismic resilience of aging highway bridges including repair cost and repair time, however, this study does not consider the non-uniform chloride-induced deterioration process.

This study evaluates the effectiveness of using carbon fiber reinforced polymer (FRP) jackets in enhancing the seismic resilience of aging highway bridges. The next section of the paper describes the framework for the estimation of seismic resilience with the help of fragility, losses, and recovery models. Next, the selection of a case-study bridge designed as per outdated seismic design guidelines and located in the Gujarat region is presented followed by a discussion on the time-dependent corrosion model. This section also discusses the bridge pier's FRP retrofit design and a detailed finite element model for the aging and FRP retrofitted bridges. The subsequent section of the study presents the seismic capacity evaluation of the aging and FRP retrofitted bridge pier using nonlinear static pushover analysis. In the final section of the paper, seismic resilience is evaluated for the aging and FRP retrofitted bridge pier using developed fragility curves, losses, and recovery models. The paper finishes with the conclusion and suggestions for future work.

2 SEISMIC RESILIENCE ASSESSMENT FRAMEWORK FOR BRIDGES

Previous research has developed and computed the resilience of several lifeline systems, such as transportation networks (Amdal and Swigart 2010; Cimellaro et al. 2010). In general, resilience is described as a dimensionless measure showing the rapidity with which a system may recover from a damaged state and resume its pre-damaged functionality level. Losses that occurred due to the extreme event and post-event recovery path are the two main factors used to measure the resilience of civil infrastructure systems. Seismic resilience for a single earthquake event can be expressed as (Cimmeralo et al. 2010):

$$R = \int_{(t_{0E})}^{(t_{0E}+T_{LC})} \frac{Q(t)}{T_{LC}}\,dt \tag{1}$$

where t_{0E} is the time when an event E occurs, T_{LC} is the control time and $Q(t)$ denotes the time-dependent functionality of the system and can be represented as:

$$Q(t) = 1 - [L(I, T_{RE}) \times \{H(t - t_{0E}) - H(t - (t_{0E} + T_{RE}))\} \times f_{RE}(t, t_{0E}, T_{RE})] \tag{2}$$

where $L(I,T_{RE})$ represents the loss function, $H(.)$ is the Heaviside step function, f_{RE} is the recovery function, T_{RE} is the time required for recovering the functionality of the damaged bridge. Figure 1 (a) represents the seismic resilience diagram of degrading bridges, which can be calculated from the normalized area under the functionality curve from the time of the seismic event (t_{0E}) to a subsequent time instant ($t_{0E} + T_{LC}$).

Figure 1 (b) shows the framework for the evaluation of enhancement in seismic resilience of the aging bridges using FRP retrofitting. The overall framework is divided into six steps. Step

(A) of the framework involves the assessment of chloride-induced corrosion deterioration of the bridge, with detailed discussion provided in Section 3. Step (B) involves the development of the finite element (FE) model of the bridge incorporating deterioration effects. Next, in Step (C) time-dependent seismic fragility curves are developed using a suite of site-specific ground motions. The seismic fragility curves can be expressed for the damage state *DS* as:

$$Pf_{DS|IM} = \Phi\left[\frac{\ln(IM/med_{DS})}{\zeta_{DS}}\right] \tag{3}$$

where $Pf_{DS|IM}$ denotes the probability of failure associated with the damage state *DS* conditioned on intensity measure *IM*. Φ represents the standard normal distribution function, med_{DS}, and ζ_{DS} represents the median and dispersion of the fragility curves, respectively. Step (D) of the framework involves the calculation of seismic resilience for aging bridge utilizing seismic losses and recovery function. The loss function comprises direct and indirect loss resulting from seismic event. Direct losses arise from the cost associated with the post-event repair and restoration and are computed by multiplying the failure probability determined by fragility curves (Equation 3) by the damage ratios (HAZUS-MH MR4 2003). The indirect losses occur due to various factors such as traffic delays, network outages, and casualties during the system's recovery. The ratio between indirect loss and direct loss ranges from 5-20 (Denneman 2009). For this study, the indirect losses are considered to be 13 times that of direct losses (Venkitraman and Banerjee 2014). The recovery function (f_{RE}) represents the path that should be followed after an event to restore bridges. However, the lack of precise data makes it challenging to trace the accurate recovery path. Cimmeralo et al. (2010) introduced simple mathematical models such as linear and exponential functions as the recovery path of the system. According to Jonas (2007), sigmoidal curves can also be used to represent recovery path and are adopted in this study. The time required for post-event recovery (T_{RE}) for different damage states is adopted from HAZUS (HAZUS-MH MR4 2003).

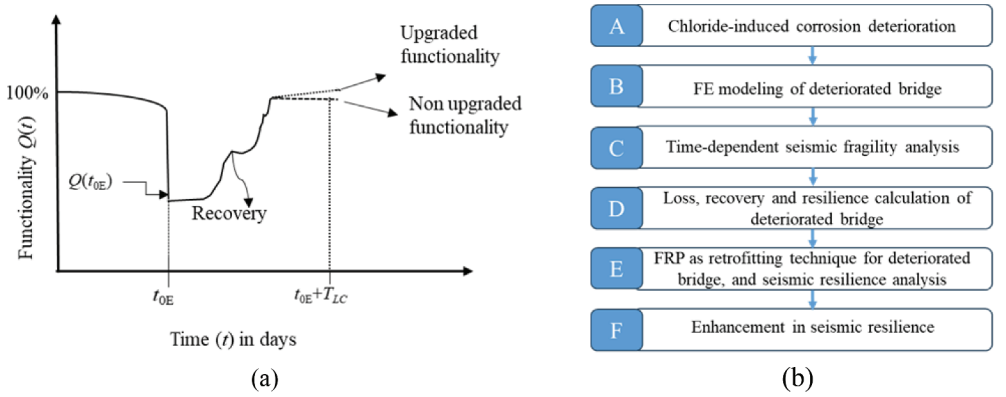

Figure 1. (a) Schematic illustration of seismic resilience of the aging bridge (b) framework for the evaluation of enhancement in seismic resilience of aging bridge after retrofitting.

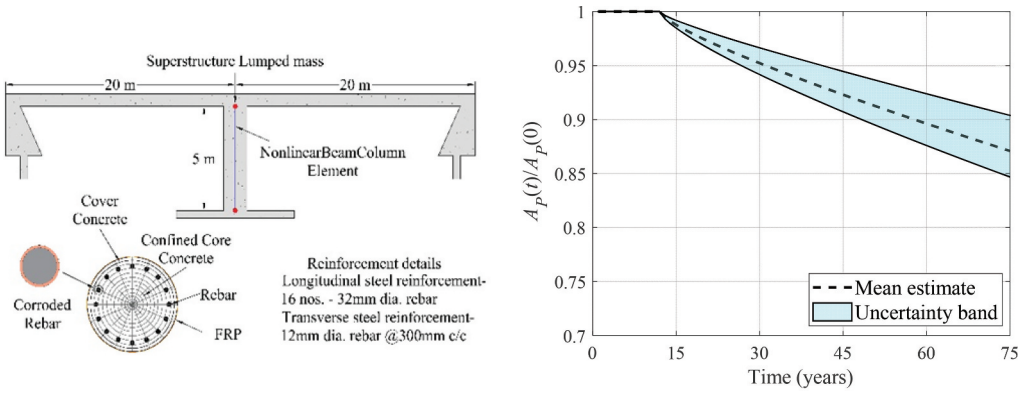
3 REPRESENTATIVE CASE-STUDY BRIDGE

To investigate the effect of FRP jacket on the seismic resilience of the aging highway bridge, a semi-integral bridge is assumed to be situated in Gujarat, India region which is near the coastline and comes under seismic zone V (IS 1893: 2016). The deck of the bridge is 20 m long and 7.5 m wide resulting in a gravity load of 4000 kN on the reinforced concrete (RC) bridge pier. The height (*H*) and diameter (*D*) of the bridge pier are adopted as 5.0 m and 1.4 m,



respectively. The bridge is designed according to outdated seismic design standards; therefore, the pier is primarily designed for gravity loads and negligible lateral forces. The reinforcement detailing of the bridge pier depends on the minimum reinforcement criteria because of the absence of ductile detailing provisions in the seismic standards (Shekhar et al. 2020). Figure 2 (a) shows the general layout of the bridge along with the reinforcement details of the pier.

3.1 *Time dependent corrosion modeling of the bridge pier*

For RC bridges, chloride-induced corrosion deterioration has become a major concern for bridge owners (Choe et al. 2008). During their design life, several bridge components continuously deteriorate due to corrosion. The deterioration of bridge piers due to corrosion significantly affects the seismic response of the bridge (Andisheh et al. 2016). The corrosion deterioration in the RC structures commences after a time gap which is denoted as corrosion initiation time (T_i). Throughout this period, chloride ions progressively penetrate the concrete cover, depassivating the reinforcement and starting the corrosion process. The corrosion initiation time depends on parameters such as chloride diffusion coefficient, surface chloride concentration, critical chloride concentration, and concrete cover depth, among others, and can be evaluated using Fick's second law of diffusion. The statistical distribution of the above-mentioned parameters considering marine splash zone is adopted from Duracrete (2000). The mean corrosion initiation time for the case-study bridge structure has been calculated as 12 years. After initiation, the corrosion propagation phase begins with the depassivation of steel. Steel area loss during this phase is greatly influenced by the rate of corrosion and is calculated based on the model proposed by Vu and Stewart (2000). The time-dependent non-uniform pitting corrosion can be calculated as (Dizaj et al. 2023):

$$A_P(t) = \beta A_{ave}(t) \tag{4}$$

where, $A_P(t)$ represents the time-dependent cross-sectional area of reinforcement, including pitting corrosion effects, $A_{ave}(t)$ is the average time-dependent cross-sectional area of steel reinforcement, and β is the pitting coefficient. The statistical distribution of the pitting coefficient is adopted from Dizaj et al. (2023). After considering the uncertainties in the corrosion degradation process, Figure 2 (b) illustrates the decrease of mean reinforcing steel area with time, as well as the lower and upper bounds, corresponding to the 5th and 95th percentile. Apart from the reduction of reinforcing steel area, corrosion deterioration can also cause several secondary effects such as a reduction in cover and core concrete strength, and steel rebar strength and ductility. These secondary effects are calculated based on past literature (Du et al. 2005; Biondini and Vergani 2015).

(a) (b)

Figure 2. (a) General layout of case study bridge and details of FE modeling, and (b) variation of mean reinforcement steel area over time, and the uncertainty bands.

3.2 *FRP retrofit design and details of the bridge pier*

To enhance the seismic resilience of the deteriorated non-seismically designed bridge pier, this study uses carbon fiber reinforced polymer (FRP) as retrofit jacket material for the bridge pier which is widely used for retrofitting structures. Carbon FRP is chosen for its high strength to weight ratio, ease of implementation, and resistance towards corrosion. It consists of unidirectional or bidirectional high-strength fibers. The carbon FRP used in this study has tensile strength and elastic modulus of 3000 MPa and 230 GPa, respectively (He et al. 2019). The thickness of one ply FRP is 0.167mm and for this study, two ply of FRP is applied over the full length of the bridge pier. An adequate amount of jacket thickness plays a significant role in retrofitting, as it prevents the lateral expansion of the concrete which increases load bearing capacity and ductility of the structure.

3.3 *FE modeling of aging and retrofitted bridge piers*

The seismic performance of semi-integral bridges is mainly governed by the response of bridge piers, wherein the RC piers are connected monolithically with the deck (Kolias et al. 2012). The analytical model of the bridge in this study considers the 2D beam-column element representing the bridge pier with the mass of the superstructure lumped at the top of the bridge pier. The bridge pier's boundary condition is modeled to be fixed, assuming that the pier is located on firm soil. The finite element (FE) model of the bridge pier is developed in OpenSees (Mckenna et al. 2000) by utilizing a nonlinear beam column element using a fiber section approach with distributed plasticity which consists of circular concrete patches along with circular layers of reinforcement. The unconfined and confined concrete is modeled using *Concrete01*, where the confined concrete properties are derived using the model obtained from Mander et al. (1988). A *uniaxialmaterial Hysteretic* material is used to model the longitudinal steel reinforcement. The loss in steel area due to corrosion is modeled as the reduction in diameter of rebar which includes the time-dependent uncertainty caused by corrosion rate. The pier elements are divided into five integration points, and separate fiber sections are assigned at each integration point considering the spatial and temporal variability of the pitting corrosion. Based on the lognormal distribution as suggested by Kashani et al. (2013), samples of pitting coefficients are generated and assigned randomly to rebars at fiber sections. The secondary effects due to corrosion deterioration are also included in the FE modeling of the deteriorated bridge pier. The FRP confined concrete is modeled using *ConfinedConcrete01* material to precisely represent the concrete confinement caused by the use of FRP.

4 SEISMIC CAPACITY OF THE AGING AND RETROFITTED BRIDGE PIER

The seismic fragility of the structure requires information on demand and capacity which involves the assessment of demand through non-linear time history analyses (NLTHAs) and comparing it to particular capacity estimates or thresholds of various *DS*s (Slight, Moderate, Extensive, and Complete). Due to the corrosion, lateral load capacity may be reduced with respect to time. The present study evaluates the time-dependent capacity of *DS*s for the aging and FRP retrofitted bridge pier using pushover analyses. The *DS* thresholds in terms of drift ratio (*DR*) for various *DS*s are derived using concrete and steel material strain criteria.

Figure 3 depicts the threshold value for different *DS*s shown on the pushover curve of as-built (0-year), 75-year corroded, and 75-year corroded bridge pier retrofitted with FRP. For the bridge pier, Slight *DS* threshold is considered as *DR* corresponding to the idealized yield point determined analytically through elastoplastic idealization of the pushover curve (Ni Choine 2014). For the as-built and aging bridge pier, the Moderate *DS* threshold occurs either at the concrete spalling or when the residual crack width reaches 1mm. Concrete spalling is considered to occur when the strain value of extreme compressive fiber in cover concrete attains a value of 0.003 (Bae and Bayrak 2003), while initiation of residual crack width occurs at a strain value of 0.015 in reinforcement (Kowalsky 2000). In the case of retrofitted bridge

pier, Moderate *DS* threshold is achieved either at the loss of aggregate interlocking or FRP delamination. The aggregate interlocking loss and FRP delamination are considered to occur at strain values of 0.004 and 0.008 of cover concrete, respectively (Bakis et al. 2002). Complete *DS* threshold for both cases is attained when any of the following conditions are met - crushing of core concrete, buckling of the rebar, or fracture of rebar. For retrofitted bridge pier, the assumed strain value for core concrete crushing is 0.035 (Parghi and Alam 2017). The strain value for fracture and buckling of the longitudinal bar is obtained from the expression given by Berry and Eberhard (2008). The Extensive *DS* threshold is considered at the geometric mean of the Moderate and Complete *DS*s. From Figure 3, it is observed that corrosion caused a reduction of 32.8% in load-carrying capacity of the 75-year deteriorated pier as compared to the as-built state. After retrofitting it has been seen that there is slight increase in load carrying capacity, but the drift capacity of the deteriorated bridge pier has increased considerably. At Complete *DS*, the drift capacity of the 75-year deteriorated bridge pier retrofitted with FRP is 118% higher than the 75-year deteriorated bridge pier.

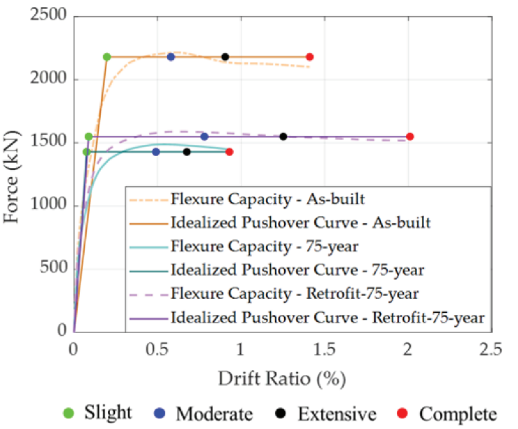


Figure 3. Pushover curve showing damage state thresholds for the as-built, 75-year corroded, and 75-year FRP retrofitted bridge piers.

5 SEISMIC RESILIENCE OF THE AGING AND RETROFITTED BRIDGE

Seismic fragility curves indicate the probability of exceedance of damage state for the specific ground motion intensity measure. Peak ground acceleration (*PGA*) is used as an intensity measure (*IM*) to develop the seismic fragility curves. Seismic fragility curves for as-built, corroded, and FRP retrofitted bridges are derived using Step (C) of the previously defined framework.

Figure 4 (a) demonstrates the seismic fragility curves of as-built (0-year), 75-year corroded, and 75-year FRP retrofitted bridge piers for Complete *DS*. It is observed that there is an increase in the vulnerability of the 75-year bridge pier when subjected to chloride exposure compared to the as-built state. The median *PGA* (corresponding to 50% failure probability) for 75-year deteriorated bridge is 37.8% lower compared to the as-built bridge. The FRP retrofitting of the 75-year deteriorated bridge results in a significant decrease in the vulnerability, with a 47.42% increase in the median *PGA* compared to the corroded state. Similarly, trends in fragility curves are observed for other *DS*s, which are further used in seismic resilience assessment.

Following the development of fragility curves, seismic losses are computed. Damage specific recovery functions (f_{RE}) and control time are utilized to compute the functionality, and seismic resilience of the bridge is calculated using Step (D) of the framework (Equations (1) and (2)). Using Step (E) and Step (F) of the framework, enhancement in seismic resilience is evaluated using carbon FRP retrofit. Figure 4 (b) represents the seismic resilience for a range of *PGA* for as-built, 75-year corroded, and FRP retrofitted 75-year corroded bridge. It is found that with the increase in *PGA*, seismic resilience is reduced, and this reduction is higher for the

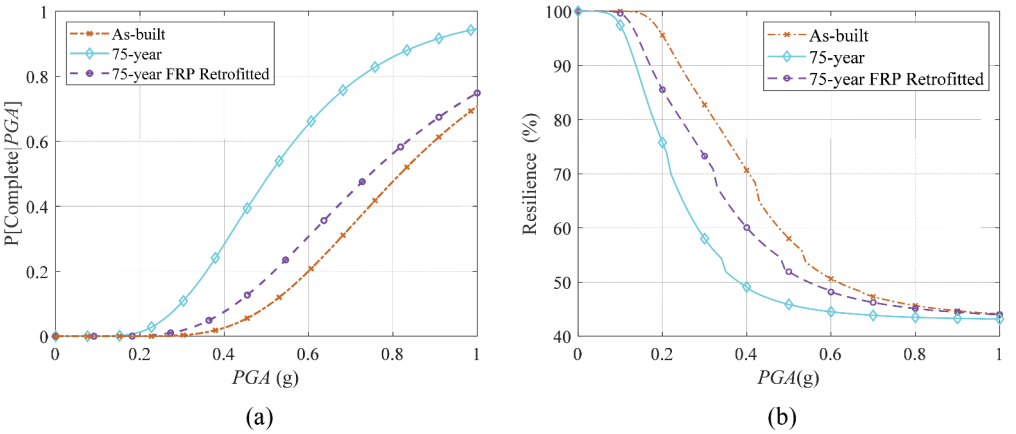

Figure 4. (a) Comparison of seismic fragility curves for Complete *DS* for as-built, 75-year corroded, and 75-year FRP retrofitted bridge piers, and (b) Comparison of seismic resilience curves for as-built, 75-year corroded, and 75-year FRP retrofitted bridge piers.

75-year deteriorated bridge. At 0.4g *PGA,* the loss in seismic resilience of the as-built and 75-year corroded bridges are 29.4% and 50.9%, respectively. The FRP retrofitting of the 75-year deteriorated bridge increases the seismic resilience, and for 0.4g *PGA*, the resilience loss is 40%, which is less than the corroded bridge highlighting the effectiveness of FRP in improving the resilience of corroded bridges.

6 CONCLUSION

The current study investigates the effectiveness of FRP retrofitting in improving the seismic resilience of deteriorating highway bridges. A semi-integral bridge located near the coastline of high seismicity Gujarat region is selected as the case-study bridge, and the corrosion deterioration path incorporating non-uniform pitting corrosion under marine splash chloride exposure condition is estimated for the bridge pier. Carbon FRP is selected for retrofitting the corrosion-deteriorated bridge pier. FRP retrofitting of the deteriorated bridge pier (t=75 years), results in an increase in the Complete damage state drift capacity. To develop the seismic fragility curves, a full probabilistic approach is conducted considering the different sources of uncertainty. Results obtained from the seismic fragility analysis indicate that the seismic vulnerability increases significantly for the deteriorated bridge pier and vulnerability is reduced after retrofitting the bridge pier. For the Complete *DS*, the median *PGA* for a 75-year deteriorated bridge is 37.8% lower as compared to the as-built bridge and for FRP retrofitted 75-year deteriorated bridge, the median *PGA* is increased by 47.42% as compared to the 75-year deteriorated bridge. Next, seismic resilience is evaluated with the help of the information obtained from the seismic fragility, direct and indirect losses, and the recovery model. Results reveal that seismic resilience decreases with the increase in *PGA.* For 0.4g *PGA*, the loss in seismic resilience for the as-built bridge is 29.4% which is increased to 50.9% because of the corrosion-induced deterioration at 75-year, and after retrofitting the bridge the reduction in seismic resilience reduced to 40%, which highlights the effectiveness of applying FRP retrofit to enhance the seismic resilience of aging bridge. Future work will consider the influence of different retrofitting techniques in enhancing the seismic resilience of multi-span simply supported aging highway bridges.

Y. Tsompanakis
Technical University of Crete, Chania, Greece

ABSTRACT: The main objective of this study is to present an efficient method for developing seismic fragility curves for regular and irregular reinforced concrete (RC) bridges based on the capacity spectrum assessment, i.e., FRACAS method. Accordingly, 3D models of unbalanced, skewed, and curved irregular bridges were considered, taking into account uncertainties related to geometry, material as well as seismic excitation characteristics. In the presented methodology, the FRACAS method, which was initially developed for buildings, was appropriately modified to become suitable for the 3D analysis of the examined bridges, reducing also the demand error compared to -computationally demanding- non-linear time-history analysis (NTHA) approach. For this purpose, the fragility curves obtained from the proposed 3D FRACAS were compared with those obtained via NTHA. Results illustrate that the 3D FRACAS approach can be efficiently used for developing the fragility curves for regular and irregular bridges in a computationally efficient and accurate manner.

1 INTRODUCTION

Undoubtedly, the seismic behavior of bridges is strongly influenced by various types of irregularities in their geometry. The main types of irregularities are related to curved, skewed, and unbalanced bridges (e.g., Rezaei et al. (2022a); Rezaei et al. (2023)). In recent years, bridge irregularities have been thoroughly studied (e.g., Mangalathu et al. (2019); Rezaei et al. (2022b); Rezaei et al. (2023)). As it is commonly reported in relevant studies, the increased complexity of the seismic behavior of irregular bridges compared to simpler regular bridges. Moreover, uncertainties related to mechanical, geometric and seismic excitation characteristics further increase the difficulty to assess the seismic performance and vulnerability of such bridges. In addition, due to the excessive computational cost required for the dynamic analyses of real-life bridges, necessitates the development of simple and fast methods that are capable of accurately assessing the complex seismic response of regular and -mainly- irregular bridges.

The Capacity Spectrum Method (CSM) is a non-linear static technique for obtaining structural response for different seismic hazard scenarios. To perform structural capacity assessment, CSM uses non-linear static pushover analysis. Structural capacity is derived via modal analysis in the form of a spectral acceleration versus spectral displacement curve, whereas spectral demand is derived using acceleration-displacement response spectrum (ADRS). Due to the direct comparison of spectral capacity with spectral demand curves, an estimation of the structural response can be obtained, the so-called performance point. Generally, CSM-based methods can be considered as a very efficient tool in integrity assessment for various types of structural systems under seismic

DOI: 10.1201/9781003483755-72

loads that require repeated and time-consuming dynamic analyses, due to their reduced computational cost and sufficient accuracy in estimating structural capacity.

Within this framework, Rossetto et al. (2016) proposed a fragility through capacity spectrum assessment approach, the so-called FRACAS method, which is capable of considering record-by-record variability and was effectively applied to develop fragility curves of buildings. Herein, the standard FRACAS method has been modified for 3D irregular bridge models and further improved to reduce the demand error compared to non-linear time-history analysis (NTHA) approach. The main aim of this work is to provide a computationally efficient method, i.e., 3D FRACAS method, which can accurately and reliably estimate the dynamic non-linear response of regular and irregular bridges and facilitate the generation of the fragility curves of various bridge components for several damage levels without the need to perform computationally expensive non-linear time-history analyses.

2 PROPOSED 3D FRACAS METHODOLOGY

In this paper, unbalanced, skewed and curved irregular bridges, considering geometry, material and seismic excitation uncertainties have been examined. For each bridge type, regular configurations as well as with slight, moderate and extreme irregularities have been studied. Three-dimensional (3D) numerical models have been developed for all cases utilizing the advanced capabilities of OpenSees finite-element software. Non-linear time-history analyses (NTHA) have been performed for 160 ground motions. The NTHA results have been used to validate the fragility results obtained via the proposed 3D capacity spectrum assessment fragility methodology (3D FRACAS). In particular, the error distribution functions of the 3D FRACAS method were estimated for each bridge class. To determine the error distribution functions, a normal distribution is fitted on the difference between the responses of the "accurate" NTHA method and 3D FRACAS method for each EDP. The obtained error distribution functions were used to develop the probabilistic seismic demand models, which in turn were used to develop the fragility curves of important bridge components as well as for the whole bridge system. The obtained fragility curves of the improved 3D FRACAS were compared with those derived via NTHA method.

The error of the estimated demand is calculated and included in the improved method to reduce the estimation error. Hence, in the improved 3D FRACAS approach, an appropriate distribution function $\varepsilon\ (\mu, \sigma)$ is obtained for each EDP and used for developing the fragility curves. In the proposed framework, the obtained seismic demand and the fitting error are compared with the capacity distributions of the bridge components to generate the fragility curves. In brief, 3D FRACAS analysis is conducted via the following main steps:

1. First, a 3-D numerical model of the bridge structure is constructed and the pushover curve of the structure is calculated, both in longitudinal and transverse directions. The pushover loading pattern is in accordance with the sum of the modal shapes, utilizing at least 90% of the total mode participation. In order to determine the seismic demand values, the deformations of the structural components are recorded at each step of the pushover process.
2. Second, the goal is to simplify the 3-D structure of the bridge with an equivalent 3DOF system with equivalent mass and capacity curve for the examined bridge in both directions.
3. Third, the time-history analysis of the 3DOF system is performed for a ground motion scaled to the desired IM level. The orthogonal components of the earthquake are randomly applied along bridge longitudinal and transverse directions. The 3DOF system represents the capacity in both directions according to the previous step.
4. Fourth, the performance point of the structure (i.e., the intersection of the capacity curve with the response spectrum) is determined in both directions.
5. For each direction, the demand of all bridge components -at the stage equivalent to the performance point in pushover analysis- is recorded as the engineering demand parameter (EDP). The Square-Root-of-Sum-of-Squares (SRSS) of the EDPs along the two directions is considered as the EDP for each ground motion.

6. Based on the normalized fitting function of the error (ε_{EDP}), a large random number n_t (i.e., 10^6) is generated and added to the demand value (EDP_{IM}) obtained from the fifth step.
7. For a given limit state, n_t random numbers are generated for each bridge component based on the distribution assumed for that component capacity (given in Rezaei et al. (2023)). The $EDP_{IM} + \varepsilon_{EDP}$ values and resulting capacity are compared to generate a $n_t \times 1$ vector consisting of 1's and 0's, wherein "1" indicates survival (Demand < Capacity) and "0" denotes failure (Demand > Capacity). The probability of failure is the ratio of n_f to n_t (where n_f is the number of failures).
8. Steps 6 and 7 are repeated to obtain the failure probability for all IM levels. Lastly, the fragility curve parameters (median and dispersion) are estimated by logarithmic fitting of IM values versus collapse probability.

3 NUMERICAL MODELING OF IRREGULAR BRIDGES

In this study, multi-span continuous box girder RC bridges with irregularities are investigated. These irregularities include unbalanced stiffness, skewness and horizontal curvature. The examined bridges have 2, 3, and 4 spans and bents with different number of columns. Seat-type abutments with elastomeric bearing pads have been used. The bridge deck placement on elastomeric bearing pads can lead to collision and deck unseating. The structural details and the calculation of the element properties for the bridge models are typical for bridges in California, as defined by Ramanathan (2012).

Table 1. Four cases of pier heights for the unbalanced bridges, i.e., α_{U1}, α_{U2}, α_{U3} are height factors for 1st, 2nd, and 3rd bents, respectively.

Irregularity	Two-span bridge			Three-span bridge				Four-span bridge				
	Class name	subclass	α_{U1}	Class name	subclass	α_{U1}	α_{U2}	Class name	subclass	α_{U1}	α_{U2}	α_{U3}
Regular	R2	R2	1	R3	R3	1	1	R4		1	1	1
Slight	-		-	U3	US3	1	1.5	U4	US4	1	1.5	2
Moderate	-		-		UM3	1	2		UM4	1	2	3
Extreme	-		-		UI3	1	3		UI4	1	3	4

Table 2. Four cases of skewness angle, α_S, for the skewed bridges.

Irregularity	Two-span bridge			Three-span bridge			Four-span bridge		
	Class name	subclass	α_S	Class name	subclass	α_S	Class name	subclass	α_S
Regular	R2	R2	0°	R3	R3	0°	R4	R4	0°
Slight	S2	SS2	15°	S3	SS3	15°	S4	SS4	15°
Moderate		SM2	30°		SM3	30°		SM4	30°
Extreme		SI2	45°		SI3	45°		SI4	45°

Table 3. Four cases of deck radius, R, for the curved bridges.

Irregularity	Two-span bridge				Three-span bridge				Four-span bridge			
	Class name	subclass	α_C	R(m)	Class name	subclass	α_C	R(m)	Class name	subclass	α_C(m)	R
Regular	R2	R2	0°	∞	R3	R3	0°	∞	R4	R4	0°	∞
Slight	C2	CS2	45°	265	C3	CS3	45°	265	C4	CS4	45°	265
Moderate		CM2	90°	132		CM3	90°	132		CM4	90°	132
Extreme		CI2	135°	66		CI3	135°	66		CI4	135°	66

With respect to unbalanced bridge configurations, four height factors have been considered for the piers, while each factor corresponds to a certain level of irregularity. The height ratios of columns (α_U) for 2-, 3-, and 4-span bridges are given in Table 1. Evidently, there is no

unbalanced pier in 2-span models, as there is only one pier. Table 2 presents the skew angle (α_S) values, i.e., 0° (for straight bridges) 15°, 30°, and 45°; for 2-, 3-, and 4-span skewed bridges. Lastly, the main parameter for the curved bridges is the radius of the deck in the horizontal plane. Four curved bridge subclasses have been analysed with different deck radii varying from infinity, representing a straight bridge, to a sharp curve radius. Table 3 lists the radius of the curved deck (α_C) and deck radius (R) for 2-, 3-, and 4-span bridges. The subtended angle is defined as the length ratio of the bridge to its curvature radius.

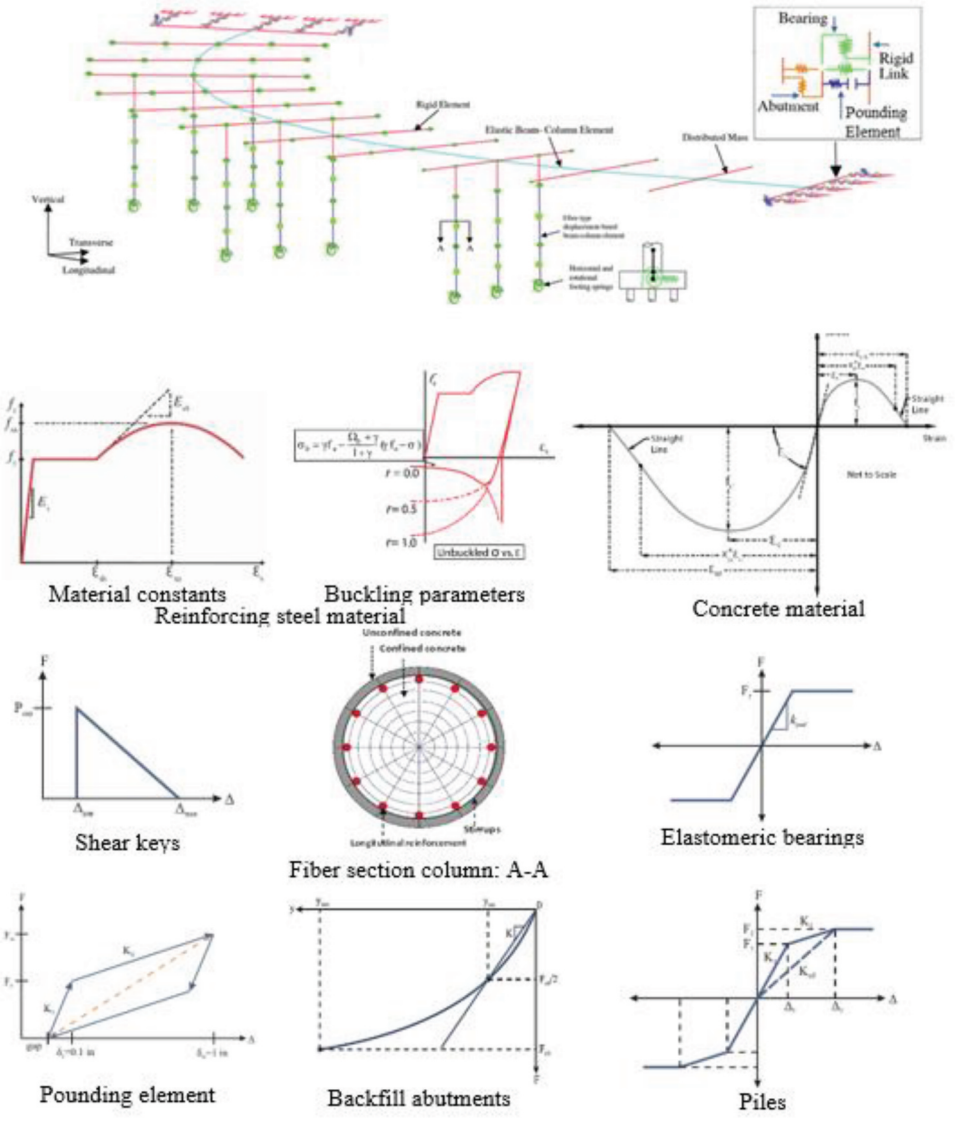

Figure 1. Finite element modeling details of bridge components.

The dynamic non-linear analyses of the bridges have been performed by modeling different bridge components as shown in Figure 1, using OpenSees software (McKenna, 2011) and considering the non-linear response of the materials. In addition, geometrical non-linearities have also been included in the analyses. Inherent damping is modeled utilizing Rayleigh damping. Other sources of damping (hysteretic) have been explicitly modeled due to non-linear force-deformation

properties. The results are presented as the seismic demand of the bridge components. The numerical modeling of bridge elements is briefly described in the sequence, while more details can be found in Rezaei et al. (2020). It should be noted that the validity of the adopted computational approaches for modeling various bridge components has been proven in several relevant studies (e.g., Rezaei et al. (2020, 2022a); Moayeddi et al. (2023)).

The 160 earthquake records used in this investigation are derived from Baker et al. (2011). These ground motions represent uncertainties with respect to potential earthquake (e.g., soil type, magnitude and focal depth) and are divided into four sub-groups, thus, each set includes forty unscaled records. More details about these four suites can be found in Baker et al. (2011). In the present study, the spectral acceleration for one second period for 5% of critical damping, S_a (1.0s), has been adopted as IM. This selection is in accordance with the extensive studies conducted by Ramanathan (2012) to derive the appropriate IM for bridges in California.

The input data of the examined bridge models are derived based on the distribution functions of the random variables. The bridge models are randomly subjected to 160 pairs of excitations in both directions. In the next step, the preferable irregularity level for each bridge class is selected and the irregular models are generated. Accordingly, 4320 non-linear time-history analyses have been conducted and the resulting EDP values have been obtained for each pair of bridge-ground motion models. These results are used for validating the proposed simplified approach. More specifically, the improved 3D FRACAS method has been applied to estimate the EDP values for each simulation. The differences between each 6 EDPs for the different bridge classes are calculated and a suitable distribution function is used for their fitting. Subsequently, these error distribution functions are used to improve the 3D FRACAS method. Lastly, the results of the proposed 3D FRACAS methodology are compared with those derived from NTHA to assess its accuracy and computational performance.

Table 4. Mean and standard deviations of the fitted normal distribution functions for the examined EDPs.

Bridge Class	CCD		SUA		EBD		APD		AAD		ATD	
	μ	σ	μ	σ	μ	σ	μ	σ	μ	σ	μ	σ

4 RESULTS AND DISCUSSION

As described in Section 2, in order to improve the standard 3D FRACAS methodology, it is necessary to determine the error histogram of EPDs. The mean values (μ) and standard deviations (σ) of the fitted normal distribution functions for the examined EDPs are shown in Table 4, in which the first index denotes the bridge type, while the number corresponds to bridge spans. More specifically, indexes R, U, C and S correspond to regular, unbalanced, curved and skewed bridges, respectively. According to the obtained results, the normalized fitting distributions on the errors exhibit better fitting for SUA, CCD and EBD demand parameters. In contrast, the fitting distribution functions on APD, AAD, and ATD errors exhibit higher dispersion. Hence, the obtained values for APD, AAD and ATD seismic responses

have slight differences with the corresponding ones of the NTHA method. It is stressed that the results in Table 4 can be generalized to all bridges with similar characteristics, i.e., they can be used in future studies without needing to perform NTHA again.

In the sequence, the fragility curves corresponding to the damage states presented in Rezaei et al. (2023) are presented. Indicatively, Figure 2 displays the fragility curves for all EDPs (i.e., CCD, SUA, EDB, APD, AAD and ATD) of the S3 bridge. Regarding the other bridge classes, due to space limitations, error statistics are presented and compared. It is observed that the improved 3D FRACAS method effectively improves the estimation of fragility curves for different limit states. This is more pronounced in estimating CCD, SUA and EBD, compared to APD, AAD and ATD parameters. The mean of percentage differences of fragility parameters has also been investigated via comparisons with NTHA results. The improved 3D FRACAS method has a mean percentage difference of approximately 18% in estimating all EDP parameters.

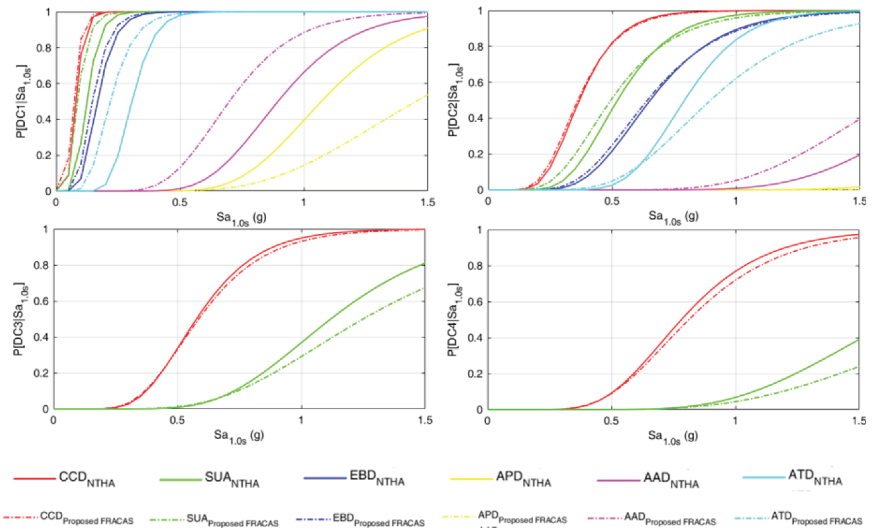

Figure 2. Comparison of fragility curves for S3 bridge for different damage states.

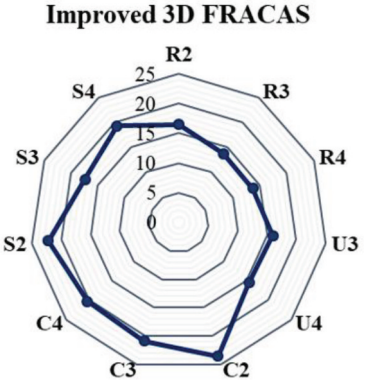

Figure 3. Mean error percentage of the median of fragility curves for all bridge classes.

Figure 3 presents a comparison of the mean error percentage of the median of fragility curves (utilizing NTHA results) for the improved method for all bridge classes. In this comparison, all four damage states and number of spans are taken into account. The average

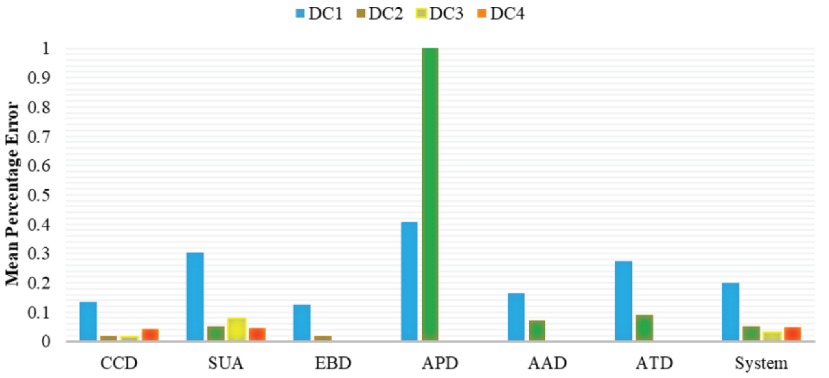

Figure 4. Mean percentage error of the improved 3D FRACAS compared to NTHA method.

error values for the improved method are 14.7, 15.8, 21.6, and 19.6%, respectively. It should be noted that this difference is mainly due to the abutment-related parameters. By ignoring the abutment parameters, the mean error of the improved method is 8%. Considering the complexities of irregular bridges simulations, as well as material, geometry and ground motion uncertainties, the obtained results are considered satisfactory.

Figure 4 depicts the mean percentage error of fragility median value of the improved 3D FRACAS compared to NTHA method based on different damage levels and EDPs. The comparison of the entire bridge system fragility shows that the average error of 8% in improved 3D FRACAS, while in the three damage levels of DC 2, 3 and 4, the error is less than 5%. A comparison of system fragility for bridge class S3 is shown in Figure 5.

Finally, the comparison of computational effort required in this study shows that, using the same computational environment, the computing time ratio of the improved 3DFRACAS method versus NTHA is equal to approximately 0.13. More specifically, the time of a NTHA is on average equal to 1796 seconds, while the duration of the analysis is substantially reduced to 240 seconds when using the improved 3DFRACAS method, i.e., the proposed method achieves a 87% reduction in computational cost for each analysis. Moreover, it should be stressed that in order to calculate the total computational cost, the number of considered IMs for the generation of fragility curves should be multiplied with the time needed for a single analysis.

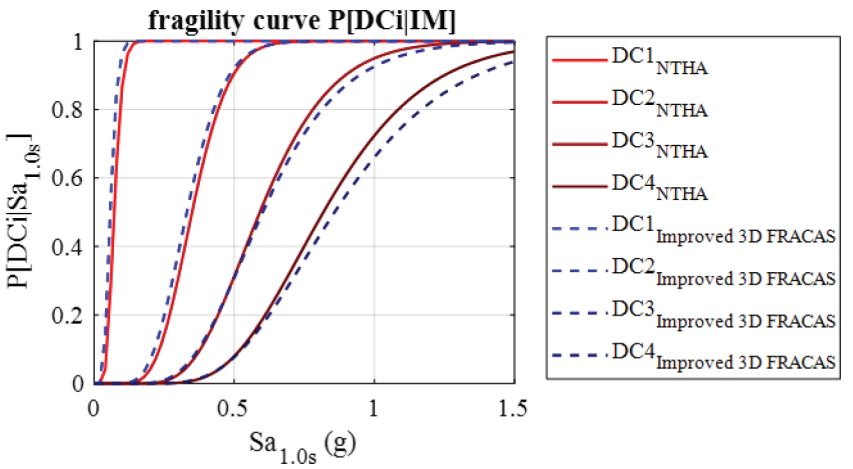

Figure 5. Comparison of system fragility curves for S3 bridge for different damage states.

5 CONCLUSIONS

This study aims to establish an efficient methodology for the development of fragility curves for regular and irregular RC Bridges using non-linear static analysis in a probabilistic manner, by achieving an optimal balance among efficiency, accuracy and computational cost. Accordingly, an efficient 3D FRACAS method has been proposed and implemented for the seismic fragility analysis of box-girder highway bridges. Three types of irregularities including unbalanced, horizontally curved, and skewed bridges have been examined, for three irregularity levels (slight, moderate and extreme). Furthermore, uncertainties related to mechanical, geometrical and ground motion characteristics have been considered.

In total, 4320 NTHA analyses have been conducted for the examined two-, three-, and four-span bridge models and the 160 records. For each EDP, an appropriate distribution function is fitted on the error. Accordingly, an efficient methodology is utilized for developing seismic fragility curves using the obtained error distribution functions. The presented results justify that the improved method can reliably estimate the EDPs with acceptable accuracy and substantially smaller computational cost compared to NTHA, i.e., approximately 87% less computing time per analysis on average.

The proposed method can provide an acceptable estimation of fragility curves for unbalanced, skewed, and curved bridges despite all complexities involved. It should be noted that the improved 3D method has been examined herein only for box-girder RC bridges. Thus, in future extensions other bridge types can be investigated as well as other structures, e.g., irregular buildings. Furthermore, the improved 3D FRACAS method needs to be further enhanced in order to estimate more accurately the response in terms of parameters related to abutments, which presented the highest errors, by considering support conditions for the simplified equivalent structure that are more suitable with the characteristics of the abutments.

Connectivity of post-earthquake bridge networks under aging of isolators

H. Matsuzaki
National Defense Academy of Japan, Yokosuka, Japan

ABSTRACT: In this study, the effects of improving the seismic performance of existing bridges by seismic isolation on the post-earthquake connectivity of a road network were investigated. As a result, it was shown that the bridge which should be retrofitted to improve the seismic performance in terms of reducing the probability of disconnection between the Origin-Destination (OD) pair is significantly affected not only by the seismic hazard but also by the spatial correlation of the intensity of ground motions, which depends on the distance between the bridge sites.

1 INTRODUCTION

Road networks play important roles during the post-earthquake rescue and recovery in the communities. Bridges are the most vulnerable components of road networks and susceptible to seismic damage (Gidaris et al., 2017). Seismic isolation is one of the key technologies for improving the seismic performance of existing bridges and maintaining the traffic function after the seismic events. During the 2011 Tohoku earthquake and the 2016 Kumamoto earthquake, rupture of laminated rubber bearings and large cracks in lead rubber bearings occurred at several bridges (Akiyama et al., 2020; Takahashi & Hoshikuma, 2013). Matsuzaki (2022) showed that the seismic safety of seismically isolated bridges can be improved by setting an adequate capacity ratio between the isolator and the column, as it can avoid the rupture of the isolator under extreme ground motions even if the aging deterioration of isolators is considered.

However, it is necessary to investigate the effects of improving the seismic performance of existing bridges by seismic isolation on maintaining the traffic function as a road network. In this study, the effects of improving the seismic performance of existing bridges by seismic isolation on the probabilistic post-earthquake connectivity of a road network (Firdaus et al., 2023) will be discussed.

2 A BRIDGE NETWORK ANALYSED

2.1 *Road network with bridges*

A hypothetical road network in Yamagata Prefecture, Japan shown in Figure 1 was analysed in this study. The hypothetical road network is located near the northern part of the western boundary fault zone of the Yamagata basin, which would cause an earthquake with a moment magnitude of 6.8 (National Research Institute for Earth Science and Disaster Resilience, 2023). The locations and fault distances of the bridges are listed in Table 1.

2.2 *Bridges*

The existing non-isolated bridges (ENI) analysed are multi-span continuous steel girder highway bridges on the stiff soil with an $AVS30$ of 400 m/s, all assuming identical bridge configurations shown in Table 2. The effects on the post-earthquake connectivity of the road network are evaluated by retrofitting only one of the nine bridges at the site shown in Table 1 with the isolators shown in Table 3. The capacity ratio of Bridges I-570 and I-700 calculated based on Matsuzaki (2022) is 0.91 and 1.25, respectively.

I-700	700 × 620	96	4 × ϕ100	5.1	6.5

3 SEISMIC HAZARD AND SEISMIC FRAGILITY ASSESSMENT

3.1 *Seismic hazard assessment*

The spatial correlation of seismic hazard intensity at the bridge site is needed to discuss the connectivity of the road network. Wang and Takada (2005) discussed the microspatial correlation of the intensity of ground motions. The variability of the intensity of ground motions at

different sites during an earthquake can be expressed using a predicted component and a residual component for each sites as:

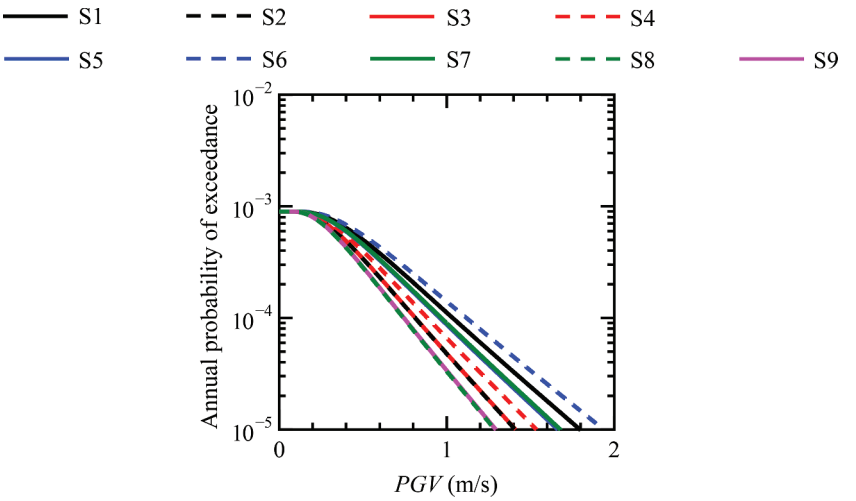

Figure 2. Seismic hazard curves at the bridge sites.

$$\log PGV_i = \log \overline{PGV} + \varepsilon_i \tag{1}$$

where $\overline{PGV}$ is the trend component and ε_i is a normal random function at bridge site i with mean zero and the standard deviation σ_{PGV}.

The trend component at the ground surface $\overline{PGV}$ is calculated as:

$$\overline{PGV} = AF_i \cdot \overline{PBV} \tag{2}$$

where $\overline{PBV}$ is the trend component at the engineering bedrock and AF_i is the amplification factor at the bridge site i calculated as:

$$\log AF_i = -0.852 \log\left(AVS30_i / V_{S,B}\right) \tag{3}$$

where $AVS30_i$ is the average shear-wave velocity in the subsurface from the surface to a depth of 30 m at the bridge site i. $V_{S,B}$ is the shear-wave velocity at the engineering bedrock.

Using the attenuation equation proposed by Si and Midorikawa (1999), the trend component at the engineering bedrock $\overline{PBV}$ is calculated as:

$$\log \overline{PBV} = 0.58M_w + 0.0038D - 1.29 - \log\left(X + 0.0028 \times 10^{0.50M_w}\right) - 0.002X \tag{4}$$

where M_w is the moment magnitude, D is the fault depth at the fault center, and X is the fault distance. The engineering bedrock in Equation (4) is defined as a shear-wave velocity of 600 m/s ($V_{S,B}$ = 600 m/s) and σ_{PGV} is treated as 0.23 (Si & Midorikawa, 1999).

The seismic hazard curves associated with the fault distance shown in Table 1 are shown in Figure 2.

Wang and Takada (2005) proposed an exponential decay function to model the site-to-site correlation of the intensity of ground motions during an earthquake expressed as:

$$\rho_{ij} = \exp\left(-\Delta_{ij}/b_c\right) \tag{5}$$

where ρ_{ij} is a correlation coefficient between bridge sites i and j, Δ_{ij} is the distance between bridge sites i and j, and b_c is the correlation distance. b_c = 30 km was adopted as the correlation distance in this study, as it has been reported that the correlation distance is approximately 30 km if the peak velocity at the engineering bedrock is used as the seismic intensity (Sokorov & Wenzel, 2013; Wang & Takda, 2005).

To calculate the site-to-site correlated intensity of ground motions, the correlation matrix **C** can be expressed as:

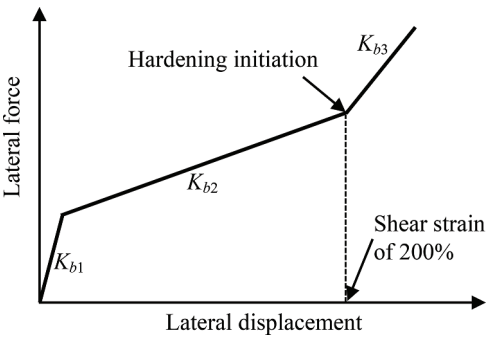

Figure 3. Skeleton of the lateral force–lateral displacement relationship of lead rubber bearings.

$$\mathbf{C} = \begin{pmatrix} 1 & \rho_{12} & \cdots & \rho_{1n} \\ \rho_{21} & 1 & \cdots & \rho_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ \rho_{n1} & \rho_{n2} & \cdots & 1 \end{pmatrix} \tag{6}$$

where n is the total number of the bridge sites (n = 9 in this study).

A lower triangular matrix is obtained by using Cholesky decomposition as:

$$\mathbf{C} = \mathbf{L}\mathbf{L}^T \tag{7}$$

The residual error ε_i in Equation (1) is calculated as:

$$\varepsilon = \mathbf{L}\mathbf{r} \tag{8}$$

where **r** is a vector containing independent normal random variables with the mean zero and the standard deviation equal to σ_{PGV}.

3.2 *Seismic fragility assessment*

In the seismic fragility assessment, dynamic nonlinear response analysis was conducted in the longitudinal direction by idealizing a reinforced concrete column with isolators as a two-degree-of-freedom model. Lead rubber bearings were idealized based on a tri-linear model considering strain hardening of rubber, as shown in Figure 3. In Figure 3, the ratio of K_{b1} to K_{b2} was set as 6.5:1 based on the Japan Road Association (2018) and the ratio of K_{b3} to K_{b2} was set based on Naito et al. (2017). The skeleton and hysteresis of reinforced concrete columns were idealized based on bi-linear model and Takeda degrading stiffness model by Takeda et al. (1970), respectively. The evaluating method for the performance of isolators considering aging deterioration is based on Matsuzaki (2022).

The ultimate displacement of the column and the rupture strain in shear of rubber layer of isolators were adopted as the structural capacity in the seismic fragility assessment.

$$g_1 = \chi_{ls3}\delta_{ls3} - \delta_{\max} \tag{9}$$

$$g_2 = \chi_{rup}\gamma_{rup} - \gamma_{\max} \tag{10}$$

where δ_{ls3} is the ultimate displacement of the column (Japan Road Association, 2017), χ_{ls3} is the model uncertainty associated with the ultimate displacement (Japan Road Association, 2023), γ_{rup} is the rupture strain in shear, χ_{rup} is the model uncertainty associated with the rupture strain in shear (Adachi, 2002), and $\delta_{\max}$ and $\gamma_{\max}$ are the peak responses of the column and isolator, respectively. If g_1 in Equation (9) or g_2 in Equation (10) is negative, the bridge cannot be restored immediately after the seismic event and is considered to be impassable. Uncertain factors considered in the seismic fragility assessment are listed in Table 4.

Table 4. Uncertain factors considered in the seismic fragility assessment.

Uncertain factor		Distribution	Characteristic value	Coefficient	
				Mean	C.O.V
Superstructure	Mass	Normal	600 ton	1.05	0.05
Isolator	Yield strength	Normal	Calculated based on Japan Road Association (2018)	1.13	0.18
	Shear stiffness	Normal	Calculated based on Japan Road Association (2018)	1.04	0.04
	K_{b3}/K_{b2}	Normal	–	3.1	0.09
	Rupture strain	Normal	250%	1.34	0.11
Column	Compressive strength of concrete	Normal	23.5 N/mm^2	1.20	0.10
	Section area of steel bar	Normal	Nominal value	0.97	0.01
	Yield strength of steel bar	Normal	345 N/mm^2	1.20	0.07
	Young's modulus of steel bar	Normal	2.06×10^5 N/mm^2	0.97	0.01
	Mass	Normal	397 ton	1.05	0.05
	Ultimate displacement δ_{ls3}	Normal	Calculated based on Japan Road Association (2017)	1.32	0.23

A total of 25 horizontal components of observed ground motions with a peak ground velocity of 0.50 m/s or higher recorded at stiff soil in Japan selected in Matsuzaki (2022) were used in this study and were adjusted to the required peak ground velocity by varying amplitude properties in the seismic fragility assessment.

The seismic fragility curves of the existing non-isolated bridges (ENI) and retrofitted bridges by seismic isolation (I-570 and I-700) are shown in Figure 4. Hereinafter, I-size of the isolator-*N*y denotes that the bridge I-size of the isolator of time after construction of *N* years. Although Bridge I-570, which is retrofitted by seismic isolation, has improved seismic safety compared to the existing non-isolated bridge ENI, it has a high probability of rupture at the isolators due to an inadequate capacity ratio of 0.91, and the probability of failure at the isolator is further increasing with aging deterioration of the isolator. On the other hand, Bridge I-700, with a sufficient capacity ratio of 1.25, has a sufficiently low probability of rupture at the isolator and is not susceptible to aging deterioration of the isolator.

4 PROBABILISTIC CONNECTIVITY ANALYSIS OF THE ROAD NETWORK

In the probabilistic connectivity analysis, the service state of individual bridges should be expressed. Bocchini and Frangopol (2011) represented the in/out service state of the bridges as binary variables. The service state (s_{Bi}) of the bridge at site *i* can be expressed by using the fragility curve (P_{Bi}) of the bridge at site *i* as:

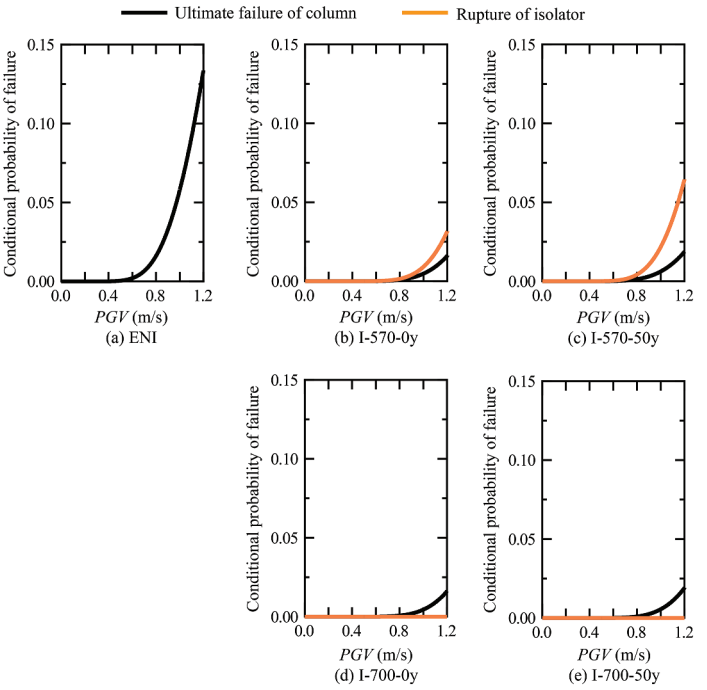

Figure 4. Fragility curves.

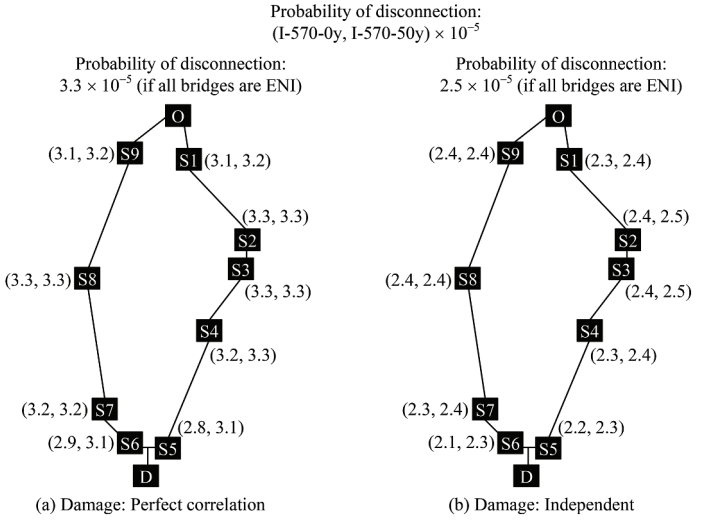

Figure 5. Effects of the bridge site where the existing non-isolated bridge is retrofitted by seismic isolation as Bridge I-570 on the probability of disconnection between the OD pair.

$$s_{Bi} = \begin{cases} 1, \text{if } P_{Bi}(PGV_i|g \le 0) q_{vBi}(\text{impassable}) \\ 0, \text{if } P_{Bi}(PGV_i|g \le 0) < q_{vBi}(\text{passable}) \end{cases} \tag{11}$$

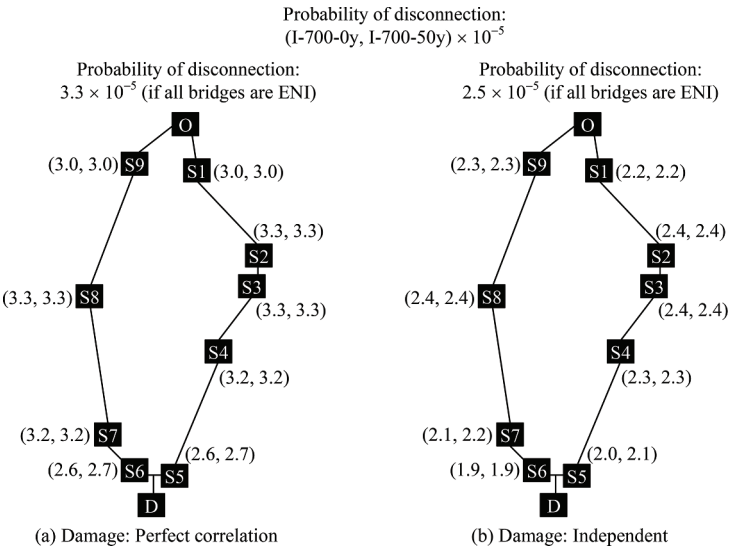

Figure 6. Effects of the bridge site where the existing non-isolated bridge is retrofitted by seismic isolation as Bridge I-700 on the probability of disconnection between the OD pair.

where g is the performance function in Equations (9)–(10), which results in the traffic closure after seismic events, q_{vBi} is the uniformly distributed random number between 0 and 1 associated with the seismic damage. The value of q_{vBi} is assumed perfectly correlated or independent among the bridges analysed. The probability of disconnection between the OD pair can be calculated by adopting the algorithm proposed by Dijkstra (1959) based on Monte Calro simulation by eliminating the impassable route.

Figures 5 and 6 show the effects of the bridge site where the only one existing non-isolated bridge (ENI) is retrofitted by seismic isolation on the probability of post-earthquake disconnection between the OD pair. The target road network has two routes between the OD pair, route O-S1-S2-S3-S4-S5-D and route O-S9-S8-S7-S6-D. The most severe seismic hazard sites within each route are identified as S1 and S6 from Figure 2. Regardless of whether the spatial correlation of damage is perfectly correlated or independent, improving the seismic performance of the bridge at S6 on the route O-S9-S8-S7-S6-D contributes to reducing the probability of post-earthquake disconnection between the OD pair. On the other hand, the results shown in Figures 5 and 6 indicate that the seismic performance of the bridge at S5 should be improved instead of the bridge at S1, where the seismic hazard is the highest on the route O-S1-S2-S3-S4-S5-D. This is due to the fact that in route O-S1-S2-S3-S4-S5-D, even S2, which is closest to S1, the distance between S1 and S2 is 11.4 km, while S6, which is on a different route from the route including S5, is only 4.4 km away from S5, which is significantly influenced by the spatial correlation of intensity of ground motions.

Furthermore, it was confirmed that if the capacity ratio between the isolator and the column is insufficient, the probability of post-earthquake disconnection between the OD pair is affected by the aging deterioration of the isolators, but if the capacity ratio is sufficient, the aging deterioration of isolators has little effect on the probability of post-earthquake disconnection between the OD pair.

5 CONCLUSIONS

Effects of improving the seismic performance of existing bridges by seismic isolation on the post-earthquake connectivity of a road network were investigated in this study. The following conclusions can be drawn:

1. The bridge which should be retrofitted to improve the seismic performance in terms of reducing the probability of post-earthquake disconnection between the OD pair is significantly affected not only by the seismic hazard but also by the spatial correlation of the intensity of ground motions, which depends on the distance between the bridge sites.
2. It was confirmed that if the capacity ratio between the isolator and the column is insuffi-cient, the probability of disconnection between the OD pair is affected by the aging deterioration of the isolators, but if the capacity ratio is sufficient, the aging deterioration of isolators has little effect on the probability of disconnection between the OD pair.

ACKNOWLEDGEMENTS

This study was supported by JSPS KAKENHI Grant Number 23K04018. It is appreciated that strong ground motions were provided by K-NET and KiK-net of NIED, JMA, JAEE and NGA databases of PEER.

Computational analysis of resilience in reinforced concrete railway bridge

A.L. Gamino, R.R. Santos, T.N. Bittencourt & M.M. Futai
Department of Structural and Geotechnical Engineering, School of Engineering, University of Sao Paulo, Sao Paulo, Brazil

ABSTRACT: This paper deals with a proposal for determining and quantifying the structural resilience of railway bridges in reinforced concrete using a computational modeling technique. In the technical literature, structural resilience is a quantitative parameter related to the ability of an asset or its parts to resist eventual damage events (explosions, impacts, fires, or overloads) to be efficiently rehabilitated in the face of loss of performance caused by fortuitous events. Thus, three-dimensional computational models were developed based on real explosion events (unusual disturbance) that caused damage to some structural elements of the evaluated asset using CSi-Bridge v. 21. A FNA (Fast Non-Linear Analysis) dynamic time history analysis was used, which, according to the technical literature, produces greater accuracy and efficiency when compared to the direct integration technique. Damping was also used for all vibration modes. A soil-structure interaction law was applied to the asset's foundations with elastic springs calibrated according to the geometric characteristics of the foundation and soil elements, which produced confinement in the infrastructure elements. The elastic supports in neoprene bridge bearings were modeled using Winkler springs according to the characteristics of the elements used in the construction of the asset and the law of representation of stiffness. The results obtained allowed quantification of the resilience of the degraded structural elements through the dynamic responses obtained in the passage of the railway composition due to the time used during rehabilitation and reinforcement. In this way, the capacity of the structural elements affected by the explosion unusual event was measured and the recovery capacity was evaluated. The proposed proposal opens new horizons for a quantitative assessment of the resilience of structural elements of railway bridges due to unusual degradation events, repair time, and efficient recovery.

1 INTRODUCTION

1.1 *Structural resilience*

Resilience consists of a metric to assess the capacity of a system to withstand unexpected disruptions and to recover efficiently from the induced damage. For civil infrastructure, resilience is typically associated with its capability to maintain a specific service level despite the occurrence of an extreme event and to recover the desired functionality thereafter (Bocchini et al. 2014). The structural resilience study proposed in this work was based on the research developed by Bocchini et al. (2014). Therefore, structural resilience can be determined from a loss of functionality related to a performance reduction due to a fortuitous event (explosions, fires, or impact loads).

In this way, resilience can be associated with displacement, acceleration, velocity, or natural frequency quantified in the structure by computational dynamic analysis techniques, which was the methodology applied in the present paper.

Bocchini et al. (2014) analyzed the concept of resilience applied to the construction and operational costs of road bridges in a more comprehensive way. The basic concept was to analyze maintenance costs combined with the useful life of the asset and its parts using assumptions regarding the flow of vehicles over the bridge. In this study, different types of damage to

DOI: 10.1201/9781003483755-74

the asset were considered; the authors concluded that the joint study between resilience and sustainability should be done using probability techniques.
